HAM RADIO OUTLET

WORLDWIDE DISTRIBUTION

DISCOVER THE POWER OF DSP WITH ICOM!

IC-7800 All Mode Transceiver

- 160-6M @ 200W
- 32 bit IF DSP+ 24 bit AD/DA converter
- 7" color TFT w/spectrum scope
- Selectable IF filter shapes for SSB & CW
- Twin Receivers
- SSB/CW Synchronous tuning
- Multiple DSP controlled AGC loops
- Advanced CW functions
- Separate RX only antenna jack
- 101 alphanumeric memories
- Transverter I/O port
- Live band scope
- Digital & analog meter
- Dual receive
- Digital voice recorder

IC-756PROII All Mode Transceiver

- 160-6M* @ 100W
- 32 bit IF DSP+ 24 bit AD/DA converter
- Enhanced 5" color TFT w/spectrum scope
- Selectable IF filter shapes for SSB & CW
- Enhanced Rx performance
- SSB/CW Synchronous tuning
- Multiple DSP controlled AGC loops
- Advanced CW functions
- Separate RX only antenna jack
- 101 alphanumeric memories
- Transverter I/O port
- Live band scope
- Digital & analog meter
- Dual receive
- Digital voice recorder

IC-746PRO All Mode Transceiver

- 160-2M* @ 100W
- 32 bit IF-DSP+ 24 bit AD/DA converter
- Selectable IF filter shapes for SSB & CW
- Improved 3rd order intercept point
- CW memory keyer
- Automatic antenna tuner
- Auto & manual notch
- Digital twin passband tuning
- Built-in RTTY demodulator & decoder
- 102 Alphanumeric memories
- Enhanced RX performance
- 9600 Baud packet capable
- RX audio equalizer
- SWR analyzer
- Sweeping scope

IC-718 HF Transceiver

- 160-10M* @ 100W
- 12V Operation
- Band stacking register
- CW Keyer Built-in
- One Touch Band Switching
- Direct frequency input
- Optional DSP
- VOX Built-in
- IF shift
- Preamp & attenuator
- Mic compressor
- Digital S/RF meter

IC-706MKIIG All Mode Transceiver

- 160-10M*/6M/2M/70cm
- HF/6M @ 100W, 2M @ 50W, 70cm @ 20W
- 107 Alphanumeric memories
- CTCSS encode/decode w/tone scan
- AM, FM, WFM, SSB, CW, RTTY w/DSP
- Auto repeater
- Plug-n-play filters
- Backlit function keys
- Built-in keyer
- IF shift
- Tone squelch
- Removable head (optional RMK-706 required)

IC-703 HF QRP Transceiver

- HF & HF/6M Versions
- 10W~0.1W @ 13.5V SSB, CW, RTTY, FM
- 4W~0.1W @ 13.5V AM
- Newly designed PA unit
- Internal antenna tuner
- Detachable control panel
- DSP with auto notch filter & noise reduction
- Automatic battery save mode

The ARRL Handbook

For Radio Communications

Editor

R. Dean Straw, N6BV

Contributing Editors

Steven R. Ford, WB8IMY
Charles L. Hutchinson, K8CH
Rick Lindquist, N1RL
Larry D. Wolfgang, WR1B

Editorial Assistants

Helen W. Dalton, KB1HLF
Maty Weinberg, KB1EIB

Technical Consultants

Michael E. Gruber, W1MG
Edward F. Hare, Jr., W1RF1
Zachary H.J. Lau, W1VT
Michael D. Tracy, KC1SX

Cover Design

Sue Fagan
Bob Inderbitzen, NQ1R

Production

Michelle Bloom, WB1ENT
Michael Daniels
Jodi Morin, KA1JPA
David F. Pingree, N1NAS
Joe Shea

CD-ROM Production

Dan Wolfgang

Proofreader

Kathy Ford

Additional Contributors to the 2006 Edition:

Wayde S. Bartholomew, K3MF
David J. Benson, K1SWL
Albert C. Buxton, W8NX
L. B. Cebik, W4RNL
John J. Champa, K8OCL
Paul M. Danzer, N1II
Donald R. Greenbaum, N1DG
John C. Hennessee, N1KB
George L. Heron, N2APB
Howard S. Huntington, K9KM
Sylvia K. Hutchinson, K8SYL
Richard M. Jansson, WD4FAB
Shawn A. Reed, N1HOQ
Douglas T. Smith, KF6DX
Frederick J. Telewski, WA7TZY
James L. Tonne, WB6BLD
Edward E. Wetherhold, W3NQN
Rosalie A. White, K1STO

Cover Info:

Background: The circuit board modified by K1SWL to prototype his 60-Meter transceiver design. This new project is found in Chapter 15.

To the left of the *Handbook CD-ROM* image, the popular HF receiver project by N1TEV (Ch. 14) is shown. To the upper left, these new antenna projects can be found in Ch. 22.

Cover circuit board photography for the 2006 ARRL *Handbook* by Dan Wolfgang.

Contents

Foreword

Amateur's Code

Schematic Symbols

Chapter 1 — What is Amateur (Ham) Radio?

Hobby of Diversities	1.2
Your License	1.3
US Amateur Bands	1.4
Ham Radio Action	1.5
Getting Started	1.7
Governing Regulations	1.11
Resources	1.15
Glossary	1.16

Chapter 2 — Activities in Amateur Radio

Awards	2.1
Contests	2.2
Nets	2.3
Amateur Radio Education	2.4
Emergency Communications	2.4
Specialized Communications	2.6

Chapter 3 — Safety

Antenna and Tower Safety	3.1
Power Lines	3.2
Electrical Wiring around the Shack	3.3
Lightning/Transient Protection	3.5
Grounds	3.7
<i>Project: An Earth-Continuity Tester</i>	3.9
Station Power	3.11
FCC RF-Exposure Regulations	3.12
Safe Homebrewing	3.14
RF Radiation and EMF Safety	3.15
Other Hazards in the Ham Shack	3.19

Chapter 4 — Electrical Fundamentals

DC Circuits and Resistance	4.1
Series and Parallel Resistances	4.3
Power and Energy	4.6
Circuits and Components	4.8
AC Theory and Reactance	4.11
Frequency and Period	4.13
Capacitance and Capacitors	4.18
Inductance and Inductors	4.25
Quality Factor (Q) of Components	4.32
Calculating Practical Inductors	4.32
Ohm's Law for Reactance	4.37
Impedance	4.42
Resonant Circuits	4.47
Transformers	4.54

Chapter 5 — Electrical Signals and Components

Analog Glossary	5.1
Analog Signal Processing	5.2
Analog Devices	5.6
Practical Semiconductors	5.17
Transistor Amplifier Design	5.26
Digital Fundamentals	5.38
Number Systems	5.39
Physical Rep. of Binary States	5.41
Combinational Logic	5.42
Sequential Logic	5.45
Digital Integrated Circuits	5.51
Computer Hardware	5.58

Chapter 6 — Real-World Component Characteristics

Lumped vs Distributed Elements	6.1
Low-Frequency Component Models	6.2
Components at RF	6.10
Thermal Considerations	6.16
The Thermistor in Homebrew Projects	6.20
Low-Frequency Transistor Models	6.23

Chapter 7 — Component Data and References

Component Values	7.1
Component Markings	7.1
Inductors and Core Materials	7.5
Other Sources of Component Data	7.11
Semiconductors	7.15
Integrated Circuits	7.28
Vacuum Tubes	7.32
Other	7.36
References	7.38
General/Electronics/Computers	7.38
Components/Equipment	7.45
Antennas/Transmission Lines	7.46
Modes	7.50
Operating and Interference	7.52
Message Handling	7.63

Chapter 8 — Circuit Construction

Shop Safety	8.1
Tools and their Uses	8.1
<i>Project: A Deluxe Soldering Station</i>	8.6
<i>Project: Soldering-Iron Temperature Control</i>	8.7
Electronic Circuits	8.7
Surface Mount Construction Techniques	8.12
From Schematic to Working Circuit	8.18
Microwave Construction Techniques	8.22
High-Voltage Techniques	8.23
Mechanical Fabrication	8.25

Chapter 9 — Modes and Modulation Sources

Issues Common to all Transmission Modes	9.1
Voice Modes	9.2
Text Modes	9.11
Morse Telegraphy (CW)	9.11
Digital Communications	9.15
Image Modes	9.32
Facsimile	9.32
Slow-Scan Television (SSTV)	9.34
Fast-Scan Television (ATV)	9.40
Radio Control (R/C)	9.48
Spread Spectrum	9.51
High Speed Multimedia (HSMM) Radio	9.55

Chapter 10 — Oscillators and Synthesizers

How Oscillators Work	10.2
Phase Noise	10.5
Oscillator Circuits and Construction	10.12
VHF and UHF Oscillators	10.28
Frequency Synthesizers	10.32
Phase-Locked Loops	10.33
Synthesizer in an MF/HF Transceiver	10.49
Trends in Oscillator Applications	10.52

Chapter 11 — Mixers, Modulators and Demodulators

The Mechanism of Mixers and Mixing	11.1
Practical Building Blocks	11.13
Testing and Calculating IMD in Receivers	11.20

Chapter 12 — RF and AF Filters

Basic Concepts	12.1
Filter Synthesis	12.5
Designs using Software/SVC Tables	12.8
Chebyshev Filter Design	12.11
Quartz Crystal Filters	12.16
Monolithic Crystal Filters	12.18
SAW Filters	12.18
Transmission-Line Filters	12.19
Helical Resonators	12.23
Active Filters	12.27
<i>Project: Crystal Filter Evaluation</i>	12.27
<i>Project: Band-Pass Filters for 144 or 222 MHz</i>	12.30
<i>Project: High-Performance Passive CW Filter</i>	12.31
<i>Project: Broadcast Band Rejection Filter</i>	12.35
<i>Project: A Wave Trap for Broadcast Stations</i>	12.36
<i>Project: Second-Harmonic-Optimized LP Filters</i>	12.37
<i>Project: The Diplexer Filter</i>	12.39

Chapter 13 — EMI/Direction Finding

The Scope of the Problem	13.1
Responsibility	13.2
EMC Fundamentals	13.3
Cures	13.5
TVI Troubleshooting Chart	13.8
Amateur Harmonics/CATV Chart	13.10
<i>Project: Finding Shack Noise Sources</i>	13.15
Radio Direction Finding	13.17
<i>Project: The Simple Seeker</i>	13.28
<i>Project: Active Attenuator for VHF-FM</i>	13.30

Chapter 14 — Receivers and Transmitters

A Single-Stage Building Block	14.1
Negative Feedback in RF Design.....	14.4
Receiver Design Techniques	14.14
The Superheterodyne Receiver	14.20
VHF and UHF Receivers	14.34
<i>Project: GaAsFET Preamp for 430 MHz</i>	14.36
<i>Project: Microwave Receiver for 10 GHz</i>	14.41
Transmitter Design	14.42
<i>Project: A Rock-Bending Receiver for 7 MHz</i>	14.61
<i>Project: A Wideband MMIC Preamp</i>	14.64
<i>Project: A Binaural I-Q Receiver</i>	14.66
<i>Project: A Superregenerative Receiver with Squelch</i>	14.72
<i>Project: A Broadband HF Amp using MOSFETS</i>	14.74
<i>Project: A Drift-Free VFO</i>	14.81
<i>Project: A Simple Regenerative HF Receiver</i>	14.85

Chapter 15 — Transceivers, Transverters and Repeaters

Transceiver Example	15.1
<i>Project: The Norcal Sierra—An 80-15 M CW Transceiver</i> .	15.9
<i>Project: A 10-Watt SSB Transceiver for 60-M Band</i>	15.15
Transverters	15.19
Repeaters	15.20

Chapter 16 — DSP and Software Radio Design

DSP Fundamentals	16.1
DSP Algorithms for Radio	16.5
Analytic Signals and Modulation.....	16.9
Digital Speech Processing	16.16
Interference-Reduction Techniques	16.17
Fourier Transforms	16.19
Radio Architectures for DSP	16.26
Software Radios	16.31
Hardware for Embedded DSP Systems	16.32
DSP System Software	16.34
DSP Projects	16.36
<i>Project A: Decimation</i>	16.36
<i>Project B: FIR Filter Design Variations</i>	16.36
<i>Project C: Analytic Filter Pair Generation</i>	16.39
<i>Project D: Newton’s Method for Square Roots</i>	16.39
<i>Project E: A Fast Square-Root Algorithm</i>	16.39
<i>Project F: A High-Performance DDS</i>	16.41
<i>Project G: Fast Binary Multiplier in High-Speed CMOS Logic</i>	16.42

Chapter 17 — Power Supplies

Glossary	17.1
Alternating-Current Power	17.2
Rectifier Types	17.4
Rectifier Circuits	17.5
Filtration	17.11
Regulation	17.12
High-Voltage Techniques	17.20
Batteries and Charging	17.20
Emergency Operations	17.24
Power-Supply Projects	17.24
<i>Project: Series-Regulated 4.5- to 25-V Supply</i>	17.25
<i>Project: 13.8-V, 40-A Switching Supply</i>	17.28
<i>Project: 28-V, High-Current Supply</i>	17.37
<i>Project: Commercial-Quality, High-Voltage Supply</i>	17.40
<i>Project: Micro M+ Charge Controller</i>	17.41
<i>Project: The UPS—A Universal Supply</i>	17.44
<i>Project: A Portable Power Supply</i>	17.46

Chapter 18 — RF Power Amplifiers

Types of Power Amplifiers	18.1
Design Examples	18.19
<i>Project: 3CX1500D7 kW HF Amplifier</i>	18.29
<i>Project: A 6-Meter kW Amplifier</i>	18.35
<i>Project: A 144-MHz Amplifier</i>	18.38
<i>Project: A 2-Meter Brick Amp for Handhelds</i>	18.43

Chapter 19 — Station Layout and Accessories

Fixed Stations	19.1
Mobile and Portable Installations	19.13
<i>Project: Tick-2—A Tiny CMOS Keyer 2</i>	19.17
<i>Project: Vintage Radio T/R Adapter</i>	19.20
<i>Project: Quick and Easy CW with your PC</i>	19.22
<i>Project: An Expandable Headphone Mixer</i>	19.25
<i>Project: A Simple 10-Minute ID Timer</i>	19.26
<i>Project: Audio Break-Out Box</i>	19.26
<i>Project: An SWR Detector Audio Adapter</i>	19.28
<i>Project: PC Voltmeter and SWR Bridge</i>	19.29
<i>Project: Tandem Match—An Accurate Directional Wattmeter</i>	19.31
<i>Project: Automatic Antenna Switch for Yaesu or ICOM</i>	19.37
<i>Project: A Trio of Transceiver/Computer Interfaces</i>	19.41
<i>Project: Computer-Controlled Two-Radio Switchbox</i>	19.44
<i>Project: TR Time-Delay Generator</i>	19.48
<i>Project: A Switched Attenuator</i>	19.52
<i>Project: Simple QRP TR Changeover</i>	19.53
<i>Project: QRP L-Match ATU</i>	19.54
<i>Project: QRP T-Match ATU</i>	19.56
<i>Project: An Ugly Transformer for Heavy-Load Stations</i>	19.57

Chapter 20 — Propagation of RF Signals

Fundamentals of Radio Waves	20.1
Propagation Summary by Band	20.4
MUF Prediction	20.17
Propagation in the Troposphere	20.19
Extraterrestrial Propagation	20.24

Chapter 21 — Transmission Lines

Basics	21.1
Matched Lines	21.3
Reflections on the Smith Chart	21.4
Matching the Antenna to the Line	21.10
Matching the Line to the Transmitter	21.13
Loads and Balancing Devices	21.14
Waveguides	21.17

Chapter 22 — Antennas

Antenna Polarization	22.1
Dipoles and the Half-Wave Antenna	22.4
<i>Project: 135-FT Multiband Dipole</i>	22.11
Antenna Modeling by Computer	22.12
<i>Project: A 40/15-M Dual-Band Dipole</i>	22.13
<i>Project: K8SYL 75/10-M Dual-Band Dipole</i>	22.14
<i>Project: W4RNL Inverted-U Antenna</i>	22.14
<i>Project: Two W8NX Multiband, Coax-Trap Dipoles</i>	22.19
Vertical Antennas	22.23
Optimum Ground Systems for Vertical Antennas	22.23
<i>Project: Dual-Band Verticals for 17/40M or 12/30M</i>	22.27
Inverted L and Sloper Antennas	22.28
<i>Project: 1.8-MHz Inverted L</i>	22.29
<i>Project: Half-Wave Vertical Dipole (HVD)</i>	22.30
<i>Project: The Compact Vertical Dipole (CVD)</i>	22.31
<i>Project: All Wire 30-M CVD</i>	22.32
Yagi and Quad Directive Antennas	22.33
Quad Antennas	22.38
<i>Project: Five-Band, Two-Element HF Quad</i>	22.39
<i>Project: Simple Quad for 40 M</i>	22.42
<i>Project: Simple Loop for 28 MHz</i>	22.45
HF Mobile Antennas	22.45
VHF/UHF Antennas	22.53
<i>Project: Simple Portable Groundplane Antenna</i>	22.56
<i>Project: Dual-Band Antenna for 146/446 MHz</i>	22.57
<i>Project: A Quick Antenna for 223 MHz</i>	22.58
<i>Project: An All-Copper 2-M J-Pole</i>	22.58
VHF/UHF Yagis	22.60
<i>Project: 3- and 5-Element Yagis for 6 M</i>	22.60
<i>Project: A Medium Gain 2-M Yagi</i>	22.61

Chapter 23 — Space Communications

An Amateur Satellite Primer	23.1
Amateur Satellite History	23.4
Phase 3E—The Next Generation	23.13
<i>Project</i> : Single Brick L-Band Amplifier	23.17
<i>Project</i> : Double Brick L-Band Amplifier	23.17
<i>Project</i> : Parabolic Dish Construction	23.28
<i>Project</i> : Helix Feed for an Offset Dish	23.29
<i>Project</i> : Integrated AO-40 Antenna System	23.30
Glossary of Satellite Terminology	23.34
Earth-Moon-Earth (EME)	23.37

Chapter 24 — Web, Wi-Fi, Wireless and PC Technology

The World Wide Web (www)—The Internet	24.1
Ham’s Guide to Useful Internet Sites	24.2
Glossary/Wireless Fidelity (Wi-Fi)	24.3
Glossary of Wireless Technology	24.4
Wireless Technology	24.6
Personal Computers in the Shack	24.10
Mode-Specific Software	24.12

Chapter 25 — Test Procedures

Test and Measurement Basics	25.1
DC Instruments and Circuits	25.3
AC Instruments and Circuits	25.8
<i>Project</i> : The Microwattter	25.11
Frequency Measurement	25.14
<i>Project</i> : Marker Generator with Selectable Output	25.15
<i>Project</i> : A Dip Meter with Digital Display	25.17
Other Instruments and Measurements	25.20
<i>Project</i> : A Wide-Range Audio Oscillator	25.20
<i>Project</i> : Measure Inductance and Capacitance with a DVM ...	25.21
Oscilloscopes	25.22
<i>Project</i> : HF Adapter for Narrow Bandwidth Scopes	25.27
<i>Project</i> : A Calibrated Noise Source	25.27
<i>Project</i> : Signal Generator for Receiver Testing	25.31
<i>Project</i> : Hybrid Combiners for Signal Generators	25.34
<i>Project</i> : Compensated Modular RF Voltmeter	25.35
Receiver Performance Tests	25.41
Transmitter Performance Tests	25.49

Chapter 26 — Troubleshooting and Repair

Safety First	26.1
Where to Begin	26.5
Testing within a Stage	26.9
Look for the Obvious	26.11
Typical Symptoms and Faults	26.12
Troubleshooting Hints	26.17
After the Repairs	26.27
Professional Repairs	26.28

About the ARRL

About the Included CD-ROM

Foreword

The enormously successful 2005 Edition of *The ARRL Handbook* has been updated in this 2006 Edition. Thanks to the sharp eyes of a number of readers, the minor errors in the massive 2005 Edition rewrite have been fixed.

A brand-new, high-power HF linear amplifier project by Jerry Pittenger, K8RA, has been added to this 2006 Edition. Feast your eyes on Jerry's beautiful workmanship building a full-featured amplifier using the new 3CX1500D7 power triode. This rugged new Eimac tube has a 50-W grid dissipation, making it capable of withstanding almost any condition of drive or tuning.

Once again, we are including the fully searchable CD-ROM containing all of the almost 1200 pages of the printed book. Readers have been very enthusiastic about the "instant search" capabilities they have when they load the *Handbook* on their hard drives.

Whether you want to tackle projects using surface-mount components or learn how a computer can enhance many aspects and areas of your Amateur Radio pursuits, this *Handbook* has something for everyone.

So, whether you prefer to open this comprehensive reference book on your workbench, in your favorite reading chair, or using the CD drive of your computer, enjoy all that this 2006 Edition *Handbook* has to offer.

David Summer, K1ZZ
Executive Vice President
Newington, Connecticut
September 2005

The Amateur's Code

The Radio Amateur is:

CONSIDERATE...never knowingly operates in such a way as to lessen the pleasure of others.

LOYAL...offers loyalty, encouragement and support to other amateurs, local clubs, and the American Radio Relay League, through which Amateur Radio in the United States is represented nationally and internationally.

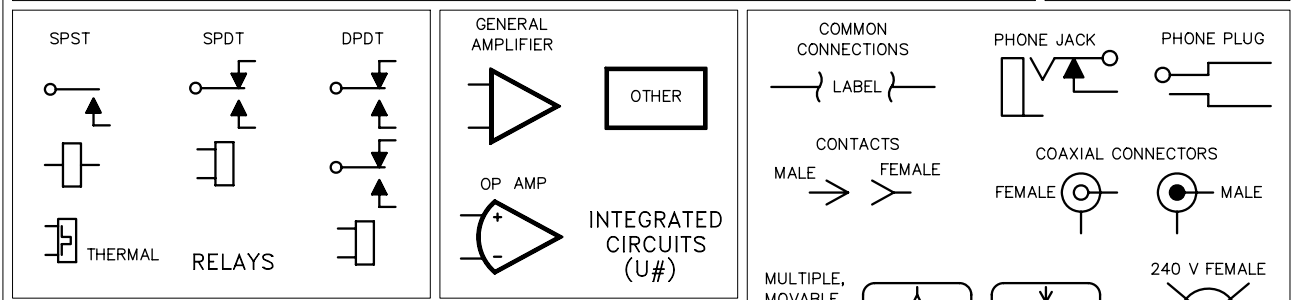

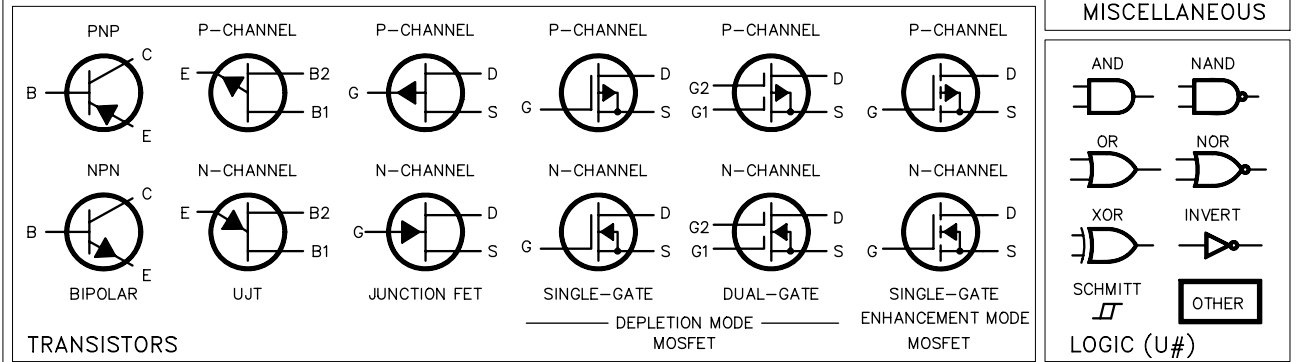

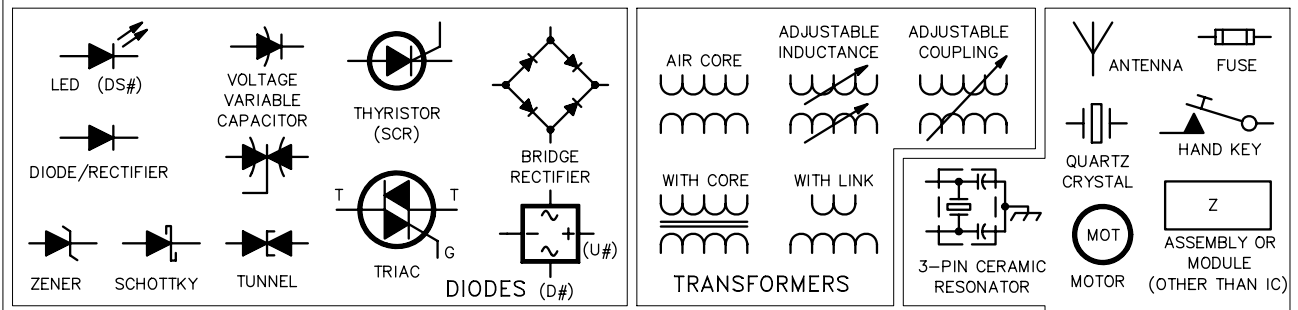

PROGRESSIVE...with knowledge abreast of science, a well-built and efficient station and operation above reproach.

FRIENDLY...slow and patient operating when requested; friendly advice and counsel to the beginner; kindly assistance, cooperation and consideration for the interests of others. These are the hallmarks of the amateur spirit.

BALANCED...radio is an avocation, never interfering with duties owed to family, job, school or community.

PATRIOTIC...station and skill always ready for service to country and community.

—*The original Amateur's Code was written by Paul M. Segal, W9EEA, in 1928.*

The ARRL—At Your Service

ARRL Headquarters is open from 8 AM to 5 PM Eastern Time, Monday through Friday, except holidays. Call **toll free** to join the ARRL or order ARRL products: **1-888-277-5289** (US), M-F only, 8 AM to 8 PM Eastern Time.

If you have a question, try one of these Headquarters departments . . .

You can send e-mail to any ARRL Headquarters employee if you know his or her name or call sign. The second half of every Headquarters e-mail address is **@arrl.org**. To create the first half, simply use the person's call sign. If you don't know their call sign, use the first letter of their first name, followed by their complete last name. For example, to send a message to John Hennessee, N1KB, Regulatory Information Specialist, you could address it to **jhennessie@arrl.org** or **N1KB@arrl.org**.

If all else fails, send e-mail to **hq@arrl.org** and it will be routed to the right people or departments.

Technical Information Service

The ARRL answers questions of a technical nature for ARRL members and nonmembers alike through the Technical Information Service. Questions may be submitted via e-mail (**tis@arrl.org**); Phone (860-594-0214); Fax (860-594-0259); or mail (TIS at ARRL, 225 Main Street, Newington, CT 06111). The TIS also maintains a home page on **www.arrl.org/tis**. See the **Component Data and References** chapter (page 7.11) of this *Handbook* for more details. Also, please note that the "Technical Information Server" or *Info Server* service previously available via e-mail has been discontinued.

ARRL ON THE WORLD WIDE WEB

You'll find ARRL at: **www.arrl.org/**

At the ARRL Web page you'll find the latest W1AW bulletins, a hamfest calendar, exam schedules, an on-line ARRL Publications Catalog and much more. We're always adding new features, so check it often!

Members-Only Web Features

As an ARRL member you enjoy exclusive access to our Members-

Only Web features. Just point your browser to **www.arrl.org/members/** and you'll open the door to benefits that you won't find anywhere else.

- *QST* Product Review Archive. Get copies of *QST* product reviews from 1980 to the present.
- *QST/QEX* searchable index (find that article you were looking for!)
- Previews of contest results. See them here before they appear in *QST!*
- Access to your information in the ARRL membership database. Enter corrections or updates on line!

Stopping by for a visit?

We offer tours of Headquarters and W1AW at 9, 10 and 11 AM, and at 1, 2 and 3 PM, Monday to Friday (except holidays). Special tour times may be arranged in advance. Bring your license and you can operate W1AW anytime between 10 AM and noon, and 1 to 3:45 PM!

Would you like to write for *QST*?

We're always looking for new material of interest to hams. Send a self-addressed, stamped envelope (2 units of postage) and ask for a copy of the *Author's Guide*. (It's also available via the ARRL Web page at **www.arrl.org/qst/aguide/**.)

Press Releases and New Products/Books

Send your press releases and new book announcements to the attention of the *QST* Editor (e-mail **qst@arrl.org**). New product announcements should be sent to the Product Review Editor (e-mail **reviews@arrl.org**).

ARRL Amateur Radio News on the Web

The primary focus of the ARRL Web site, **www.arrl.org**, is Amateur Radio news and general-interest features and columns—available to all. This is the Amateur Radio community's most comprehensive and immediate source for news and information on issues of importance and interest to radio amateurs.

The ARRL Letter

The ARRL Letter has become the League's flagship Amateur Radio news medium. The *Letter* is a weekly news summary for those who want to be on top of what's happening in the world of Amateur Radio. ARRL members can request Friday e-mail delivery via their Member Data Page. It's also available to all on the Web, **www.arrl.org/arrlletter**. *The ARRL Letter* is published 50 times a year.

ARRL Audio News

Another way to keep up with fast-moving events in the ham community is to listen to the *ARRL Audio News*. It's as close as your telephone at 860-594-0384, or on the Web at **www.arrl.org/arrlletter/audio/**.

Interested in Becoming a Ham?

Just pick up the telephone and call toll free 1-800-326-3942, or send e-mail to **newham@arrl.org**. We'll provide helpful advice on obtaining your Amateur Radio license, and we'll be happy to send you our informative Prospective Ham Package.

Chapter 1

What is Amateur (Ham) Radio?

You are reading this book because you are an interesting person whose curiosity is piqued by unusual things. Or you enjoy talking to other people, or you want to understand a little about electronics — our world is full of electronic tools. You may

want to know enough about electronics to tackle building your own electronics project. You may be a user of a personal radio station, purely for noncommercial purposes, with other radio hobbyists. We call that ham radio or Amateur Radio. We

call ourselves Amateur Radio operators, ham radio operators or just plain “hams.”

You know that ham radio operators communicate with other hams — on a distant continent or around the block — or from an orbiting space station! Some talk

Fig 1.1 — Hams are always willing to help others who are excited about becoming ham radio operators. You will find more information in this chapter about how to locate ham radio operators in your local area.

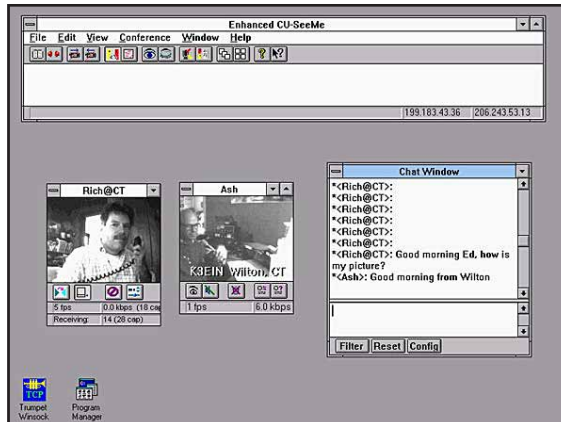

Fig 1.2 — Computers are an integral part of ham radio, and the Internet plays a large role. Rich Roznoy, K1OF and Ed Ashway, K3EIN, use their PCs to hold a video conference. Audio transmission was by way of their VHF transmitters. (Photo courtesy of Rich Roznoy, K1OF)

Fig 1.3 — Brian Wood, W0DZ, like many hams, enjoys restoring antique radios.

Fig 1.4 — Ham radio, sun and fun. Peter Venlet, N8YEL, enjoys hilltop operating. Lightweight, portable rigs and small batteries give you many opportunities to pick your operating spot.

via computers and ham radio; others prefer to use regular voice communication. Still others enjoy using one of the oldest forms of radio communication — Morse code — even though it is not a requirement to know Morse in order to earn a ham license. Some hams help save people's lives by handling emergency communication following a natural disaster or other emergency. Some become close friends with the people they talk to on the other side of the globe — then make it a point to travel and meet one or more of them in person. Some can take a bag full of electrical parts and turn it into a radio.

This chapter, by Rosalie White, K1STO, covers the basics — what hams do, and how they do it.

HOBBY OF DIVERSITIES

If you wrote down a list of all of the unusual, interesting things you can do as an Amateur Radio operator, you would fill a few pages. What types of people will you meet as a ham? If you walk down a city street, you'll pass men and women, girls and boys, and people of all ages, ethnic backgrounds and physical abilities. Any of them might be a ham you will meet tonight on your radio. They're office workers and students, nurses and mail carriers, engineers and truck drivers, housewives and bankers.

If you drive your car on the interstate

this weekend, you'll see people on their way to a state park, a Scout camp, a convention, an airport or a computer show. The young couple going to the park to hike for the day have their hand-held ham radio transceivers in their backpacks. When they stop on a scenic hilltop for a rest, they'll pull out their radios and see how far away they can communicate with the radio's 3 watts of power. And, the radios will be handy just in case they break down on the road or lose the hiking trail.

The father and son on their way to Scout camp will soon be canoeing with their Scout troop. After setting up camp, they'll get out a portable radio, throw a wire antenna over a branch, and get on the air. Aside from the enjoyment of talking with other hams from their campsite, their radios give them the security of having reliable communication with the outside world, in case of emergency.

The family driving to the ham radio convention will spend the day talking with their ham friends, including two they've never met but know quite well from talking to them on the air every week. They will also look at new and used radio equipment, listen to a speaker talk about the latest ways computers can be used to operate on the Amateur Radio bands, and enjoy a banquet talk by a NASA astronaut who is also a ham radio operator.

The couple on the way to the airport to take a pleasure flight in their small plane has their hand-held radios in their flight bags. Once they're airborne, they'll contact hams on the ground all along their flight path. Up at 5,000 feet, they can receive and transmit over much greater distances than they can from the ground. Hams enjoy the novelty of talking to other hams in a plane. The radios are an ideal means of backup communication, too.

The two friends on their way to the computer show are discussing the best interface to use between their computers and their radios for several of the operating modes that use computers. They're looking forward to seeing a number of their ham friends who are into computers.

What other exciting things will you do on the Amateur Radio bands? You might catch yourself excitedly calling (along with 50 other hams) a Russian cosmonaut in space or a sailor on the Coast Guard's tall ship *Eagle*. You could be linked via packet radio with an Alaskan sled-dog driver, a rock star, a US legislator, a major league baseball player, a ham operating the Amateur Radio station aboard the ocean liner *Queen Mary*, an active-duty soldier, a king or someone who is building the same power supply that you are from a design in this *ARRL Handbook*.

On the other hand, a relaxing evening at

All Types of Physical Abilities

People who aren't as mobile as they'd like find the world of Amateur Radio a rewarding place to make friends — around the block or the globe. Many hams with and without certain physical abilities belong to Courage Handi-Hams, an international organization of radio amateurs. Courage Handi-Ham members live in all states and many countries, and they are ready to help however they can. The Handi-Ham System provides members with study materials and aids for physical disabilities. Local Handi-Hams will assist you with studies. Once you receive your license, the Handi-Ham System may lend you basic radio equipment to get you on the air.

hand hams

Fig 1.5 — A ham's operating area is called *the shack*. It may be a corner of a room, a basement area or in this case part of a former battleship. The Mobile (AL) Amateur Radio Club installed a temporary station, W4IAX, on this imposing structure.

home could find you in a friendly radio conversation with a ham in Frankfort, Kentucky, or Frankfurt, Germany. Unlike any other hobby, Amateur Radio knows no country boundaries and brings the world together as good friends.

Although talking with astronauts isn't exactly an everyday ham radio occurrence, more and more hams are doing just that, as many NASA astronauts are ham radio operators.

YOUR LICENSE

You must have a license granted by the FCC to operate an Amateur Radio Station in the United States, in any of its territories and possessions, or from any vessel or aircraft registered in the United States. The FCC sets no minimum or maximum age requirement for obtaining a license, nor does it require that an applicant be a US citizen. However, US citizens are required to pass an FCC license exam to obtain a US Amateur Radio license.

An Amateur Radio license incorporates two kinds of authorization. For the individual, the license grants operator privileges in one class. The class of license the operator has earned determines these privileges. The license also authorizes the licensee to operate transmitting equipment physically present at the licensed station location. Therefore, the full license includes a class-specific *Operator license* and a *Station license*.

The Technician License: Your Path to Amateur Radio Fun!

Most people start in Amateur Radio with a Technician Class license. They hold that license for a while to learn the ways of the hobby. Then they move to the next class of ham license. The Technician license presents an excellent way for beginners to start enjoying the fun and excitement of Amateur Radio. The only requirement for the Technician license is that you pass a single 35-question written exam. The exam covers Federal Communications Commission (FCC) rules and regulations that govern the airways, courteous operating procedures and techniques, and some basic electronics. There is no Morse code requirement for a Technician license.

Technician license frequency privileges begin at 50 MHz and extend through the very high frequency (VHF) and ultra high frequency (UHF) ranges, and into the microwave region. All of these frequency bands give Technicians plenty of room to explore. They aren't restricted to only certain operating modes, either. They can use any communication methods allowed to hams.

Fig 1.6 — Bill Carter, KG4FXG, helps young Andrea Hartlage, KG4IUM, work her way through her first CW contact.

Fig 1.7 — The gang's all here. Who said ham radio is a solo activity? Standing are KC9XT, N9LVL, KB9ATR, WZ9M, N9IOX and N9LBT. Seated are Chris Kratzer, W9XD and KB9GRP. (Photo courtesy of Mike McCauley, KB9GNU)

Most new hams will operate first on the popular 2-meter band. With plenty of *repeaters* across the country, the FM voice signals from their low-power hand-held and mobile radios reach many other hams. Technicians also communicate through *satellites* and *packet radio* networks. They use *single-sideband (SSB)* voice and *Morse code (CW)*.

Technician licensees can gain additional operating privileges on the amateur high frequency (HF) bands by passing a 5-wpm Morse code test. Passing another 35-question written exam completes the upgrade to a General class license. Generals enjoy worldwide communication using SSB and CW as well as *slow-scan television (SSTV)* and a variety of *digital communication* modes.

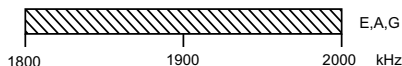

One more written exam, this one containing 50 questions, will take you to the top of the Amateur Radio license ladder

— the Amateur Extra class license. Amateur Extra class licensees enjoy full amateur privileges on all bands. The exam may be challenging, but many hams find it to be well worth the effort!

WHAT'S IN A CALLSIGN?

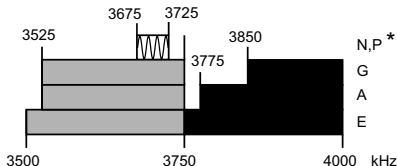

When you earn your Amateur Radio license, you receive a unique *call sign*. Many hams are known by their call signs more than by their names! All US hams get a call sign, a set of letters and numbers, assigned to them by the Federal Communications Commission (FCC). No one else *owns* your call sign — it's unique. Your Amateur Radio license with your unique call sign gives you permission to operate your Amateur Radio station on the air. US call signs begin with W, K, N or A, with some combination of letters and numbers that follow. When a US call sign begins with A there are always two letters for the

160 METERS

Amateur stations operating at 1900-2000 kHz must not cause harmful interference to the radiolocation service and are afforded no protection from radiolocation operations.

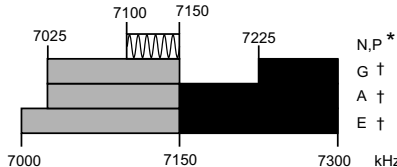

80 METERS

60 METERS

General, Advanced, and Amateur Extra licensees may use the following five channels on a secondary basis with a maximum effective radiated power of 50 W PEP relative to a half wave dipole. Only upper sideband suppressed carrier voice transmissions may be used. The frequencies are 5330.5, 5346.5, 5366.5, 5371.5 and 5403.5 kHz. The occupied bandwidth is limited to 2.8 kHz centered on 5332, 5348, 5368, 5373, and 5405 kHz respectively.

40 METERS

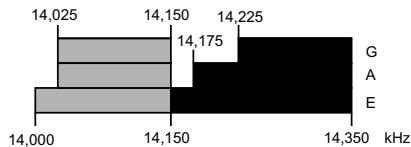

† Phone and Image modes are permitted between 7075 and 7100 kHz for FCC licensed stations in ITU Regions 1 and 3 and by FCC licensed stations in ITU Region 2 West of 130 degrees West longitude or South of 20 degrees North latitude. See Sections 97.305(c) and 97.307(f)(11). Novice and Technician Plus licensees outside ITU Region 2 may use CW only between 7050 and 7075 kHz. See Section 97.301(e). These exemptions do not apply to stations in the continental US.

30 METERS

Maximum power on 30 meters is 200 watts PEP output. Amateurs must avoid interference to the fixed service outside the US.

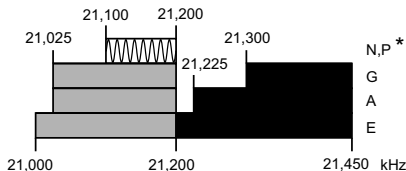

20 METERS

17 METERS

15 METERS

Novice, Advanced and Technician Plus Allocations

New Novice, Advanced and Technician Plus licenses are no longer being issued, but *existing* Novice, Technician Plus and Advanced class licenses are unchanged. Amateurs can continue to renew these licenses. Technicians who pass the 5 wpm Morse code exam *after* that date have Technician Plus privileges, although their license says Technician. They must retain the 5 wpm Certificate of Successful Completion of Examination (CSCE) as proof. The CSCE is valid indefinitely for operating authorization, but is valid only for 365 days for upgrade credit.

12 METERS

10 METERS

Novices and Technician Plus Licensees are limited to 200 watts PEP output on 10 meters.

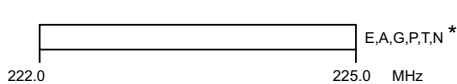

6 METERS

2 METERS

1.25 METERS ***

Novices are limited to 25 watts PEP output from 222 to 225 MHz.

70 CENTIMETERS **

33 CENTIMETERS **

23 CENTIMETERS **

Novices are limited to 5 watts PEP output from 1270 to 1295 MHz.

US AMATEUR POWER LIMITS

At all times, transmitter power should be kept down to that necessary to carry out the desired communications. Power is rated in watts PEP output. Unless otherwise stated, the maximum power output is 1500 W. Power for all license classes is limited to 200 W in the 10,100-10,150 kHz band and in all Novice subbands below 28,100 kHz. Novices and Technicians are restricted to 200 W in the 28,100-28,500 kHz subbands. In addition, Novices are restricted to 25 W in the 222-225 MHz band and 5 W in the 1270-1295 MHz subband.

KEY

- = CW, RTTY and data

Field Day: Ham Radio Alfresco

Most hams enjoy operating during Field Day. On the fourth full weekend in June, US and Canadian amateurs plus some in other parts of the world, take their radios into the great outdoors to operate away from power mains. They test how to set up efficient temporary stations to operate under emergency conditions and contact as many other stations as possible. But Field Day is, above all, fun! Hams enjoy working with a group to compete

against perhaps 100,000 other hams who are also out in the elements!

Many different Field Days are possible — from a camper, cabin or tent, maybe a view of the mountains, which is what the W7AV team did.

prefix — AA through AL. The number in the middle of the call sign indicates the station location within the country when the license was first issued. In the US, call signs that contain a 9 indicate that the ham lived in the Midwest when the license was issued, and call signs with the number 1 indicate a New England location. However, with the creation of the FCC's vanity callsign program, which permits certain FCC licensees to select their own callsign from a list of unassigned call signs based on the license class of the holder, one can no longer assume that a specific number in a US amateur call sign denotes that licensee's actual physical location. You can tell what country issued a ham's call sign by the prefix — the letters before the number.

HAM RADIO ACTION

Amateur Radio and public service go together. On a warm early-summer weekend, hams can be found directing radio communication in the aftermath of a train derailment — a simulated one, that is — to prepare for a real emergency. Others provide radio communication for a walk-a-thon. Still others hone their communication skills by setting up a station outdoors, away from electrical power. This largest public-service-related ham activity is called *Field Day*.

Biking and Cruising

Hams even operate their radios while riding on bicycle treks. They easily carry their lightweight hand-held radios in their packs, and can pull them out quickly, if needed. Or they might pull along a small

Fig 1.8 — A radio set up can be simple or complex.

trailer with sleeping bag, food and water and a small ham radio transceiver and wire antenna that they can set up in the evenings.

Other hams enjoy going to far-flung, exotic parts of the world. They get to go to new places, operate the radios, and meet new friends. Hams call these trips *DXpeditions*. Many hams enjoy operating from a sparsely populated country to provide rare ham contacts for their excited fellow hams around the world.

Nets: Scheduled Get-Togethers

If you'd enjoy finding other hams with interests like yours (such as chess, gardening, rock climbing, railroads, computer programming or teaching), you'll soon learn about *nets*. A net forms when hams with similar interests get together on the air on a regular schedule. You can find your special interest — from the Armenian Amateur Radio and Traffic Net to ARES nets — listed in *The ARRL Net Directory* on the *ARRLWeb*.

Awards and Contests: Competitive Fun

If you're competitive by nature, you'll want to explore ham radio awards and contests. These activities recognize your ability to contact many hams under specific guidelines. In the ARRL DX Contest, for example, you'll try to contact as many DX (foreign) stations as possible over a weekend. During such a weekend, experienced hams with top-notch stations easily contact more than 100 different countries!

Awards you can earn include *Worked All States*, earned by communicating with a ham in every US state, *Worked All VE*, earned by contacting hams in every Canadian province, and *DX Century Club*, for working stations in 100 or more different countries.

In an outdoor orienteering competition, "fox-hunters" track and locate hidden transmitters by car or on foot. This activity, also called direction finding, has a serious side: Skills learned in tracking the fox are useful when there's a suspected pirate (unlicensed ham station) in the area.

QRP: Talk to the World with 5 Watts of Power

For a new challenge, try operating *QRP* — using low power. Some hams enjoy operating with only 1 watt or less. It's a challenge, but with decent antennas and skillful operating, QRP enthusiasts are heard around the world. The best reason for operating QRP is that equipment is lightweight, inexpensive and easy to build. Some hams use nothing but "home-brew" equipment.

Computers and Ham Radio

If computers are your favorite aspect of today's technology, you'll soon discover that you can connect your computer to Amateur Radio equipment and operate using such digital modes as *packet radio*, RTTY, *PSK31* and High-Speed Multimedia (*HSMM*). HSMM is a popular multimedia mode used on the ultra-high-

Fig 1.9 — Ham radio operators are well-known for providing emergency communication. Famous newscaster

Walter Cronkite, KB2GSD, honored hams by narrating a show on hams saving the day with communications when all else failed.

frequency (UHF) bands for the simultaneous transmission of voice, video, text and data. With packet, you can leave messages that other packet enthusiasts will pick up and answer later. PSK31 is a popular digital mode used on the amateur high-frequency (HF) bands. It is used with common computers and sound cards, allowing you to talk great distances with a modest ham station. Computers can help you practice taking amateur license examinations or improve your Morse code abilities. ARRL, and others, offer software especially designed to help you pass amateur radio exams. You'll discover software for many ham applications, from keeping track of the stations you've contacted to designing a great antenna. See also the chapter on **Web, Wi-Fi, Wireless and PC Technology** in this *Handbook* for additional information.

Enhancing Radio Signals

Radio signals normally travel in straight lines, which limits their range. But hams have found some ingenious ways of extending the distance and improving the quality of the signals they transmit. High-frequency (HF) radio waves can be refracted or bent by a layer of the atmosphere called the ionosphere. Signals are returned to Earth, often after several "hops." This *ionospheric propagation* of radio signals allows worldwide communication on the HF bands. Hams have also learned how to bounce signals off the moon, airplanes and even meteor trails! Repeaters, located on hilltops or tall buildings, strengthen signals and retransmit them. This provides communication over distances much farther than would be possible without repeaters.

Helping out in Emergencies

When commercial communication services are disrupted by power failures or during natural disasters such as earthquakes and hurricanes, Amateur Radio operators are often first at the scene. Bat-

Fig 1.10 — John Tallon, N6OMB (standing) and Randy Hammock, KC6HUR, discuss operation of the APRS net in the LA Police Department command center during the 1998 LA Marathon. (KN6F Photo)

tery-powered equipment allows hams to provide essential communication even when power is knocked out. If need be, hams can make and install antennas on the spot from whatever materials and supports they find available. Many hams join their local Amateur Radio Emergency Service (ARES)[®] group sponsored by ARRL, and regularly practice their emergency communication skills.

Working with emergency personnel such as police and fire departments, the Red Cross and medical personnel, ham volunteers provide communication. Hams can handle communication between agencies whose normal radios are incompatible with one another, for example. The ability of radio amateurs to help the public in emergencies is one of the reasons Amateur Radio has prospered since the early days of the 20th century.

Community Events

To keep their emergency-preparedness skills honed, and to help their community, hams enjoy assisting with communication

to aid the public at any number of activities. Hams volunteer to provide communication for marathons, bike races, parades and other community events. In fact, it's rare to see a large community event that doesn't make use of public-spirited ham radio operators.

Build It Yourself!

Another favorite activity hams enjoy is building their own radio equipment. Many amateurs proudly stay at the forefront of technology, continually being challenged to keep up with advances that could be applied to the hobby. They have an incessant curiosity and an eagerness to try new techniques. They try to find ways to allow the radio frequency bands to support more users, since some portions of the

Fig 1.11 — The art of *homebrewing*, or building your own equipment, is thriving. This small receiver contains two transistors and one integrated circuit. It is assembled without special tools in one or two evenings. The thrill of operating a radio you built lasts a long time! See Chapters 14 and 15 for some receivers and transceivers you can build.

Hams at the Forefront

Over the years, the military and the electronics industry have often drawn on ham ingenuity to improve designs or solve problems. Hams provided the keystone for the development of modern military communication equipment, for example. In the 1950s, the Air Force needed to convert its long-range communication from Morse code to voice — and jet bombers had no room for skilled radio operators. At the time, hams communicated by voice at great distance with both home-built and commercial single-sideband (SSB) equipment. Air Force Generals LeMay and Griswold, both radio amateurs, hatched an experiment that used ham equipment at the Strategic Air Command headquarters and an airplane flying around the world. They found that the equipment would need only slight modification to meet Air Force needs. By using ham radio technology, two generals saved the government millions of dollars in research costs.

OSCARs: The Ham Satellites

You will be thrilled hearing your own radio signal returned from space by an orbiting “repeater in the sky” — a ham radio satellite. Hams regularly use Amateur Radio satellites, called OSCARs (for *Orbiting Satellites Carrying Amateur Radio*). Your VHF and UHF ham signals normally won’t travel much beyond the horizon. But if you route signals through a satellite, you can make global radio contacts on VHF and UHF. OSCAR-16 was built and launched in the '90s. It allows messages from Earth to be stored and forwarded back down to Earth when the spacecraft is within range of the designated station. Hams from around the globe worked together to design, build and test OSCAR 40, launched in 2000. It provided hams with communication on several radio frequencies up through the microwave bands.

OSCAR-E — the “Echo Project” — was built and launched in June 2004. The satellite has two UHF transmitters for running simultaneous operation, four VHF receivers and a multiband, multimode receiver for the 10-m, 2-m, 70-cm and 23-cm bands. Hams can use FM voice and various digital modes — including PSK31 on a 10-meter SSB uplink. Does this sound beyond your skills? It shouldn’t. All it takes is a Technician license to enjoy satellites.

Fig 1.13 — Most communication with unmanned satellites uses VHF, UHF or microwave frequencies, and many hams build their own antennas for this pursuit.

Fig 1.12 — Amateur Radio operators on the International Space Station (ISS) enjoy using its on-board ham station during their off-duty hours. They talk to friends, school students and hams around the world by voice and packet radio. Many astronauts are ham radio operators now that they are assigned long-duration ISS stints.

ham bands are very popular and can be crowded.

The projects you’ll find in this book provide a wide variety of equipment and accessories that make ham radio more convenient and enjoyable. Many manufacturers provide parts kits and etched circuit boards to make building even easier.

Hams in Space

In 1983, the first ham/astronaut made history by communicating from the space shuttle *Columbia* with ground-based hams. On that mission, NASA Payload Specialist Owen Garriott, whose Amateur Radio call sign is W5LFL, took along a hand-held amateur transceiver and placed a specially designed antenna in an orbiter

window. It was the first time ham radio operators throughout the world were to experience the thrill of working an astronaut aboard an orbiting spacecraft. In 1985, Mission Specialist Tony England, WØORE, transmitted slow-scan television via Amateur Radio while orbiting the Earth in the shuttle *Challenger*. He named the payload *SAREX*, for Shuttle Amateur Radio *EX*periment.

From then on, NASA routinely scheduled *SAREX* missions. In 1991, all five members of mission STS-37 had earned a ham radio license! NASA promotes ham activity because of its proven educational and PR value. It could be used for backup communication. In 1995, five shuttle crews requested that NASA install the

Fig 1.14 — Astronaut Susan Helms, KC7NHZ, made several dozen Field Day contacts operating from the ISS as NA1SS. (NASA Photo)

SAREX payload on their flights. A ham station was one of the first “extra” items installed in the International Space Station (ISS).

Plans began in 1996 to have Amateur Radio on the ISS, in a program called ARISS. During crew members’ on-board leisure time, the ham astronauts sometimes talk to hams, school students and friends. Because ISS missions are long-duration stints, many astronauts have decided to earn their ham licenses.

GETTING STARTED

Now that you know some things hams do, you may be asking, “Okay, how do I get started?” The first step is to earn a license.

Fig 1.15 — The St Xavier High School Amateur Radio Club assembled for this photo just before a big weekend contest. Their enthusiastic efforts led them to a high score for their type of station.

Fig 1.16 — There were no computers, satellites or TV when Clarice, W7FTX, was first licensed in 1935. One thing has not changed — the friendship of her fellow hams.

Most people start with the Technician license, which has a 35-question written exam. Exams are given by local ham Volunteer Examiners (VEs). Many clubs sponsor exam sessions regularly, so you shouldn't have to travel far. Exams are given on weekends or evenings. Exam questions are taken from a large pool of questions for each license class. The complete question pools for the three licenses are published in study guides or can be found on the Internet. (See the URL for *ARRLWeb* in the Resources section at the end of this chapter.)

Study Guides

You can prepare for the exams in a class or on your own. Help is available at every

step. The ARRL publishes study materials for all classes of licenses. Contact ARRL's New Ham Desk (the phone number and address are at the end of this chapter) for more information on getting started: nearby ham clubs, instructors who have registered with ARRL, and local VEs. You'll find a lot of information on the ARRL Web site, such as frequencies hams can use, popular operating activities and the latest versions of ARRL study guides.

ARRL's beginner manual, *Now You're Talking!*, includes the complete, up-to-date question pool with the correct answers and clear explanations. You'll also find tips for how to choose your equipment and put together your ham radio station, simple and inexpensive antennas and much more.

Now You're Talking! assumes no prior electronics background. Children as young as five years old have passed ham radio exams! You could choose ARRL's *Tech Q & A manual*, instead, if you already have some electronics background or just want brief explanations to help you understand the correct answers. Every question in the Technician question pool is included to help you prepare.

When you are ready to upgrade to a General class license, *The ARRL General Class License Manual* or *ARRL's General Q & A* will help you prepare. *The ARRL Extra Class License Manual* will guide your study efforts for the Amateur Extra class license. ARRL's *Your Introduction to Morse Code* will teach you the Morse code and prepare you for the 5-wpm exam. *ARRL's Technician Video Course* and *ARRL's General Video Course* can bring our expert instructors to your TV. Even newer is ARRL's online Technician license course—learn what you need to know to earn your license by studying at your computer when it's convenient for you!

Mentors, Sometimes Called Elmers

Ham radio operators often learn how to get on the air from a mentor. An experienced ham, called an "Elmer," teaches newcomers about Amateur Radio on a one-to-one basis. Many ham clubs have special mentor programs. Elmering was first documented in ARRL's monthly magazine, *QST*, in a story meant to be a public thank you from an appreciative student whose mentor's name was Elmer. Elmers are there for you as you study, buy your first radio and set up your station. They are proud to help you with your first on-the-air contacts.

Putting Together a Station

As with any other hobby, you can enjoy ham radio no matter how small or large

Fig 1.17 — Many hams operate radios while on the road.

your budget. You can start with a handheld transceiver that fits in your pocket or purse, and take it along when you hike, canoe or aviate. Or you can fill your "radio shack" with the latest and fanciest radios technology offers and money can buy, and talk to people in all corners of the world. You can put up a simple, inexpensive wire antenna between two trees in your backyard, or install a tower with antennas on top. Either way you'll talk to the world.

Accessories and equipment for your ham radio station come in all price ranges. *QST* contains display advertisements for new ham gear plus classified ads for previously owned items.

Used Versus New

Hams are continually upgrading their stations, so you can always find a ready supply of good previously-owned Amateur Radio gear. You can find new handheld transceivers and used HF radios for less than \$300. Many hams start with a radio that costs between \$300 and \$600. Antennas and other gear can add appreciably to the cost, but less-expensive alternatives, such as putting together your own antenna or low-power transceiver, are available.

HAMS AS WORLD CITIZENS

When you become an Amateur Radio operator, you become a "world citizen" — you join people who have earned the privilege of talking to other hams around the corner or around the world. Hams have a long tradition of spreading international goodwill. One way hams do this is to assist with getting needed medical advice or

medicine to developing countries. Another is by learning about the lives and cultures of those they contact. But you should avoid talking about sensitive political or ethical issues.

Although English is the standard language on the ham bands, English-speakers will make a good impression on hams in foreign countries if they can speak a little of the other person's language — even if it's as simple as *danke* or *sayonara*.

International Amateur Radio

Hams in other countries have formed national organizations, just as US hams organized the ARRL — the national association for Amateur Radio. These sister societies work to have a united voice in international radio affairs, such as when governments together decide how radio frequencies will be divided among users. The International Amateur Radio Union (IARU), composed of about 160 national Amateur Radio societies, works to help protect the amateur frequencies.

THE ADMINISTRATORS: ITU AND FCC

Our world has a limited spectrum of radio frequencies. These frequencies must be shared by many competing radio services: aeronautical, marine, land mobile, to name a few.

The International Telecommunication Union (ITU), an agency of the United Nations, allocates frequencies among the services. With its long tradition of public service and technological savvy, ham radio enjoys the use of many different frequency bands.

In the US, a government agency, the Federal Communications Commission (FCC), regulates the radio services, including Amateur Radio. The section of the FCC Rules that deals with Amateur Radio is Part 97. Hams are expected to know the important sections of Part 97, as serious violations (such as causing malicious interference or operating without the appropriate license) can lead to fines and even imprisonment! Aside from writing and enforcing the rules governing Amateur Radio, the FCC also assigns call signs and issues licenses.

THE ARRL

Since it was founded in 1914, the ARRL — the national association for Amateur Radio — has grown and evolved along with Amateur Radio. The ARRL Headquarters building and Maxim Memorial Station, W1AW, are in Newington, Connecticut, near Hartford. Through its dedicated volunteers and a professional staff, the ARRL promotes the advancement of

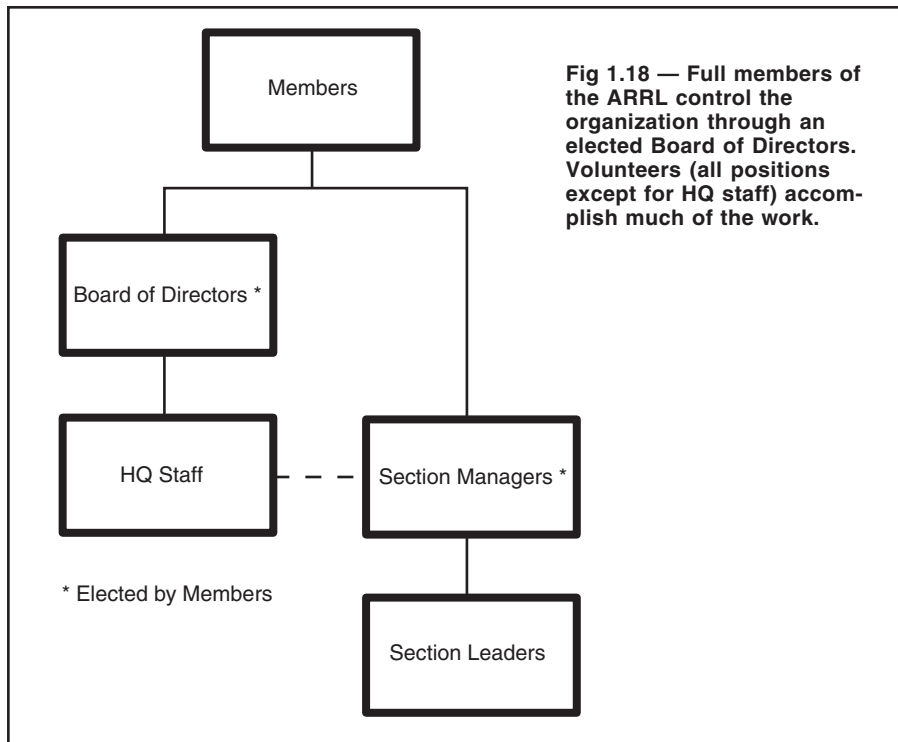

Fig 1.18 — Full members of the ARRL control the organization through an elected Board of Directors. Volunteers (all positions except for HQ staff) accomplish much of the work.

the amateur service in the US and around the world.

The ARRL is a nonprofit, educational and scientific organization dedicated to the promotion and protection of the many privileges that ham radio operators enjoy. Of, by and for the radio amateur, ARRL numbers 150,000 members — the vast majority of active amateurs in North America. Licensed hams become Full Members, while unlicensed persons become Associate Members

with all membership privileges except for voting in ARRL elections. Anyone with a good interest in Amateur Radio belongs in the ARRL.

The ARRL volunteer corps is called the Field Organization. Working at the state and local level, these volunteers work on ARRL goals to further Amateur Radio. They organize emergency communication in times of disaster and work with agencies such as Red Cross and Citizen Corps. Other

Fig 1.19 — W1AW, the station operated by the ARRL in Newington, Connecticut, is known around the world as the home of ham radio. W1AW memorializes Hiram Percy Maxim, one of the founders of the ARRL. Visitors are welcome and often operate the station. (Photo courtesy of W2ABE)

Fig 1.20 — Many hams enjoy talking to far away stations, and learn geography in the process. Here Bill, KB7JAH, and William, KB7JAG, chat with a ham in Kiribati. Don't know where Kiribati is? (Hint: Part of the island is the first in the world to greet each new day.)

Fig 1.21 — All-ham families are not unusual. Class instructor Robert Lavin, K6BOB, and VE Jonathan Fleischer, AC6GW, handed graduation certificates to the Harrises: Wesley, KG6QHT, age 7; Desiree Domingo Foraste, KD6LEW; Wesley's twin Ryan, KG6QHU, and David, KD6LET.

Fig 1.22 — Three generations of Andrew Maroneys visit W1AW. From left to right, Andrew IV, W2AJM, Andrew III, WA2QAX, and Andrew Jr, W2SON. While at Headquarters, Andrew Jr turned in QSL cards for his DXCC Honor Roll verification, bringing his total to 325.

volunteers keep state and local government officials abreast of the good that hams do at the state and local level.

Membership Services

When you join ARRL, you add your voice to those who are most involved with ham radio. The most prominent benefit of

ARRL membership is *QST*, the premiere Amateur Radio magazine. *QST* has stories you'll want to read, articles on projects to build, announcements on upcoming activities, equipment reviews, reports on the role hams play in emergencies, and much more.

But being an ARRL member is far more than a subscription to *QST*. The ARRL represents your interests to the FCC and Congress, sponsors operating events, and offers membership services at a personal level. A few are:

- Low-cost equipment insurance
- the Volunteer Examiner program
- the Technical Information Service (which gets you answers to questions about any

technical subject in Amateur Radio)

- the QSL bureau (which lets you exchange postcards with hams in foreign countries as a confirmation of your contacts with them)

Schoolteachers and Volunteer Instructors

ARRL Field & Educational Services (F&ES) provides teachers with aids for using Amateur Radio in schools, and even has equipment grants. Hundreds of teachers have found Amateur Radio an ideal way to provide hands-on, intercurricular learning, while enticing students to become interested in science and technology. F&ES also has materials, such as online newsletters and lesson plans for hams that wish to teach Amateur Radio licensing classes.

WELCOME!

For answers to any questions you may have about Amateur Radio, write or call ARRL Headquarters. See Resources, at the end of this chapter, for information.

Governing Regulations

International and national radio regulations govern the operational and technical standards of all radio stations. The International Telecommunication Union (ITU) governs telecommunication on the international level and broadly defines radio services through the international Radio Regulations. In the United States, the agency responsible for nongovernmental and nonmilitary stations is the Federal Communications Commission (FCC). Title 47 of the *US Code of Federal Regulations* governs telecommunication. Different rule Parts of Title 47 govern the various radio services in the US. The Amateur Radio Service is governed by Part 97. Some other Parts are described in the sidebar “Other FCC Rule ‘Parts’.” *The ARRL RFI Book* contains a detailed chapter on these FCC Rule parts, which affect Amateur Radio directly and indirectly.

Experimentation has been the backbone of Amateur Radio for almost a century and the amateur rules provide a framework within which amateurs have wide latitude to experiment in accordance with the basis and purpose of the service. The rules should be viewed as vehicles to promote healthy activity and growth, not as constraints that lead to stagnation. A brief overview of Amateur Radio regulations follows with special emphasis on technical standards.

BASIS AND PURPOSE OF THE AMATEUR RADIO SERVICE

There’s much more in the regulatory scheme than Part 97. The basis for the FCC regulations is found in treaties, international agreements and statutes that provide for the allocation of frequencies and place conditions on how the frequencies are to be used. For example, Article 25 of the international *Radio Regulations* limits the types of international communication amateur stations may transmit and mandates that the technical qualifications of amateur operators be verified.

It’s the FCC’s responsibility to see that amateurs are able to operate their stations in a manner consistent with the basis and purpose of the amateur rules. The FCC must also ensure that amateurs have the knowledge and ability to operate powerful and potentially dangerous equipment safely without causing harmful interference to others. A review of each of the five basic purposes of the Amateur Radio Service, as they appear in Part 97, follows:

Recognition and enhancement of the value of the amateur service to the public as a voluntary noncommercial communication service, particularly with re-

Other FCC Rule “Parts”

Part 97 is just a small piece of the overall regulatory picture. An up-to-date copy of Part 97 can be found on the Web at www.arrl.org/FandES/field/regulations/news/part97 and in *The ARRL FCC Rule Book*, which also contains hundreds of pages of interpretive materials. The *US Code of Federal Regulations*, Title 47, consists of telecommunication rules numbered as Parts 0 through 300. These Parts contain specific rules for the many telecommunication services the FCC administers. Individuals may purchase or obtain from the Web (wireless.fcc.gov/rules.html) a specific rule Part for a particular service from the Superintendent of Documents, US Government Printing Office. Here is a list of FCC Parts amateurs may find of interest:

Part

- 0 Commission organization
- 1 Practice and procedure
- 2 Frequency allocation and radio treaty matters; general rules and regulations.
- 15 Low-power radio-frequency transmitting devices
- 17 Construction, marking and lighting of antenna structures
- 18 Industrial, scientific and medical equipment
- 73 Radio broadcast services
- 76 Cable Television Service
- 90 Private Land Mobile Radio Service
- 95 Personal radio services, including CB and GMRS
- 97 Amateur Radio Service

spect to providing emergency communication [97.1(a)].

Probably the best known aspect of Amateur Radio to the general public is its ability to provide emergency communication, such as following the World Trade Center attack by terrorists in 2001. One of the most important aspects of the service is its noncommercial nature. Amateurs are prohibited from receiving any form of payment for operating their stations.

Continuation and extension of the amateur’s proven ability to contribute to the advancement of the radio art [97.1(b)].

For nearly a century, hams have carried on a tradition of learning by doing, and since the beginning have remained at the forefront of technology. Through experimenting and building, hams have pioneered advances, such as techniques for single-sideband transmissions, and are currently engaged in the development of new digital schemes which continue to improve the efficiency of such communication. Hams’ practical experience has led to technical refinements and cost reductions beneficial to the commercial radio industry. In addition, amateurs have designed and built a series of sophisticated satellites at a fraction of the cost of their commercial equivalents.

Encouragement and improvement of the Amateur Radio Service through rules which provide for advancing skills in

both the communication and technical phases of the art [97.1(c)].

Amateurs have always been experimenters and that’s what sets the Amateur Service apart from other services. The cost to the government for licensing and enforcement is minimal when compared to the benefit the public receives. Hams have contributed greatly to the development of computer communication techniques. The FCC and industry have also credited the amateur community with the development of Low-Earth-Orbit (LEO) satellite technology. The same can be said for a number of digital modes that have arrived on the scene in the 1990s, such as PacTOR, CLOVER and PSK31.

Expansion of the existing reservoir within the Amateur Radio Service of trained operators, technicians and electronic experts [97.1(d)].

Amateurs learn by doing. While all amateurs may not be able to troubleshoot and repair a transceiver, all amateurs have some degree of technical competence.

Continuation and extension of the amateur’s unique ability to enhance international goodwill [97.1(e)].

Amateur Radio is one of the few truly international hobbies. It is up to amateurs to maintain high standards and to represent the US as its ambassadors, because, in a sense, all US amateurs serve that function.

A QUICK JOURNEY THROUGH PART 97

The Amateur Radio Service rules, Part 97, are organized in six major subparts: General Provisions, Station Operation Standards, Special Operations, Technical Standards, Providing Emergency Communication and Qualifying Examination Systems. A brief discussion of the highlights of each subpart follows:

General Provisions

Subpart A covers the basics that apply to all facets of Amateur Radio. The “Basis and Purpose” of Amateur Radio, discussed above, is found at the beginning of Part 97 [97.1]. Definitions of key terms used throughout Part 97 form the foundation of Part 97 [97.3].

The remainder of the subpart is devoted to Federal restrictions on amateur installations, which include a mention of FCC standards for RF exposure. The ARRL publication *RF Exposure and You* details these RF exposure requirements.

Station Operation Standards

Subpart B, “Station Operation Standards,” concerns the basic operating practices that apply to all types of operation. Amateurs must operate their stations in accordance with good engineering and amateur practice [97.101(a)]. Part 97 doesn’t always tell amateurs specifically how to operate their stations, particularly concerning technical issues, but the FCC provides broad guidelines. The use of good engineering and amateur practice means, for example, that amateurs shouldn’t operate a station with a distorted signal and that amateurs shouldn’t operate on a busy band like 20 m just to talk to a ham across town. Also, amateurs must share the frequencies with others — no one ham or group has any special claim to any frequency [97.101(b)]. The station licensee is always responsible for the proper operation of an amateur station, except where the control operator is someone other than the station licensee, in which case both share responsibility equally [97.103(a)]. This subpart also contains regulations for the reciprocal operating authority.

The requirements for control operators, station control and reciprocal operating authority are also addressed in Subpart B. Each station must have a control point [97.109(a)]. A control operator must always be at the control point, except in a few cases where the transmitter is controlled automatically [97.109(b), (c), (d) and (e)]. The purpose of the Amateur Radio Service is to communicate with other amateurs [97.111]. Certain one-way transmissions are allowed. Amateurs can

send a one-way transmission to:

- make adjustments to equipment for test purposes
- call CQ
- remotely control devices
- communicate information in emergencies
- send code practice and information bulletins of interest to amateurs [97.111(b)]

Broadcasting to the public is strictly prohibited [97.113(b)]. The section on prohibited transmissions states that amateurs cannot: be paid for operating a station, make transmissions on behalf of an employer, transmit music (unless otherwise allowed in the rules), transmit obscenity, use amateur stations for news-gathering purposes or transmit false signals and ciphers. The FCC has relaxed the previously restrictive business rules to encourage public service and personal communication [97.113].

Station identification is addressed in this subpart. The purpose of station identification is to make the source of its transmissions known to those receiving them, including FCC monitors. The rules cover identification requirements for the various operating modes. Section 97.119 details the station-identification requirements. Amateurs must transmit their call sign at the end of the communication and every 10 minutes during communication. CW and phone may be used to identify an amateur station. RTTY and data (using a specified digital code) may be used when all or part of the communication are transmitted using such an emission. Images (Amateur Television, for example) may be used to identify when all or part of the transmission is in that mode. A final section addresses restricted operation and sets forth the conditions that must exist in an interference case involving a neighbor’s TV or radio before the Commission can impose “quiet hours” — hours of the day when a particular amateur may not operate an amateur transmitter [97.121(a)]. Imposition of quiet hours by the FCC is rare, however.

Special Operations

Subpart C, “Special Operations,” addresses specialized activities of Amateur Radio including the various types of stations an amateur may operate. This subpart gives specific guidelines concerning repeaters, beacons, space stations, Earth stations, message forwarding systems, and telecommand (remote control) stations. These rules are of particular interest to the technically minded amateur. An amateur may send ancillary functions (user functions) of a repeater on the input of the repeater — to turn on and off an autopatch, for example. However, the primary con-

trol links used to turn the repeater on and off, for example, may be transmitted only above 222.150 MHz since such one-way transmissions are auxiliary transmissions. Every repeater trustee/licensee and user should understand the rules for repeaters and auxiliary links. An important regulatory approach to solving interference problems between repeaters is addressed in that section: Repeater station licensees are equally responsible for resolving an interference problem, unless one of the repeaters has been approved for operation by the recognized repeater coordinator for the area and the other has not. In that case, the owner of the uncoordinated repeater has primary responsibility to resolve the problem [97.205(c)]. The control operator of a repeater that inadvertently retransmits communication in violation of the rules is not held accountable [97.205(g)]. The originator and first forwarding station of a message transmitted through a message forwarding system are held accountable for any violations of Part 97. Other forwarding stations are not held accountable [97.219]. For a detailed explanation, see *The ARRL FCC Rule Book*.

Technical Standards

The word *standard* means consistency and order — and this is what the technical standards in Subpart D are all about. The FCC outlines the specific frequency bands available to US amateurs [97.301] as well as the sharing agreements [97.303]. (This chapter includes a table of frequencies allocated to the Amateur Radio Service.) The Commission made these standards a basic framework so all types of amateur operation may peacefully coexist with other radio occupants in the spectrum neighborhood. Emission standards for RTTY, data and spread spectrum are discussed, as are standards for the Certification of RF power amplifiers. FCC Certification is not needed for most amateur equipment. This gives amateurs the freedom to experiment without being bound by specific equipment standards.

Providing Emergency Communication

Subpart E, “Providing Emergency Communication,” addresses disaster communication, stations in distress, communication for the safety of life and protection of property and the Radio Amateur Civil Emergency Service (RACES).

Qualifying Examination Systems

The final subpart of the rules, Subpart F, deals with the examination system and covers exam requirements and elements and standards. In 1983, the Commission dele-

gated much of the exam administration program to amateurs themselves. The rules provide for checks and balances on volunteer examiners (VEs), who administer exams at the local and regional levels. These checks and balances protect against fraud and provide integrity for the exam process.

The classes of Amateur Radio license are Novice, Technician, Technician Plus, General, Advanced, and Amateur Extra. Since April 15, 2000, the FCC has issued only *new* Technician, General and Amateur Extra licenses. (A Technician with credit for 5 wpm has the same privileges as the “old Technician Plus.”) Those who hold any of the six classes of license may have their license renewed at the same license class, however.

EMISSION STANDARDS, BANDWIDTH, POWER AND EXTERNAL POWER AMPLIFIERS

Like most of Part 97, the technical standards exist to promote operating techniques that make efficient use of the spectrum and minimize interference. The standards in Part 97 identify problems that must be solved. Section 97.307 spells out the standards FCC expects amateur signals to meet. It states, in part: “No amateur station transmission shall occupy more bandwidth than necessary for the information rate and emission type being transmitted, in accordance with good amateur practice” [97.307(a)]. Simply stated, don’t transmit a wide signal when a narrow one will do. Specific bandwidth limits are given for RTTY and data emissions. Specific bandwidth limits are not given for other modes of operation, but amateurs must still observe good engineering and operator practice.

The rules state: “Emissions resulting from modulation must be confined to the band or segment available to the control operator” [97.307(b)]. Every modulated signal produces sidebands. Amateurs must not operate so close to the band edge that the sidebands extend out of the subband,

even if the frequency readout says that the carrier is inside the band. Further: “Emissions outside the necessary bandwidth must not cause splatter or key-click interference to operations on adjacent frequencies” [97.307(b)]. The rules simply codify good operating practice. Key clicks or over-processed voice signals shouldn’t cause interference up and down the band.

Spurious emissions

Spurious emissions include harmonic emissions, parasitic emissions, intermodulation products and frequency conversion products, but do not include splatter [97.307(c)]. Definitions for *necessary bandwidth* and *out-of-band emission* appear in the **Glossary** at the end of this chapter. Also see **Fig 1.23**.

Emission standards

The FCC is very specific concerning spurious emission standards for emissions below 30 MHz and emissions from 30-225 MHz. The following requirements apply only to amateur transmitters or external HF amplifiers **below 30 MHz** [97.307(d)]:

If the amateur transmitter was installed (FCC terminology for put into operation) **after January 1, 2003**, the mean power of any spurious emission from the station transmitter or external RF power amplifier on a frequency below 30 MHz must be **at least 43 dB below the mean power of the fundamental emission**. This applies to *all* power levels, including QRP transmitters.

For transmitters installed **on or before January 1, 2003**, the mean power of any spurious emission from a station transmitter or external RF power amplifier

transmitting on a frequency below 30 MHz must **not exceed 50 mW** and must be **at least 40 dB below the mean power of the fundamental emission**. For a transmitter of mean *power less than 5 W* installed **on or before January 1, 2003**, the attenuation must be **at least 30 dB**. A transmitter built before April 15, 1977, or first marketed before January 1, 1978, is exempt from this requirement.

The following spurious emission standards apply **between 30 and 225 MHz** [97.307(e)]:

- In transmitters with **25 W or less mean output power**, spurs must be **at least 40 dB below the mean power of the fundamental emission** and never greater than 25 μ W (microwatts), but need not be reduced further than 10 μ W. This means that the spurs from a 25-W transmitter must be at least 60 dB down to meet the 25- μ W restriction.
- In transmitters with more than 25 W mean output power, spurious emissions must be at least 60 dB below the mean power of the fundamental emission.

The situation for transmitters operating between 30 and 225 MHz is more complex. The combination of the requirement that spurious emissions be less than 25 μ W and the stipulation that they don’t need to be reduced below 10 μ W makes the requirements vary significantly with power level. This ranges from 0 dB suppression required for a transmitter whose power is 10 μ W to 60 dB of suppression required for power levels above 25 W. The requirements for transmitter operation between 30 and 225 MHz are shown graphically in **Fig 1.24**. There are no absolute limits for

Emission Designators

ITU system of designating emission, modulation and transmission characteristics employed appears in the International Radio Regulations at life.itu.int/radioclub/rr/aps01.htm. The same text appears in FCC rules. The cite is 47 CFR, Section 2.201 — Emission, modulation and transmission characteristics.

Fig 1.23 — Some of the modulation products are outside the necessary bandwidth. These are out-of-band emissions, but they are not considered spurious emissions. On the other hand, these out-of-band emissions must not interfere with other stations [97.307(b)]. The harmonics and parasitics shown in this figure are spurious emissions, and they must be reduced to the levels specified in Part 97. The FCC states that all spurious emissions must be reduced “to the greatest extent practicable” [97.307(c)]. Further, if any spurious emission, including chassis or power-line radiation, causes harmful interference to the reception of another radio station, the licensee of the interfering amateur station is required to take steps to eliminate the interference.

transmitters operating above 225 MHz, although the requirements for good engineering practice would still apply.

Transmitter Power Standards

Amateurs shall not use more power than necessary to carry out the desired communication [97.313(a)]. Don't use 700 W when 10 m is wide open, for example. No station may use more than 1.5 kW peak envelope power [97.313(b)] and no station may use more than 200 W in the 30-m band. Novices and Technicians with 5 WPM credit are limited to 200 W in their HF segments [97.313(c)]. Amateurs may use no more than 50 W in the 70-cm band near certain military installations [97.313(f) and (g)].

The FCC has chosen and published the following standards of measurement: (1) Read an in-line peak-reading RF wattmeter that is properly matched; and (2) calculate the power using the peak RF voltage as indicated by an oscilloscope or other peak-reading device. Multiply the peak RF voltage by 0.707, square the result and divide by the load resistance. The SWR must be 1:1 for calculation accuracy.

The FCC requires that you meet the power output regulations, but does not require that you make such measurements or possess measurement equipment. The methods listed simply indicate how the Commission would measure your transmitter's output during a station inspection.

As a practical matter, most hams don't have to worry about special equipment to check their transmitter's output because they never approach the 1500-W PEP output limit. Many common amplifiers aren't capable of generating this much power. However, if you do have a capable amplifier and do operate close to the limit, you should be prepared to measure your output along the lines detailed above.

External RF Power Amplifiers: Certification and Standards

In 1978, the FCC banned the manufacture and marketing of any external RF power amplifier or amplifier kit capable of operation on any frequency below 144 MHz, unless the FCC has issued a grant of type acceptance (now called FCC Certification) for that model amplifier. The FCC also banned the manufacture and marketing of HF amplifiers that were capable of operation on 10 m to stem the flow of amplifiers being distributed for illegal use in and around frequencies used by CB operators.

Amateurs may still use amplifiers capable of operation on 10 m. While the rules may make it difficult to buy a new amplifier capable of operation on 10 m, the FCC allows amateurs to modify an amplifier to restore or include 10-m capability. An amateur may modify no more than one unit of the same model amplifier in any year without FCC Certification [97.315(a)].

Of course, amateurs are permitted to build amplifiers, convert equipment from any other radio service for this use or to buy used amplifiers. When converting equipment from other services, it must meet all technical standards outlined in Part 97, and it can no longer be used in the service for which it was intended since the Certification would have been voided. Non-amateurs are specifically prohibited from building or modifying amplifiers capable of operation below 144 MHz without FCC Certification [97.315(a)]. All external amplifiers and amplifier kits capable of operation below 144 MHz must be FCC Certified in order to be marketed [97.315(b)]. A number of amplifiers, manufactured prior to the April 28, 1978 cutoff were issued a waiver of the new regulations [97.315(b)(2)]. Amateurs may buy or sell an amplifier that has either been FCC Certified, granted a waiver or modified so that the Certification is no longer valid. There are restrictions that would be valid regardless of whether the amplifier was capable of operation below 144 MHz. Some amplifiers marketed before April 28, 1978, are covered under the waiver if they are the same model that was granted a waiver [97.315(b)(2)]. An individual amateur may sell his amplifier regardless of grants or waivers, provided that he sells it only to another amateur operator [97.315(b)(4)]. Amateurs may also sell a

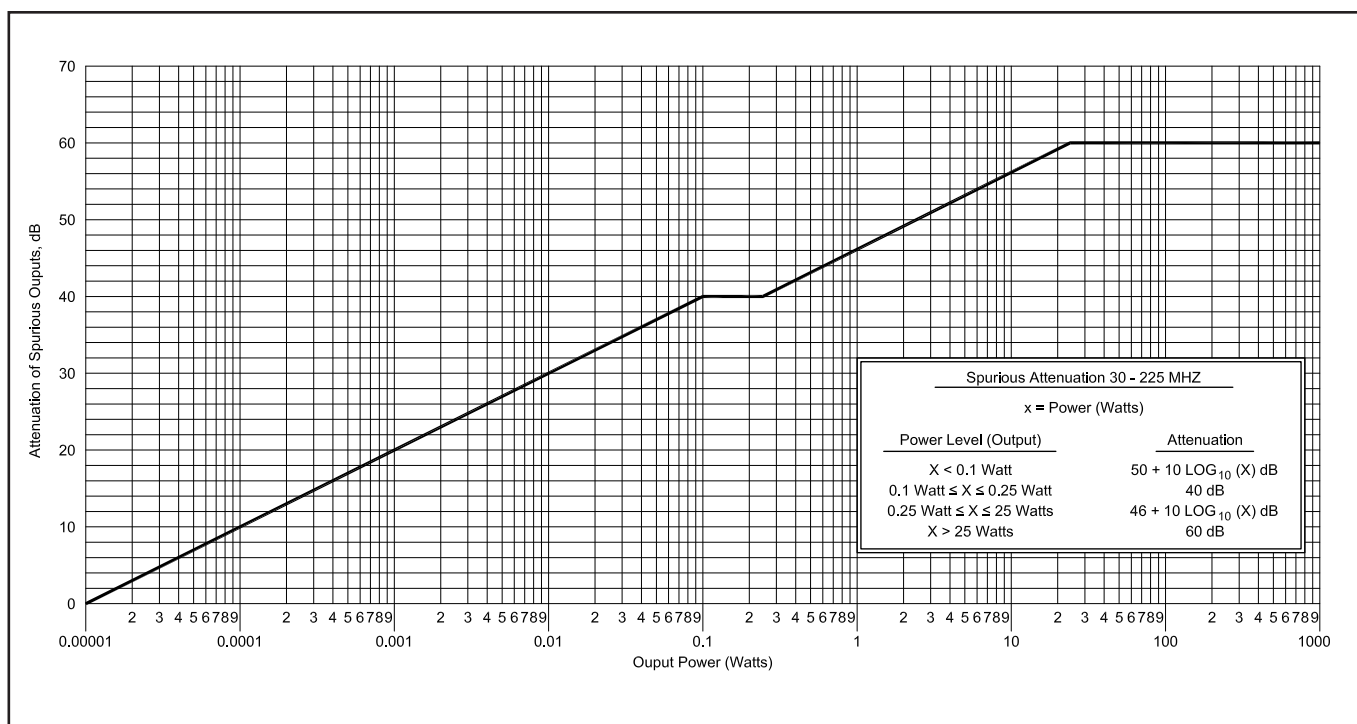

Fig 1.24 — Required attenuation of spurious outputs, 30-225 MHz.

used amplifier to a *bona fide* amateur equipment dealer. The dealer could sell those amplifiers only to other hams [97.315(b)(5)].

In some cases, the FCC will deny Certification. Some features that may cause a denial are (1) any accessible wiring which, when altered, would permit operation in a manner contrary to FCC rules; (2) circuit boards or similar circuitry to facilitate the addition of components to change the amplifier's operation characteristics in a manner contrary to FCC rules; (3) for operation or modification of the amplifier in a manner contrary to FCC rules; (4) any internal or external controls or adjustments to facilitate operation of the amplifier in a manner contrary to FCC rules; (5) any internal RF sensing circuitry or any external switch, the purpose of which is to place the amplifier in the transmit mode; (6) the incorporation of more gain than is necessary to operate in the amateur service.

CONCLUSION

A common thread in Amateur Radio's history has been a dynamic regulatory environment that has nurtured technological growth and diversity. This thread continues to sew together the elements of Amateur Radio today and prepare it for tomorrow's challenges.

Glossary

Note: Words in **boldface italics** have separate entries in the Glossary.

ADV (Amateur digital video) — A mode of operation in which *Amateur Radio* operators exchange video motion images using their personal computers.

AM (Amplitude modulation) — The oldest voice operating mode still found on the amateur bands. The more common voice mode, *SSB*, is actually a narrower-bandwidth variation of AM.

Amateur Radio — A radiocommunication service for the purpose of self-training, intercommunication and technical investigations carried out by amateurs, that is, duly authorized persons interested in radio technique solely with a personal aim and without pecuniary interest. (*Pecuniary* means payment of any type, whether money or goods.) Also called *ham radio*.

Amateur Radio operator — A person holding a license to operate a ham radio station.

Amateur Radio station — A station licensed in the amateur service, including necessary equipment.

Amateur Service — A radio communication service for the purpose of self-training, intercommunication and technical investigations carried out by amateurs, that is, duly authorized persons interested in radio technique solely with a personal aim and without pecuniary interest.

AMSAT (Radio Amateur Satellite Corporation) — An international membership organization that designs, builds and promotes the use of Amateur Radio satellites.

ARES® — An ARRL program specializing in emergency communication.

ARISS — An acronym for Amateur Radio on the International Space Station.

ARRL — The membership organization for Amateur Radio operators in the US.

ATV (Amateur television) — A mode of operation that amateur radio operators use to exchange pictures from their ham stations.

Auxiliary station — An amateur station, other than in a message-forwarding system, transmitting communication point-to-point within a system of cooperating amateur stations.

Band — A range of frequencies. Hams are authorized to transmit on many different bands.

Bandwidth — The width of a frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal within the band.

Beacon — An amateur station transmitting communication for the purposes of observation of propagation and reception or other related experimental activities.

Beam antenna — A type of ham radio antenna that can be pointed in any direction.

Broadcasting — Transmissions intended for reception by the general public, either direct or relayed.

Call sign — A series of unique letters and numbers assigned to a person who has earned an Amateur Radio license.

Carrier power — The average power supplied to the antenna transmission line by a transmitter during one RF cycle taken under the condition of no modulation.

Certification — An equipment authorization granted by the FCC. It is used to ensure that equipment will function properly in the service for which it has been accepted. Most amateur equipment does not require FCC Certification, although HF power amplifiers and amplifier kits do. Part 15 Rules require FCC Certification for all receivers operating anywhere between 30 and 960 MHz. Amateur transmitters may not be legally used in any other service that requires FCC equipment authorization. For example, it is illegal to use a modified amateur transmitter in the police, fire or business radio services.

Contact — A two-way communication between Amateur Radio operators.

Contest — An Amateur Radio activity in which hams and their stations compete to contact the most stations within a designated time period.

Control operator — An amateur operator designated by the licensee of a station to be responsible for the transmissions from that station to assure compliance with the FCC Rules.

Control point — The location at which the control operator function is performed.

Courage Handi-Ham System — Membership organization for ham radio enthusiasts with various physical disabilities and abilities.

CW — Abbreviation for *continuous wave*; another name for *Morse code* telegraphy by radio. Also, International Morse code telegraphy emissions having designators with A, C, H, J or R as the first symbol; I as the second symbol; A or B as the third symbol; and emissions J2A and J2B.

Data — Telemetry, telecommand and computer communication emissions

having designators with A, C, D, F, G, H, J or R as the first symbol; 1 as the second symbol; D as the third symbol; and emission J2D. Only a digital code of a type specifically authorized in this Part may be transmitted.

Digital communication — Computer-based communication modes such as PSK31, *packet radio* and *HSMM*.

Dipole antenna — A wire antenna often used on the high-frequency amateur bands.

DSP (Digital signal processing) — A newer technology that allows software to replace electronic circuitry.

DX — A ham radio abbreviation for *distance* or *foreign countries*.

DXCC — A popular ARRL award earned for contacting Amateur Radio operators in 100 different countries.

DX PacketCluster — A method of informing hams, via their computers, about the activities of stations operating from unusual locations.

DXpedition — A trip to an unusual location, such as an uninhabited island or other geographical or political entity which has few, if any, Amateur Radio operators, where hams operate while visiting. DXpeditions provide sought-after contacts for hams who are anxious to have a radio contact with someone in a rare location.

Elmer — A traditional term for someone who enjoys helping newcomers get started in ham radio. A mentor.

Emergency communication — Amateur Radio communication that take place during a situation where there is danger to lives or property.

External RF power amplifier — A device capable of increasing power output when used in conjunction with, but not an integral part of, a transmitter.

External RF power amplifier kit — A number of electronic parts, which, when assembled, is an external RF power amplifier, even if additional parts are required to complete assembly.

FCC (Federal Communications Commission) — The government agency that regulates Amateur Radio in the US.

Field & Educational Services (F&ES) — Staff at ARRL Headquarters that helps newcomers get started in ham radio and supports hams who help newcomers.

Field Day — A popular Amateur Radio activity during which hams set up radio stations outdoors and away from electrical service to simulate emergencies.

Field Organization — A cadre of ARRL volunteers who perform various ser-

- vices for the Amateur Radio community at the local and state level.
- FM (Frequency modulation)** — An operating *mode* commonly used on ham radio *repeaters*.
- Fox hunt** — A competitive Amateur Radio activity in which hams track down a transmitted signal.
- Frequency coordinator** — An entity, recognized in a local or regional area by amateur operators whose stations are eligible to be auxiliary or repeater stations, that recommends transmit/receive channels and associated operating and technical parameters for such stations in order to avoid or minimize potential interference.
- FSTV (Fast-scan television)** — A mode of operation that Amateur Radio operators can use to exchange live TV images from their stations.
- Ham band** — A range of frequencies on which ham communication are authorized.
- Ham radio** — Another name for *Amateur Radio*.
- Ham radio operator** — An *Amateur Radio operator* holding a written authorization to operate a ham station.
- Harmful interference** — Interference which endangers the functioning of a radionavigation service or of other safety services or seriously degrades, obstructs or repeatedly interrupts a radiocommunication service — including ham radio — operating in accordance with the international Radio Regulations.
- HF (High frequency)** — The radio frequencies from 3 to 30 MHz.
- HSMM (High Speed Multimedia)** — A digital radio communication technique using spread spectrum modes primarily on UHF to simultaneously send and receive video, voice, text, and data.
- IARU (International Amateur Radio Union)** — The international organization made up of national Amateur Radio organizations such as the ARRL.
- Image** — Facsimile and television emissions having designators with A, C, D, F, G, H, J or R as the first symbol; 1, 2 or 3 as the second symbol; C or F as the third symbol; and emissions having B as the first symbol; 7, 8 or 9 as the second symbol; W as the third symbol.
- Information bulletin** — A message directed only to amateur operators consisting solely of subject matter of direct interest to the amateur service.
- International Morse code** — A dot-dash code as defined in International Telegraph and Telephone Consultative Committee (CCITT) Recommendation F.1 (1984), Division B, I. Morse Code.
- ITU (International Telecommunication Union)** — An agency of the United Nations that allocates the radio spectrum among the various radio services.
- Key clicks** — Undesired switching transients beyond the necessary bandwidth of a Morse code transmission caused by improperly shaped modulation envelopes.
- Mean power** — The average power supplied to an antenna transmission line during an interval of time sufficiently long compared with the lowest frequency encountered in the modulation taken under normal operating conditions.
- Mode** — A type of ham radio communication; examples are *frequency modulation (FM voice)*, *slow-scan television (SSTV)* and *SSB (single sideband voice)*.
- Morse code** — A popular communication mode transmitted by on/off keying of a radio-frequency signal. Hams use the *international Morse code*.
- Necessary bandwidth** — The width of the transmitted frequency band which is just sufficient to ensure the transmission of information at the rate and with the quality required under specified conditions.
- Net** — An on-the-air meeting of hams at a set time, day and radio frequency.
- Network** — A system of interconnected radios to allow more than one station access to shared resources.
- Out-of-band emission (splatter)** — An emission on a frequency immediately outside the necessary bandwidth caused by overmodulation on peaks (excluding spurious emissions).
- Packet radio** — A computer-to-computer radio communication mode in which information is broken into short bursts. The bursts (packets) contain addressing and error-detection information.
- PEP (peak envelope power)** — The average power supplied to the antenna transmission line by a transmitter during one RF cycle at the crest of the modulation envelope taken under normal operating conditions.
- Phone** — Emissions carrying speech or other sound information having designators with A, C, D, F, G, H, J or R as the first symbol; 1, 2 or 3 as the second symbol; E as the third symbol. Also speech emissions having B as the first symbol; 7, 8 or 9 as the second symbol; E as the third symbol.
- Power** — Power is expressed in three ways: (1) Peak envelope power (PEP); (2) Mean power; and (3) Carrier power.
- Public service** — Activities involving Amateur Radio that hams perform to benefit their communities.
- Pulse** — Emissions having designators with K, L, M, P, Q, V or W as the first symbol; 0, 1, 2, 3, 7, 8, 9 or X as the second symbol; A, B, C, D, E, F, N, W or X as the third symbol.
- QRP** — An abbreviation for low power.
- QSL bureau** — A system for sending *QSL cards* to and from ham radio operators.
- QSL cards** — Cards that serve to confirm communication between two hams.
- QST** — The premiere ham radio monthly magazine, published by the *ARRL*. *QST* means “calling all radio amateurs.”
- RACES (Radio Amateur Civil Emergency Service)** — A radio service that uses amateur stations for civil defense communication during periods of local, regional or national civil emergencies.
- Radio Regulations** — The latest ITU *Radio Regulations*.
- RF (Radio frequencies)** — The range of frequencies that can travel through space in the form of electromagnetic radiation.
- RIC (Radio interface card)** — A PCMCIA device with an antenna port used in *HSMM* radio to allow a personal computer to control a radio transceiver.
- RLAN (Radio Local Area Network)** — This is similar to a wireless LAN, except that hams replace the small antennas with larger outdoor antennas and use the equipment to cover several miles or more.
- RMAN (Radio Metropolitan Area Network)** — This is an *HSMM* radio technique, usually longer range or higher data rates, to interconnect amateur radio RLANS.
- Radio (or Ham) shack** — The room where Amateur Radio operators keep their station.
- Radiotelegraphy** — See *Morse code*.
- Receiver** — A device that converts radio signals into a form that can be heard.
- Remote control** — The use of a control operator who indirectly manipulates the operating adjustments in the station through a control link to achieve compliance with the FCC Rules.
- Repeater** — An amateur station, usually located on a mountaintop, hilltop or tall building, that receives and simultaneously retransmits the signals of other stations on a different channel or channels for greater range.
- RTTY** — Narrow-band direct-printing telegraphy emissions having designators with A, C, D, F, G, H, J or R as the first symbol; 1 as the second symbol; B as the third symbol; and emission J2B.
- SAREX (Space Amateur Radio Experiment)** — Amateur Radio equipment

flown in space and operated by astronauts who are licensed Amateur Radio operators.

Space station — An amateur station located more than 50 km above the Earth's surface.

Splatter — See *Out-of-band emission*.

Spread Spectrum — A technology, originated during World War II, which distributes or spreads a radio signal over a broad frequency range. This spreading prevents narrow band signals and noise sources from interfering with the spread spectrum signal. The spread spectrum signal is heard as noise to the traditional narrow band receiver. Also, emissions using bandwidth-expansion modulation emissions having designators with A, C, D, F, G, H, J or R as the first symbol; X as the second symbol; X as the third symbol.

Spurious emission — An emission, on frequencies outside the necessary bandwidth of a transmission, the level of which may be reduced without affecting the information being transmitted. They include harmonic emissions, intermodulation products and fre-

quency conversion products, but exclude out-of-band emissions.

SSB (Single sideband) — A common *mode* of voice operation on the amateur bands.

SSTV (Slow-scan television) — A *mode* of operation in which ham radio operators exchange still pictures from their stations.

SWL (Shortwave listener) — A person who enjoys listening to shortwave radio broadcasts or Amateur Radio conversations.

Telecommand — A one-way transmission to initiate, modify, or terminate functions of a device at a distance.

Telecommand station — An amateur station that transmits communication to initiate, modify, or terminate functions of a space station.

Telemetry — A one-way transmission of measurements at a distance from the measuring instrument.

Test — Emissions containing no information having the designators with N as the third symbol. Test does not include pulse emissions with no information or modulation unless pulse emissions are

also authorized in the frequency band.

TIS (Technical Information Service) — A service of the *ARRL* that helps hams solve technical problems.

Transceiver — A radio transmitter and receiver combined in one unit.

Transmitter — A device that produces radio-frequency signals.

UHF (Ultra-high frequencies) — The radio frequencies from 300 to 3000 MHz.

VE (Volunteer Examiners) — Amateur Radio operators who give Amateur Radio licensing examinations.

VHF (Very-high frequencies) — The radio frequencies from 30 to 300 MHz.

WAS (Worked All States) — An *ARRL* award that is earned when an Amateur Radio operator talks to and exchanges QSL cards with a ham in each of the 50 states in the US.

WAVE (Worked All VE) — An award that is earned when a ham talks to and exchanges QSL cards with a ham in each Canadian province.

Wavelength — A means of designating a frequency *band*, such as the 80-meter band.

Work — To contact another ham.

Chapter 2

Activities in Amateur Radio

One of the best things about this hobby we call Amateur Radio is its *flexibility*. In other words, Amateur Radio can be whatever *you* want it to be. Whether you are looking for relaxation, excitement, or a way to stretch your mental (and physical) horizons, Amateur Radio can provide it. This chapter was written by Larry Kollar, KC4WZK, with some new material by John Champa, K8OCL and Shawn Reed, N1HOQ. Let's take a brief tour through the following topic areas:

Awards — the individual and competitive pursuits that make up the tradition we call “paper chasing.”

Contests — the challenge of on-the-air competition.

Nets — both traffic nets, where amateurs pass messages on behalf of hams and non-hams, and the casual nets, where groups of people with common interests often meet on the air to swap equipment, anecdotes and information.

Ragchewing — meeting new friends on the air.

Amateur Radio Education — Educating current and future hams brings in new blood (and revitalizes old blood!); educating our neighbors about ham radio is good for public relations and awareness.

ARRL Field Organization — Amateur Radio in general, and the ARRL in particular, depend on the volunteer spirit. As part of the Field Organization, you can exercise your administrative, speaking and diplomatic skills in service of the amateur community.

Emergency Communications — When disaster strikes, hams often have the only reliable means to communicate with the outside world. Practice and preparation are key to fulfilling this mission.

DF (Direction Finding) — If you've ever wanted to know where a transmitter (hidden or otherwise) is located, you'll find DFing is an enjoyable and useful skill.

HSMM (High Speed Multimedia) — Making contacts using video, voice, text, and data simultaneously on the ham radio

version of a wireless Internet called the Hinternet.

Satellite Operation — You may be surprised to learn that hams have their own communications satellites! Satellite operation can be great fun and a technical challenge for those who want to operate on the “final frontier.”

Repeaters — Using and operating repeaters is one of the most popular activities for both new and old hams.

Image Communications — Although it's fun to talk to other amateurs, it's even more fun to *see* them.

Digital Communications — Use your computer to communicate with stations around your town or around the world.

VHF, UHF and Microwave Weak-Signal Operating — Explore the challenging, quirky and surprising world above 50 MHz.

EME (Earth-Moon-Earth), Meteor Scatter and Aurora — Making contacts by bouncing your signals off the moon, the fiery trails of meteors and auroras.

AWARDS

Winning awards, or “paper chasing,” is a time-honored amateur tradition. For those who enjoy individual pursuits or friendly competition, the ARRL and other organizations offer awards ranging from the coveted to the humorous.

DX Awards

The two most popular DX awards are DXCC (DX Century Club), sponsored by the ARRL and WAC (Worked All Continents), sponsored by the International Ama-

Fig 2.1 — One of the most prized awards in Amateur Radio: the DX Century Club.

teur Radio Union (IARU). The WAC award is quite simple: all you have to do is work one station on each of six continents. The DXCC is more challenging: you must work at least one station in each of 100 countries!

How-to's of DXCC — Direct QSLs and DX Bureaus

Since DX stations are often inundated with QSL cards (and QSL requests) from US hams, it is financially impossible for most of them to pay for the return postage. Hams have hit upon several ways to lighten the load on popular DX stations.

The fastest, but most expensive, way to get QSL cards is the *direct* approach. You send your QSL card, with one or two International Reply Coupons (IRCs) or one or two dollars and a self-addressed airmail envelope to the DX station. International Reply Coupons are available from your local post office and can be used nearly anywhere in the world for return postage. Some DX hams prefer that you send one or two “green stamps” (dollar bills) because they can be used to defray posting, printing and other expenses. However, it is illegal in some countries to possess foreign currency. If you’re not sure, ask the DX station or check DX bulletins available on the DX Cluster System, accessible by either packet radio or Telnet.

Many DX hams have recruited *QSL managers*, hams who handle the QSL chores of one or more DX stations. QSL managers are convenient for everyone. The DX station need only send batches of blank cards and a copy of the logs; hams wanting that station’s card need only send a First Class stamp for US return postage and can expect a prompt reply. (In the case of QSL managers located outside the United States, you must still send IRCs (or dollars) and a self-addressed return envelope.)

The easiest (and slowest) way to send and receive large batches of QSL cards is through the incoming and outgoing QSL bureaus. The outgoing bureau is available to ARRL members. The incoming bureaus are available to all amateurs. Bureau instructions and addresses are printed periodically in *QST*; they appear in the *ARRL Operating Manual*, and they are available from ARRL Headquarters for an SASE.

Alternatively, you can submit your QSO log electronically to ARRL’s Logbook of The World. All submissions are free; you only pay when you “redeem” your QSO credits for an award, such as DXCC. Once you are signed up as a Logbook user, you can submit new contact records whenever you wish. Your contacts will be matched against the logs of other Logbook users. Whenever a match occurs, you receive instant credit for the contact. You can learn more about Logbook of The World by visiting its Web site at www.arrl.org/lotw/.

DXpeditions

What does the avid DXer who has worked them all (or almost all of them) do for an encore? Answer: *become* the DX! DXpeditions journey to countries with few or no hams, often making thousands of contacts in the space of a few days.

In 1991, Albania opened its borders and legalized Amateur Radio for the first time

in many years. To train the first new generation of Albanian hams and to relieve the pileups that were sure to happen, a contingent of European and American hams organized a DXpedition to Albania. The DXpedition made over 10,000 contacts and changed Albania from one of the rarest and most-desired countries to an “easy one.”

In March/April, 2004, one of the largest DXpeditions ever organized completed 153,113 QSOs during a 25-day period from tiny Rodriguez Island in the Indian Ocean. With only one resident amateur, Rodriguez is quite difficult to work for most hams, and it counts as a separate country for the DXCC award. The 3B9C DXpedition team worked amateurs worldwide on all current HF bands, including contacts on the 6-meter band. 3B9C even worked stations via EME (earth-moon-earth) and satellite communications on the 70-cm (432 MHz) UHF band.

DX Nets

The beginning DXer can get a good jump on DXCC by frequenting DX nets. On DX nets, a net control station keeps track of which DX stations have checked into the net. He or she then allows a small group of operators (usually 10) to check in and work one of the DX stations. This permits weaker stations to be heard instead of being buried in a pileup. Since the net control station does not tolerate net members making contacts out-of-turn, beginning operators have a better chance of snagging a new country. Nets and frequencies on which they operate vary. For the latest information on DX nets, check with local DXers and DX bulletins.

Efficient DX Operation

The best DXers will tell you the best equipment you have is “the equipment between your ears.” Good operators can make contacts with modest power. The details of efficient DX operating cannot be covered in this brief space.

WAS (Worked All States)

The WAS certificate is awarded to amateurs who have QSL cards from at least one operator in each of the 50 United States. Chasing WAS is often a casual affair, although there are also nets dedicated to operators who are looking for particular states.

Endorsements

The initial DXCC or WAS award does not mean the end. There are over 300 DXCC countries. As you reach certain levels in your country count, you qualify for endorsements. Endorsements arrive in

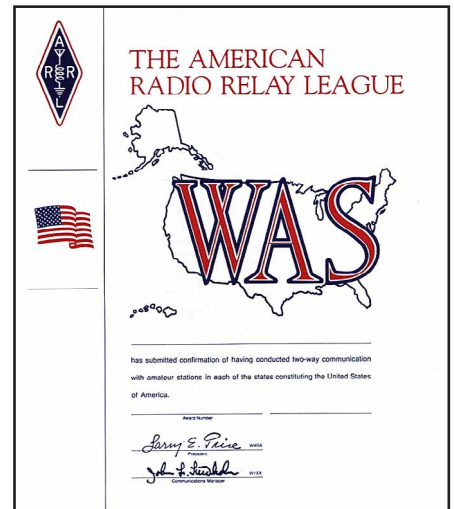

Fig 2.2 — Work one station in each of the 50 states and you’re eligible for the ARRL’s Worked All States (WAS) award.

the form of stickers that you attach to your DXCC certificate.

Both WAS and DXCC offer endorsements for single-band or single-mode operation. For example, if you work all 50 United States on the 15-m band, your certificate has an endorsement for 15 m. The most difficult endorsement is the 5-band (5B) endorsement. Rare indeed is the operator who can display a 5BDXCC certificate!

CONTESTS

Some people enjoy the thrill of competition, and Amateur Radio provides challenges at all levels in the form of operating contests. Besides the competitive outlet, contests have provided many hams with a means to hone their operating skills under less-than-optimum conditions. On the VHF and higher bands, contests are one way to stimulate activity on little-used segments of the amateur spectrum.

This section briefly discusses a few ARRL-sponsored contests. The Contest Corral section of *QST* provides up-to-date information on these and other contests. The ARRL also publishes the *National Contest Journal (NCJ)*, which is good reading for any serious (or semi-serious) contester.

Field Day

Every year on the fourth full weekend in June, thousands of hams take to the hills, forests, campsites and parking lots to participate in Field Day. The object of Field Day is not only to make contacts, but also to make contacts under conditions that simulate the aftermath of a disaster. Most stations are set up outdoors and use

Fig 2.3 — Elaine Larson, KD6DUT, takes a turn at logging as Fred Martin, KI6YN, works the paddles during the Conejo Valley Amateur Radio Club's Field Day operation.

emergency power sources.

Many clubs and individuals have built elaborate Field Day equipment, and that is all to the best — if a real disaster were to strike, those stations could be set up quickly, wherever needed, and need not depend on potentially unreliable commercial power!

Other Contests

Other popular contests include:

QSO Parties. These are fairly relaxed contests — good for beginners. There are many state QSO parties, and others for special interests, such as the QRP ARCI Spring QSO Party.

Sweepstakes. This is a high-energy contest that brings thousands of operators out of the woodwork each year.

Various DX contests. DX contests offer good opportunities for amateurs to pursue their DXCC award contacts. A good operator can work over 100 countries in a weekend!

VHF, UHF and microwave contests. These contests are designed to stimulate activity on the weak-signal portions of our highest-frequency bands. The ARRL VHF/UHF contests are held in January, June and September. There is also a contest for 10-GHz operators, and another one for EME (moonbounce) enthusiasts.

Each issue of *QST* lists the contests to be held during the next two months.

NETS

A net is simply a group of hams that meet on a particular frequency at a particular time. Nets come in three classes: public service, traffic and special interest.

Public Service/Traffic Nets

Public service and traffic nets are part of a tradition that dates back almost to the dawn of Amateur Radio. The ARRL, in fact, was formed to coordinate and promote the formation of traffic nets. In those

Keeping a Log Book

At one time, keeping a log of your contacts was an FCC requirement. The FCC has dropped this requirement in recent years, but many amateurs, both new and old, still keep logs.

Why Keep a Log?

If keeping a log is optional, why do it? Some of the more important reasons for keeping a log include:

Legal protection — If you can show a complete log of your activity, it can help you deal with interference complaints. Good recordkeeping can help you protect yourself if you are ever accused of intentional interference, or have a problem with unauthorized use of your call sign.

Awards tracking — A log helps you keep track of contacts required for DXCC, WAS, or other awards. Keeping a log lets you quickly see how well you are progressing toward your goal.

An operating diary — A log book is a good place for recording general information about your station. You may be able to tell just how well that new antenna is working compared to the old one by comparing recent QSOs with older contacts. The log book is also a logical place to record new acquisitions (complete with serial numbers in case your gear is ever stolen). You can also record other events, such as the names and calls of visiting operators, license upgrades, or contests, in your log.

Paper and Computer Logs

Many hams, even those with computers, choose to keep their logs on paper. Paper logs still offer several advantages (such as flexibility) and do not require power. Paper logs also survive hard-drive crashes!

Preprinted log sheets are available, or you can create your own. Computers with word processing and publishing software let you create customized log sheets in no time.

On the other hand, computer logs offer many advantages to the serious contester or DXer. For example, the computer can search a log and instantly tell you whether you need a particular station for DXCC. Contesters use computer logs in place of *dupe sheets* to weed out duplicate contacts before they happen, saving valuable time. Computer logs can also tell you at a glance how far along you are toward certain awards.

Computer logging programs are available from commercial vendors. Some programs may be available as shareware (you can download it from a website and pay for the program if you like the way it works). If you can program your computer, you can also create your own custom logging program, and then give it to your friends or even sell it!

early days, nets were needed to communicate over distances longer than a few miles. (Thus the word “Relay” in “American Radio Relay League.”)

Public service and traffic nets benefit hams and non-hams alike. Any noncommercial message — birthday and holiday greetings, personal information or a friendly hello — may be sent anywhere in the US and to foreign countries that have third-party agreements with the United States. Many missionaries in South America, for example, keep in touch with stateside families and sponsors via Amateur Radio.

The ARRL National Traffic System (NTS) oversees many of the existing traffic nets. Most nets are local or regional. They use many modes, from slow-speed CW nets in the Novice HF bands, to FM repeater nets on 2 m.

Since the amateur packet-radio network

now covers much of the US and the world, many messages travel over packet links. Amateurs use the packet radio network not only for personal or third-party traffic, but also for lively conferences, discussions and for trading equipment.

HF and Repeater Nets

HF nets usually cover a region, although some span the entire country. This has obvious advantages for amateurs sending traffic over long distances. Repeater nets usually cover only a local area, but some linked repeater nets can cover several states.

Both types of nets work together to speed traffic to its destination. For example, think of the HF nets as a “trunk” or highway that carries traffic quickly and reliably toward its *approximate* destination. From there, the local and regional nets take over and pass the traffic directly to the city or town. Finally, a local ama-

teur delivers the message to the recipient.

Routine traffic handling keeps the National Traffic System (NTS) prepared for emergencies. In the wake of Hurricane Andrew in 1992, hams carried thousands of messages in and out of the stricken south Florida region. The work that hams do during crisis situations ensures good relations with neighbors and local governments.

Other Nets

Many nets exist for hams with common interests inside and outside of Amateur Radio. Some examples include computers, owners of Collins radio equipment, religious groups and scattered friends and families. Most nets meet on the 80- and 20-m phone bands, where propagation is fairly predictable and there are no short-wave broadcast stations to dodge.

RAGCHEWING

Ragchewing is the fine art of the long contact. Old friends often get together on the air to catch up on current events. Family members use ham radio to keep in touch. And, of course, new acquaintances get to know each other!

In many cases, friends scattered across the country get together to create ragchewing nets. These nets are very informal and may not make much sense to the outsider listening in.

AMATEUR RADIO EDUCATION

Elmering (helping new and prospective operators) is a traditional amateur activity. Much of an amateurs' educational efforts go toward licensing (original and upgrading), but there are other opportunities for education, including public relations.

License Classes

Anyone can set up license classes. Many Amateur Radio clubs hold periodic classes, usually for the Novice and Technician elements with CW practice sessions. The ARRL supports Registered Amateur Radio Instructors, but registration is not necessary to conduct a class.

If you are looking for a class to attend, and do not have an "Elmer" to answer your questions, write ARRL Field & Educational Services for a list and schedule of classes in your area. If you want to become an instructor, you can request the same list of classes from Field & Educational Services — most classes will welcome another helping hand.

Volunteer Examiners (VEs)

To become a VE, you must hold a General or higher amateur license and be certified by one of the VE Coordinators (VECs). The

Fig 2.4 — The ARRL VEC processes 30,000 applications annually.

ARRL supports the largest VE program in the nation; other organizations run VE programs on a national or regional basis. General and Advanced licensees on a VE team must be supervised by at least one Extra Class licensee.

School Presentations

Amateur Radio complements any school program. Schoolchildren suddenly find that Amateur Radio gives them a chance to apply their studies immediately. The math and science used in Amateur Radio applies equally to the classroom. Even geography takes on a new meaning when a student works a new country!

Unfortunately, many schools do not have an active Amateur Radio presence — and that is why local volunteers are important. An HF or satellite station, or even a 2-m hand-held transceiver tuned to the local repeater, can prove an exciting and educational experience for both the vol-

unteer and the students.

Thanks to NASA's ARISS (Amateur Radio aboard International Space Station) program, amateurs all over the nation have put schoolchildren in direct contact with astronauts. Who knows how many future scientists received their inspiration while sitting behind an amateur's microphone?

ARRL FIELD ORGANIZATION

ARRL members elect the Board of Directors and the Section Managers. Each Section Manager appoints volunteers to posts that promote Amateur Radio within that Section. (The United States is divided into 15 ARRL *Divisions*. These Divisions are further broken down into 69 *Sections*.) A few of the posts include:

Assistant Section Managers — ASMs are appointed as necessary by the SM to assist the SM in responding to membership needs within the Section.

Official Observers (OO) / Amateur Auxiliary — Official Observers are authorized by the FCC to monitor the amateur bands for rules discrepancies or violations. The Amateur Auxiliary is administered by Section Managers and OO Coordinators, with support from ARRL Headquarters.

Technical Coordinators (TC) and Technical Specialists (TS) — Technical Coordinators and Technical Specialists assist hams with technical questions and interference problems. They also represent the ARRL at technical symposiums, serve on cable TV advisory committees and advise municipal governments on technical matters.

Fig 2.5 — Dry run just before an International Space Station pass. Keilah Meuser is practicing with others looking on.

EMERGENCY COMMUNICATIONS

The FCC Rules list emergency communications as one of the purposes of the

Fig 2.6 — Ham Radio on the scene after terrorists attack New York City in September 2001. On the left, in the American Red Cross radio room in Brooklyn, Mark Dieterich, N2PGD (standing), and Simone Lambert, KA1YVF, check the volunteer shift schedule and handle schedule management from the World Trade Center Disaster Relief Communications Website. On the right, Ed Cravey, KF4HPY, at the controls of the Chattahoochee Baptist Association's W4CBA mobile unit in Edison, New Jersey. The W4CBA station used a local 2-Meter repeater to communicate with deployed kitchens and showers in the old Brooklyn Navy Yard and near Ground Zero in Manhattan.

Amateur Radio Service — and in reality, the ability to provide emergency communications justifies Amateur Radio's existence. The FCC has recognized Amateur Radio as being among the most reliable means of medium- and long-distance communication in disaster areas. The terrorist attacks on the United States September 11, 2001 launched the Amateur Radio community into a real-life test of individual and collective communications skills.

Amateur Radio operators have a long tradition of operating from backup power sources. Through events such as Field Day, hams have cultivated the ability to set up communication posts wherever they are needed. Moreover, Amateur Radio can provide computer networks (with over-the-air links where needed) and provide other services such as video (ATV) and store-and-forward satellite links that no other service can deploy on a wide scale. One can argue, therefore, that widespread technology makes Amateur Radio even more crucial in a disaster situation.

If you are interested in participating in this important public service, you should contact your local EC (Emergency Coordinator). Plan to participate in preparedness nets and a yearly SET (Simulated Emergency Test).

ARES AND RACES

The Amateur Radio Emergency Service (ARES) and the Radio Amateur Civil

Fig 2.7 — Shown here in his Worcester, MA ham shack, the original W1LC — Herman R. Sanborn (SK). In June 1953, Sanborn provided emergency communications for the American Red Cross and others in the aftermath of the deadly Worcester Tornado. Sanborn's station was also on the air to assist during two other historic New England weather events — the Flood of 1936 and the Hurricane of '38. The cat atop the radio gear is *Scorpio*. (photo courtesy of Nancy Riik)

Emergency Service (RACES) are the umbrella organizations of Amateur Radio emergency communications. The ARES is sponsored by ARRL, although ARRL membership is not required for ARES participation, and handles many different kinds of public-service activities. On the other hand, RACES is administered by the

Federal Emergency Management Agency (FEMA) and operates only for civil preparedness and in times of civil emergency. RACES is activated at the request of a local, state or federal official.

Amateurs serious about emergency communication may carry dual RACES/ARES membership. FCC rules make it possible for ARES and RACES to use many of the same frequencies, so that an ARES group also enrolled in RACES can work in either organization as required by the situation.

MILITARY AFFILIATE RADIO SERVICE (MARS)

MARS is administered by the US armed forces, and exists for the purpose of transmitting communications between those serving in the armed forces and their families. This service has existed in one form or another since 1925.

There are three branches of MARS: Army MARS, Navy/Marine Corps MARS and Air Force MARS. Each branch has its own requirements for membership, although all three branches require members to hold a valid US Amateur Radio license and to be 18 years of age or older (amateurs from 14 to 18 years of age may join with the signature of a parent or legal guardian).¹

MARS operation takes place on frequencies adjoining the amateur bands and usually consists of nets. Nets are usually scheduled to handle traffic or to handle administrative tasks. Various MARS branches may also maintain repeaters or packet systems.

MARS demonstrated its importance during the 1991 Desert Storm conflict, when MARS members handled thousands of messages between the forces on the front lines and their friends and families at home. While MARS usually handles routine traffic, the organization is set up to handle official and emergency traffic if needed.

DIRECTION FINDING (DF)

If you've ever wanted to learn a skill that's both fun *and* useful, then you'll enjoy direction finding, or DFing. DFing is the art of locating a signal or noise source by tracking it with portable receivers and directional antennas. Direction finding is not only fun, it has a practical side as well. Hams have been instrumental in hunting down signals from aircraft ELTs (emergency locator transmitters), saving lives and property in the process.

We will just scratch the surface of DF activities in this section. There is much more in the **EMI/Direction Finding** chapter.

Fox Hunting

Fox hunting, also called *T-hunting* or sometimes *bunny hunting*, is ham radio's answer to hide-and-seek. One player is designated the fox; he or she hides a transmitter, and the other player attempts to find it. Rules change from place to place, but the fox must generally locate the transmitter within certain boundaries and transmit at specific intervals.

Fox hunts vary around the world. American fox hunts often employ teams of fox hunters cruising in their cars over a wide area. European and other fox hunters employ a smaller area and conduct fox hunts on foot. *Radiosport* competitions are usually European style.

Locating Interference

Imagine trying to check into your favorite repeater or HF net one day, only to find reception totally destroyed by noise or a rogue signal. If you can track down the interference, then you can figure out how to eliminate it.

Finding interference sources, accidental or otherwise, has both direct and indirect benefits. Touch lamps are a notorious noise source, especially on 80 m. If you can find one, the owner is legally obligated to eliminate the interference. Even better, if you can show your neighbors that something other than your station is interfering with their TV reception, you might gain an ally next time you petition the local government to let you have a higher tower!

SPECIALIZED COMMUNICATIONS

Satellite Operation

Amateur Radio has maintained a presence in space since 1961, with the launch of OSCAR 1 (OSCAR is an acronym for Orbiting Satellite Carrying Amateur Radio). Since then, amateurs have launched over three dozen satellites, with over 20 still in orbit today.

Amateurs have pioneered several developments in the satellite industry, including low-orbit communication “birds” and PACSATs — orbiting packet bulletin board systems. Operating awards are available from ARRL and other organizations specifically for satellite operation, such as WAS (Worked All States), WAZ (Worked All Zones), DXCC and many more.

Satellite operation does not have to be complex and difficult to learn. When someone mentions satellite operation, many people conjure up an image of large dishes and incredibly complex equipment. Actually, you can probably work several OSCARs with the equipment you have in your shack right now!

The entire collection of OSCARs — and their operating modes — can be broken down into four basic categories:

Voice/CW (Analog)

Analog satellites range from the low-orbit FO (Fuji OSCARs) built in Japan, and AO (AMSAT OSCAR) birds built by a co-op of many nations, to the high orbit Phase 3 satellites such as OSCAR 40 and

Fig 2.10 — A portable, all purpose, mode V/U/S earth station. This station works LEOs and HEOs (high earth orbiters) like AO-40, and future birds like Eagle. If you live in an area of dense tree growth that impedes your antenna performance, you might consider portable operation at a location with a very low horizon. (photo courtesy of Shawn Reed, N1HOQ).

soon to be launched AMSAT EAGLE and PHASE 3-E. Operating on analog satellites is much like operating on HF — you'll find lots of SSB and CW contacts, with some RTTY, Hellschreiber, even SSTV and other digital modes thrown in. You may even work a vintage satellite (AO-7), launched in November of 1974!

Packet (Digital)

The digital satellites are orbiting packet mailboxes and/or APRS digipeaters. APRS stands for Automatic Position Reporting System. Store and forward packet “mail”

can be sent and received, and position reports can be sent to be plotted on maps in APRS software. Real-time “keyboarding” QSOs are also seen digipeating through these birds. Several digital satellites carry an experiment called RUDAK, a versatile system that allows experimentation with packet, analog and crossband FM modes. Many of these satellites carry systems that allow switching between digital and analog operation.

FM Repeater Satellites

Some of the digital satellites are fixed on, or can be switched to FM “bent pipe” repeater mode. This allows one FM channel of communication very similar to terrestrial FM repeaters. These birds are often the first satellite experience for many amateurs, and because of the relatively modest equipment and skill level required to operate them, they are referred to as “Easy Sats”. Most of these LEO, low-earth orbiters, can be operated with as little as a dual-band handheld transceiver and handheld beam antenna! They are popular with portable and mobile operators, award chasers and “Grid Expeditioners”, who seek contacts from different maidenhead grid squares around the country and the world. Some of these birds include AO-27 (AMRAD OSCAR), SO-41 and SO-50 (SAUDI OSCARS) built by the Kingdom of Saudi Arabia. The FM repeater mode will be available on AMSAT-ECHO, which may be launched and in orbit by late 2004, VUSAT, being built by AMSAT India, and others.

ARISS

The multi-national team that developed the International Space Station recognizes the value of Amateur Radio in space. Carrying forward the tradition of the SAREX (Shuttle Amateur Radio EXperiment) and Amateur Radio aboard the former MIR space station, a permanent ham shack now resides on the new space station. The ARISS (Amateur Radio aboard International Space Station) program allows for digital and analog/voice communication with the expedition crew aboard ISS and other amateurs via an on board packet mailbox and APRS digipeater. Scheduled contacts are frequently made with demonstration stations in school classrooms around the world. Questions and answers are exchanged between astronauts and schoolchildren via FM voice on VHF.

Nearly all the astro/cosmonauts assigned to ISS are licensed amateurs in their home countries, so your chances of making a contact with space travelers is quite good! ARISS and the former SAREX and MIR projects have proven their worth in

education and goodwill, over and over. The Amateur equipment also provides a backup for the astronauts in case of normal communications failure.

Repeaters

Many amateurs make their first contacts on repeaters. Repeaters carry the vast majority of VHF/UHF traffic, making local mobile communication possible for many hams.

Hams in different regions have different opinions on repeater usage. In some areas, hams use repeaters only for brief contacts, while those in other areas encourage socializing and ragchewing. All repeater users give priority to mobile emergency communications.

The best way to learn the customs of a particular repeater is to listen for a while before transmitting. This avoids the misunderstandings and embarrassment that can occur when a newcomer jumps in. For example, in some repeater systems it is assumed that the word “break” indicates an urgent or emergency situation. Other systems recognize “break” as a simple request to join or interrupt a conversation in progress. Neither usage is more “correct,” but you can imagine what might happen to a traveling ham who was unaware of the local customs!

Most repeaters are *open*, meaning that any amateur may use the repeater. Other repeaters are *closed*, meaning that usage is restricted to members. Many repeaters have an *autopatch* capability that allows amateurs to make telephone calls. However, most autopatches are closed, even on otherwise open repeaters. The *ARRL Repeater Directory* shows repeater locations, frequencies, capabilities and whether the repeater is open or closed.

Most repeaters are maintained by clubs and other local organizations. If you use a particular repeater frequently, you should join and support the repeater organization. Some hams set up their own repeaters as a service to the community.

Image Communications

Several communications modes allow amateurs to exchange still or moving images over the air. Advances in technology in the last few years have brought the price of image transmission equipment within reach of the average ham’s budget. This has caused a surge of interest in image communication.

ADV

Amateur Digital Video (ADV) is the transmission of full-motion digital video on the Amateur Radio microwave bands. The output of a conventional, full motion,

video source, such as a camcorder, web cam, or digital camera, is digitized by PC-based communications software called a CODEC (coder-decoder). The processed video is then transmitted on a amateur microwave band. This process is sometimes called videoconferencing or streaming video.

The image quality of ADV is often lower than that of ATV, but the equipment cost is significantly less. Digital video can be transmitted and received on some microwave ham bands by using inexpensive WiFi equipment, also known as IEEE 802.11 WLAN. This equipment comes with a rubber duck antenna, which can be replaced with an outdoor, high-gain directive antenna array. A useful range of several miles can be easily covered in most terrain. This increasing popular approach is part of new amateur technology called HSMM (high speed multimedia) radio.

Why multimedia? Along with your PC, HSSM technology, and inexpensive microwave equipment, you can share high-speed Internet access, send text files, high resolution still images, or instant messages all at the same time. Some hams play interactive electronic games or use HSMM to control another ham’s entire radio station so they can split the cost of the equipment, or take advantage of a better radio site, such as a higher altitude, lower noise remote location. For more information on HSMM radio, see the Spread Spectrum and Multimedia section of Chapter 9, Modes and Modulation Sources.

ATV

Amateur TV is full-motion video over the air. (It is sometimes referred to as *fast scan*, or *FSTV*.) ATV signals use the same format as broadcast (and cable) TV. Watching an ATV transmission is the same as watching your own television. With ATV, however, you can turn a small

Fig 2.11 — Give him the specifications and Sam, K6LVM, can show you the radiation pattern of your antenna — via ATV! (photo by Tom O’Hara, W6ORG)

space in your home into your own television studio. Amateur communication takes on an exciting, new dimension when you can actually *see* the person you're communicating with!

The costs of ATV equipment have declined steadily over the years. The popularity of the camcorder has also played a significant role. (The family camcorder can do double duty as a station camera!) It is now possible to assemble a versatile station for well under \$1000. Amateur groups in many areas have set up ATV repeaters, allowing lower-powered stations to communicate over a fairly wide area. If you're fortunate enough to live within range of an ATV repeater, you won't need complicated antenna arrays or high power.

If you can erect high-gain directional antennas for your ATV station, you can try your hand at DXing. When the bands are open, it's not uncommon to enjoy conversations with stations several hundred miles away. In addition to your directional antennas, you must run moderate power levels to work ATV DX. Most DXers use at least 50 W or more.

Since this is a wide-bandwidth mode, operation is limited to the UHF bands (70 cm and higher). The *ARRL Repeater Directory* and the *ARRL Operating Manual* list band plans. The *Repeater Directory* includes lists of ATV repeaters. The **Modes and Modulation Sources** chapter provides details on setting up an ATV station with dedicated or converted video gear.

SSTV

SSTV, or slow-scan TV, is a narrow-bandwidth image mode. Instead of full-motion video at roughly 24 frames per second, SSTV pictures are transmitted at 8, 16 or 32 seconds per frame. In the beginning, SSTV was strictly a black-and-white mode. The influx of computers (and digital interfaces) has spawned color SSTV modes. Since SSTV is a narrow-band mode, it is popular on HF. Some experimenters run SSTV on satellites as well.

An SSTV signal is generated by breaking an image into individual *pixels*, or

Fig 2.12 — An SSTV image as seen on a standard TV set using a digital scan converter.

dots. Each color or shade is represented by a different audio tone. This tone is fed into the audio input of an SSB transmitter, converting the tones into RF. On the receive end, the audio tones are regenerated and fed into a dedicated SSTV converter or into a simple computer interface to regenerate the picture. For more information about SSTV, see the **Modes and Modulation Sources** chapter.

Fax

Fax, or *facsimile* transmission, is one of

the original image communication modes. Fax was once unavailable to amateurs due to FCC regulations, but is now a legal communication mode on most HF and higher bands.

Amateur Radio fax works much like old analog fax systems: an image is scanned from paper and converted into a series of tones representing white or black portions of a page. Amateurs are working on standards for the use of digital fax machines over radio as well.

Uses for amateur fax are as limitless as

QSLing

A QSL card (or just "QSL") is an Amateur Radio tradition. QSL cards are nearly as old as Amateur Radio itself, and the practice has spread so that short-wave listeners (SWLs) can get cards from shortwave and AM broadcast stations.

Most amateurs have printed QSL cards. QSL card printers usually have several standard layouts from which to choose. Some offer customized designs at extra cost. If

you are just starting out, or anticipate changing your call sign (just think, you could get a call like "KC4WZK"), you may want to purchase a pack of "generic" QSL cards available from many ham stores and mail-order outlets.

YANKEE CLIPPER		MASSACHUSETTS	
		K5MA	
CONTEST CLUB		Barnstable County FOC 1256 FN41QO Life Member ARRL	
Confirming QSO with:			
Day/Month/Year	UTC	MHz	2-way RST
			CW SSB
PSE QSL TNX	Contest:	73,	
			Jan Carman P. O. Box 930 West Falmouth, MA 02574 USA

K5MA's QSL is an example of a properly formatted card. Notice how all of the information is on one side of the card.

Filling Out Your Cards

QSL cards must have certain information for them to be usable for award qualification. At a minimum, the card must have:

- Your call sign, street address, city, state or province and country. This information should be preprinted on one side of your QSL card.
- The call of the station worked.
- The date and time (in UTC) of the contact.
- The signal report.
- The band and mode used for the contact.

Awards for VHF and UHF operations may also require the grid locator (or "grid square") in which your station is located. Current practice is to include your 6-digit grid square on your QSL card even if you have no plans to operate VHF and UHF, since some HF competitions and awards require your grid square designator.

Many hams provide additional information on their QSL cards such as the equipment and antennas used during the contact, power levels, former calls and friendly comments.

Sending and Receiving Domestic QSLs

Although most QSL cards can be sent as post cards within the United States, usually saving some postage costs, post card style QSL cards often arrive with multiple cancellations and other unintended markings that can obscure or obliterate the printed and written information. It is best to send all QSL cards in a protective envelope. Back when postage was cheap, you could send out 100 post cards for a few dollars and domestic stations would send QSLs as a matter of course. Currently, if you really need a particular QSL, it is best to send a self-addressed stamped envelope along with your card.

QSLing for DX stations is somewhat more involved and is discussed elsewhere in this chapter.

Fig 2.13 — Dave Patterson, WB8ISZ, checks into his local packet bulletin board as his cat Sam looks on. (photo by WB8IMY)

Fig 2.14 — John Shew, N4QQ (at a portable station set up by KG5OG) makes an EME CW contact with VE3ONT. (photo by WB8IMY)

your imagination. Suppose you were having trouble with the design of your new home-brewed widget. You could fax a copy of the schematic to a sympathetic ham, who could mark in some changes and fax it back to you. And how about faxing QSL cards? No hunting for stamps or waiting for the mail to arrive!

Digital Communications

Digital communications predate the personal computer by many years. In fact, some amateurs consider CW to be a digital mode in which the amateur's brain handles the encoding and decoding of information. For the purposes of this *Handbook*, however, we consider digital modes to be those traditionally encoded and decoded by electronic means. Currently, the use of PC digital sound cards to encode and decode digital communication modes has become the ham radio standard. Common sound card-based digital modes in use today include RTTY, PSK31, Packet Radio, and the vhf/uhf weak-signal mode software package WSJT, created by Joe Taylor, K1JT.

Packet Radio

Packet radio is much less popular in today's ham radio world than it was in the 1990s. Packet radio's most important applications include networking and unattended operation. The two most common uses are the worldwide DX Cluster network and regional or local general use networks. Do you need to give some information to an absent friend? Send an electronic mail message (or *e-mail* in networking parlance). Would you like to see what 20-meter DX stations in Asia have been worked or heard recently by east-coast USA stations? Log onto your local DX Cluster node and find out. Is your

friend out of range of your 2-meter packet radio? Send your message through the packet network.

In packet radio, transmitted data is broken into "packets" of data by a TNC (terminal node controller). Before sending these packets over the air, the TNC calculates each packet's checksum and makes sure the frequency is clear. On the receive end, a TNC checks packets for accuracy and requests retransmission of bad packets to ensure error-free communication.

Packet radio works best on frequencies that are relatively uncrowded. On busy frequencies (or LANs), it is possible for two stations to begin transmitting at once, garbling both packets (this is called a *collision*). Another common problem is the *hidden transmitter*, which happens when one of two stations (that are out of range of each other) is in contact with a third station within range of *both* (see Fig 2.15). Collisions can easily occur at the third station since neither of the other two stations

can hear each other and thus may transmit simultaneously.

APRS

APRS (Automatic Position Reporting System) uses the unconnected packet radio mode to graphically indicate the position of moving and stationary objects on maps displayed on a computer monitor. Unconnected packets are used to permit all stations to receive each transmitted APRS packet on a one-to-all basis rather than the one-to-one basis required by connected packets.

APRS is used for tracking stations or objects in motion or in fixed positions. Weather-monitoring equipment can be interfaced to an APRS station to disseminate real-time weather information.

Like standard packet-radio transmissions, APRS data are relayed through digipeaters. Unlike standard packet radio, APRS stations use generic digipeater paths so that no prior knowledge of the network is needed. In addition, the Internet is an integral part of the system that is used for collecting and disseminating current APRS data in real time.

Virtually all VHF APRS activity occurs on 2 meters, specifically on 144.39 MHz, which is recognized as *the* APRS operating channel in the United States and Canada. On UHF, you'll find the activity on 445.925 MHz.

Many groups and individuals that participate in public service and disaster communications find APRS a useful tool. Others find it interesting to view real-time weather reports from around their area.

RTTY

RTTY is the original data communication mode, and it remains in active use today. While RTTY does not support the

Fig 2.15 — The "hidden transmitter" problem. Site B has established contact with site C, but cannot hear site A. However, site C can hear *both* stations. If site B transmits, or vice versa, a packet collision occurs.

features of the newer data modes, such as frequency sharing or error correction, RTTY is better suited for “roundtable” QSOs with several stations. It also is the most popular mode for worldwide digital contest events.

RTTY was originally designed for use with mechanical teleprinters, predating personal computers by several decades. Amateurs first put RTTY on the air using surplus teletypewriters (TTYs) and homebrewed vacuum-tube-based interfaces. Today, of course, RTTY uses computers, computer sound cards, or dedicated controllers, many of which also support other digital modes such as CW, PSK31 and packet.

Other HF Digital Modes

One of the most common HF digital modes for general domestic and DX con-

tacts is PSK31. This mode is particularly effective for low power (QRP) communications. PSK31 uses phase-shift keying techniques most often generated by PC-based software operating through a common PC sound card. There are many PC software (terminal) programs available that support PSK31, most of which are available as ‘freeware.’

There are a number of HF digital modes based on an old system called Hellschreiber, which uses facsimile technology. These modes can all be generated by PC-based software using the PC sound card to handle the processing and generate the audio signal for your HF transmitter. One of the Hellschreiber modes, called PSK Hell, is quite popular for HF keyboard-to-keyboard communications. Another variant called Feld-Hell is often heard on the HF bands. Finally, there are

two freeware programs written by IZ8BLY, MFSK8 and MFSK16, which transmit at higher data rates and show improved immunity to HF propagation variations.

Microwave and VHF/UHF Weak-Signal Operating

Hams use many modes and techniques to extend the range of line-of-sight signals. Those who explore the potential of VHF/UHF communications are often known as *weak-signal* operators. Weak-signal enthusiasts probe the limits of propagation. Their goal is to discover just how far they can communicate.

They use directional antennas (beams or parabolic dishes) and very sensitive receivers. In some instances, they employ considerable output power, too. As a result of their efforts, distance records are

Amateur Voice Over the Internet: VoIP

Fueled partly by the improvements in Internet bandwidth, hams have been using the Internet as a means to link stations over great distances. This typically involves passing voice signals through a technique known as *VoIP*, or Voice Over Internet Protocol.

Some FM repeater systems now include Internet VoIP linking so that they can share signals with other repeaters and individuals throughout the world. Hams who cannot otherwise set up HF stations are using VoIP links to enjoy long-distance communication.

One of the most successful amateur VoIP systems was (and still is) the Internet Radio Linking Project, or *IRLP*. *IRLP* experimenting began in the fall of 1997 with use of the Internet to link several Amateur systems in Canada, with the first full-time hookup running coast-to-coast between Vancouver and Saint John, New Brunswick. After a few false starts, Dave Cameron, VE7LTD, settled on the open-source operating system called Linux as the platform for the next generation of *IRLP*. Since then, *IRLP* has flourished into a reliable, worldwide network, with more than 1200 repeaters and simplex stations in early 2004.

A few other enterprising hams continued experimenting with *Windows*-based systems, on which the original *Internet Phone* experiments had been conducted. In 2001, Graeme Barnes, M0CSH, developed a program called *iLINK*, which had two compelling features: it allowed access directly from a desktop computer, and it worked remarkably well over conventional dial-up Internet connections. This helped put Internet linking in the hands of thousands of hams who already had *Windows*-based computers and dial-up Internet access, and gave rise to a whole new classification of Internet-linked Amateur “stations”: licensed amateurs who were connecting themselves to distant repeaters using only a computer.

The doors opened even wider with *eQSO*, developed by Paul Davies, M0ZPD. Like *iLINK*, *eQSO* runs on conventional *Windows* PCs, and allows direct PC-based access to remote links. It specifically permits access by

A typical EchoLink screen.

non-hams, either in a listen-only mode, or in off-air conferences. *eQSO* remains popular today.

Yaesu (Vertex Standard) entered the world of Amateur Internet linking with a hardware-software product called *WIRES-II*, in 2002. In conjunction with a set of Internet-based servers operated by Yaesu, the product functions similarly to some of the other linking systems, providing a “plug-and-play” solution for hams wishing to set up a link on a *Windows*-based computer.

Following the success of *iLINK*, my own contribution (in mid-2002) was a compatible software package called *EchoLink*. The program was originally designed to offer an alternative look-and-feel and feature set for *iLINK* users, but quickly evolved into a complete system of its own, due to its rapid (and unexpected) rate of acceptance. By early 2004, *EchoLink* had been installed and registered by more than 110,000 licensed hams in 147 countries, and typically carried more than 1,400 repeaters and simplex links and about 700 PC-based users at any given time.—Jonathan Taylor, K1RFD

broken almost yearly! On 2 m, for example, conversations between stations hundreds and even thousands of miles apart are not uncommon. The distances decrease as frequencies increase, but communications have spanned several hundred miles even at microwave frequencies.

One of the more recent developments in VHF/UHF communications is a suite of computer programs using state of the art digital techniques. WSJT by Joe Taylor, K1JT, contains four separate modules optimized for meteor scatter, EME and extreme troposcatter, meteor scatter optimized for the 50 MHz band, and a special program for measuring the strength of your own echoes off the moon. The programs run on Microsoft Windows based computers equipped with a sound card. In addition to the four communication modes, WSJT offers a 'measure' mode for testing sun noise and an EME Calculator to help you estimate the strength of your own and other stations' echoes from the moon. For further information on the WSJT suite of programs, visit K1JT's Web site at pulsar.princeton.edu/~joe/K1JT/index.htm.

EME

EME (Earth-Moon-Earth) communication, also known as "moonbounce," continues to fascinate many amateurs. The concept is simple: use the moon as a passive reflector for VHF and UHF signals. With a total path length of about 500,000 miles, EME is the ultimate DX.

Amateur involvement in moonbounce grew out of experiments by the military after World War II. While the first amateur signals reflected from the moon were received in 1953, it took until 1960 for the first two-way amateur EME contacts to take place. Using surplus parabolic dish antennas and high-power klystron amplifiers, the Eimac Radio Club, W6HB, and the Rhododendron Swamp VHF Society, W1BU, achieved the first EME QSO in July 1960 on 1296 MHz. Since then, EME activity has proliferated onto most VHF and higher amateur bands.

Advances in low-noise semiconductors and Yagi arrays in the 1970s and 1980s

have put EME within the grasp of most serious VHF and UHF operators. Further advances in technology will bring forth sophisticated receivers with digital signal processing (DSP), such as the WSJT programs discussed above, that may make EME affordable to most amateurs.

EME activity is primarily a CW mode. However, improvements in station equipment now allow the best-equipped stations to make SSB contacts under the right conditions. Regardless of the transmission mode, successful EME operating requires:

- Power output as close to the legal limit as possible.
- A good-sized antenna array. Arrays of 8, 16, or more Yagis are common on the VHF frequencies, while large parabolic dish antennas are common on UHF and microwave frequencies.
- Accurate azimuth and elevation.
- Minimal transmission line losses.
- The best possible receiving equipment, generally a receiver with a low system noise figure and a low-noise preamplifier mounted at the antenna.

The ARRL sponsors EME contests to stimulate activity. Given the marginal nature of most EME contacts, EME contests designate a "liaison frequency" on HF where EME participants can schedule contacts. Contest weekends give smaller stations the opportunity to make many contacts with stations of all sizes. See the **Space Communications** chapter for more about EME.

Meteor Scatter

As a meteor enters the Earth's atmosphere, it vaporizes into an ionized trail of matter. Such trails are often strong enough to reflect VHF radio signals for several seconds. During meteor showers, the ionized region becomes large enough (and lasts long enough) to sustain short QSOs.

Amateurs experimenting with meteor scatter propagation use high power (100 W or more) and beam antennas with an elevation rotor (to point the beam upward at the incoming meteors). Most contacts are made using CW, as voice modes experience distortion and fading. Reflected CW signals often have a rough note.

The *ARRL UHF/Microwave Experimenter's Handbook* contains detailed information about the techniques and equipment used for meteor scatter. Also, the WSJT software modules, FSK441 and JT6M support meteor scatter communications.

Auroral Propagation

During intense solar storms, the Earth's magnetic field around the poles can become heavily charged with ions. In higher latitudes, this often produces a spectacular phenomenon called the *aurora borealis* (or northern lights) in the Northern Hemisphere and the *aurora australis* (or southern lights) in the Southern Hemisphere. The ionization is often intense enough to reflect VHF radio signals. Many amateurs experiment with aurora contacts on 10, 6 and 2 m. Aurora contacts are often possible even when the aurora is not visible.

Equipment used to make aurora contacts is similar to that used for meteor-scatter contacts: high power, directional antennas and CW. Antenna pointing is less critical, however, since the antenna need only be aimed at the aurora curtain. Reflected CW signals often have a rough buzz-saw-like note and can also be Doppler-shifted. Reflected aurora SSB signals are difficult to understand, but careful listening will often produce understandable voice on the 10- and 6-meter bands. SSB aurora signals are extremely difficult to understand at 144 MHz and higher frequencies, which is why CW is so popular for the aurora mode.

The *ARRL UHF/Microwave Experimenter's Handbook* contains detailed information about the techniques and equipment used for auroral propagation.

Chapter 3

Safety

This chapter was written by James N. Woods, W7PUP, and includes additional contributors as well. This chapter will focus on how to avoid potential hazards as we explore Amateur Radio and its many facets. We need to learn as much as possible about what could *go wrong* so we can avoid factors that might result in accidents. Amateur Radio activities are not inherently hazardous, but like many things in modern life, it pays to be informed. Stated another way, while we long to be creative and innovative, there is still the need to act responsibly. Safety begins with our attitude. Make it a habit to plan work carefully. Don't be the one to say, "I didn't think it could happen to me."

Having a good attitude about safety is not enough, however. We must be knowledgeable about common safety guidelines and follow them faithfully. Safety guidelines cannot possibly cover all situations, but if we approach each task with a measure of common sense, we should be able to work safely.

This chapter will address some of the most popular ham radio activities: building and erecting antennas, constructing radio equipment, and the testing and troubleshooting of our radios. Safety as-

sociated with emergency disaster operations are covered best by the agencies and organizations affected.

Although the RF, ac and dc voltages in most amateur stations pose a potentially grave threat to life and limb, common sense and knowledge of good safety practices will help us avoid accidents. Building and operating an Amateur Radio station can be, and is for almost all amateurs, a perfectly safe pastime. Carelessness can lead to severe injury, or even death, however. The ideas presented here are only guidelines; it would be impossible to cover all safety precautions. *Remember: There is no substitute for common sense.*

Fires in well-designed electronic equipment are not common but are known to occur. Proper use of a suitable fire extinguisher can make the difference between a small fire with limited damage and loss of an entire home. Make sure you know the limitations of your extinguisher and the importance of reporting the fire to your local fire department immediately.

Several types of extinguishers are suitable for electrical fires. The multipurpose dry chemical or "ABC" type units are relatively inexpensive and contain a solid powder that is nonconductive. Avoid buying the

smallest size; a 5-pound capacity will meet most requirements in the home. ABC extinguishers are also the best choice for kitchen fires (the most common location of home fires). One disadvantage of this type is the residue left behind that might cause corrosion in electrical connectors. Another type of fire extinguisher suitable for energized electrical equipment is the carbon dioxide unit. CO₂ extinguishers require the user to be much closer to the fire, are heavy and difficult to handle, and are relatively expensive. For obvious reasons, water extinguishers are not suitable for fires in or near electronic equipment.

Involve your family in Amateur Radio. Having other people close by is always beneficial in the event that you need immediate assistance. Take the valuable step of showing family members how to turn off the electrical power to your equipment safely. Additionally, cardiopulmonary resuscitation (CPR) training can save lives in the event of electrical shock. Classes are offered in most communities. Take the time to plan with your family members exactly what action should be taken in the event of an emergency, such as electrical shock, equipment fire or power outage. Practice your plan!

Antenna and Tower Safety

Since antennas are generally outdoors, they are affected by such potentially hazardous weather as wind, ice and lightning. Learning about the potential hazards of towers and antennas and how to do antenna work safely will pay dividends.

ARRL Technical Advisor Paul Krugh, N2NS, reminds us to remember that putting up a tower has a set of responsibilities associated with it. *Any heavy, large and permanent structure that fails or collapses can potentially hurt or even kill somebody.*

The complete installation *must* comply with all applicable structural and building codes. Professional engineers design towers to withstand code loadings — that is, dead weight, wind and ice loadings that are applicable to the environment at your particular location. The latest revision of the EIA-222 standard is the document from which professional engineers work to ensure that their tower designs are structurally safe. For further information, contact the Electronic Industries Alliance

(EIA) in Arlington, CA.

To ensure structural safety and integrity, you must demonstrate that your tower has been designed by a qualified engineer to withstand EIA-222 loadings at your specific geographic area. Further, the tower, foundation, guys and anchors must be installed (and maintained) according to any drawings, instructions and specifications supplied by the professional engineer. Remember: A properly designed, installed and maintained tower should be

as safe as a building or a bridge!

It is not feasible to discuss each type of antenna and tower in detail, so this section will include only highlights. For a full understanding of the specific hardware you will be working with, consult the manufacturer or supplier. You should discuss your antenna plans with a qualified engineer. The ARRL Volunteer Consulting Engineer program can steer you to a knowledgeable engineer.

In addition, your town or city will probably require that you obtain a building permit to erect a tower or antenna. This is their way to help ensure that the installation follows good practices and that the installation is safe. Wise amateurs realize that an independent review of drawings and site inspections are beneficial and can result in fewer problems in the future.

Towers must have a properly engineered support, both for the tower sections themselves as well as guy wire attachments. Sometimes towers are braced to buildings for added support. The Antenna Supports chapter of *The ARRL Antenna Book* covers this subject in greater detail. Towers are available commercially in both guyed and self-supporting styles, and constructed of both steel and aluminum materials. Masts may be wood or metal. One popular and inexpensive mast used to support small antennas is the tubular mast often sold for TV antenna use. These come in telescoping sections, in heights from 20 to 50 ft.

Aluminum extension ladders are sometimes used for temporary antenna supports, such as at Field Day sites. One problem with this approach is the difficulty in holding down the bottom section while “walking up” the ladder. Do *not* try to erect this type of support alone.

Trees are sometimes pressed into service for holding one end of a wire antenna. When using slingshots or arrows to string up the antenna, be sure no one is in range before you launch.

FACTORS TO CONSIDER WHEN SELECTING A TOWER

- Towers have design load limitations. Make very sure the tower you consider has the capacity to safely handle the antenna(s) you intend to install in the kind of environment that is applicable to your QTH.
- The antenna must be located in such a position that *it cannot possibly tangle with power lines, both during normal operation or if the structure should fall.*
- Sufficient yard space must be available to position a guyed tower properly. A rule of thumb is that the guy anchors should be between 60% and 80% of the tower height in distance from the base

of the tower.

- Provisions must be made to keep children from climbing the support.
- Always write to the manufacturer of the tower before purchasing and ask for installation specifications, including guying data.
- Soil conditions at the tower site should be investigated. The footings need to be designed around actual soil conditions, particularly on a rocky site.

TOWER TIPS

- Beware of used towers. Have them professionally inspected and contact the manufacturer for installation criteria.
- Always follow manufacturer’s instructions, using only parts that are designed for the model you have.
- Never rush into projects. Consult the most experienced amateurs in your community for assistance, especially if you are new to tower installation.
- Check with your local building officials.
- Liability may be increased with a tower installation. Check with your insurer to ensure your coverage is adequate.
- Consider your neighbors about any hazards your antennas may present to them.
- Don’t let your installation become an “attractive nuisance.” Take steps to install barriers so your tower cannot easily be climbed by others, particularly adventurous children.
- Use only the highest quality materials in your system.
- Make sure you have all the tools needed before starting. Some specialized tools (such as a gin pole) may be required.
- Never erect an antenna, tower or rotor during an electrical storm or rainstorm, or when lightning is a possibility.
- The assembly crew as well as those climbing the tower during erection must wear hard hats and use appropriate personal protective equipment including gloves, boots, climbing belt or harness. Don’t forget that lifelines are needed when the belt is unattached from the tower while moving.
- Be careful not to over-stress the tower when it is being assembled. The tower manufacturer can offer suggestions that will avoid jeopardizing the tower.
- Install guy wires using the proper tools. Care should be exercised especially when handling loose, un-terminated, and sharp guy wire ends! Avoid wrapping guy wire around your hands to pull it into place, and instead use sufficient length to easily attach it to the anchors. Use tower-rated turnbuckles or similar devices to adjust tension evenly around the tower.
- Assign someone in the erection crew to monitor the use of safety equipment.

- After the tower is installed, keep the installation safe. Inspection and maintenance recommended by the tower’s manufacturer should be carefully followed.
- If making attachments to houses or installations on roofs, have a qualified person determine that the method is adequate and the loading conditions are satisfactory.
- Avoid metal ladders if there are any utility lines in the vicinity. Assume that any line is energized — including cable television and telephone lines.

POWER LINES

Hundreds of people have been killed or seriously injured when attempting to install or dismantle antennas. In virtually all cases, the victim was aware of the hazards, including the potential for serious electrical shock, but did not take the necessary steps to eliminate the risks. Never install antennas, towers and masts near power lines. How far away is considered safe? Towers and masts should be installed twice the height of the installation away from power lines. Every electrical wire must be considered dangerous. If the installation should contact power lines, you or those around you could be killed! If you have any questions about power lines, contact your electrical utility, city inspector or a qualified professional.

If, for some reason your tower or antenna structure begins to fall, get away from it immediately! If it contacts energized lines, it can become a lethal hazard if you are touching any part of the conductive structure. If a coworker becomes energized, **do not touch the person!** The safest practice is to keep all others clear of the area, call 911, and just wait for the power company and rescue team to arrive and assist the victim. At some greater risk, a well-insulated pole such as fiberglass or PVC pipe — as long as possible for safety — can be utilized in an attempt to dislodge the live wire or collapsed metal structure from the victim (with moisture, etc., wood can be a *poor insulator* — especially at high voltages!). If the victim can be well cleared of the hazard and is not breathing, immediately start CPR procedures and seek emergency assistance. **Remember, use caution and understand that during such an accident, the live conductor or live antenna structure can further move (lurch) suddenly and without warning. One accident is bad enough — there is no need to have two victims! It is best to just seek qualified emergency help if you are unsure of the situation-specific hazards.**

Further information about tower safety appears in *The ARRL Antenna Book*.

Electrical Wiring Around the Shack

The standard power available from commercial mains in the United States for residential service is 120/240-V ac. The “primary” voltages that feed transformers in our neighborhoods may range from 2000 to about 10,000 V. Generally, the responsibility for maintaining the power distribution system belongs to a utility company, electric cooperative or city. The “ownership” of conductors usually transfers from the electric utility supplier to the homeowner where the power connects to the meter or weatherhead. If you are unsure where the division of responsibility falls in your community, a call to your electrical utility will provide the answer. **Fig 3.1** shows the typical division of responsibility between the utility company and the homeowner.

There are two facets to success with electrical power: safety and performance. Since we are not professionals, we need to pursue safety first and consult professionals for alternative solutions if performance is unacceptable.

STATION CONCERNS

The primary electrical power supplied to your radio equipment should be controlled by one master switch so that it is easy to kill the power in an emergency. One convenient means is a switched outlet strip, as used for computer equipment. The strip should be listed by a nationally recognized testing laboratory such as Underwriters Lab and incorporate a circuit breaker. See “What Does UL Listing Mean?” and “How Safe are Outlet Strips?” for warnings about poor quality products. It is poor practice to “daisy-chain” several power strips. If you need more outlets than are available on a strip, have additional convenience outlets installed.

Before adding equipment to your home, be sure that it does not overload the circuit. National and local codes set permissible branch capacities according to a rather complex process. Here’s a safe rule of thumb: consider adding a new circuit if the total load is more than 80% of the circuit breaker or fuse rating. (This assumes that the fuse or breaker is correct. If you have any doubts, have an electrician check it.)

Do It Yourself Wiring?

Amateurs sometimes “rewire” parts of their homes to accommodate their hobby. Most local codes *do* allow for modification of wiring (by building owners), so long as the electrical codes are met. Generally, the building owner must obtain an electrical permit before beginning changes or additions to permanent wiring. Some

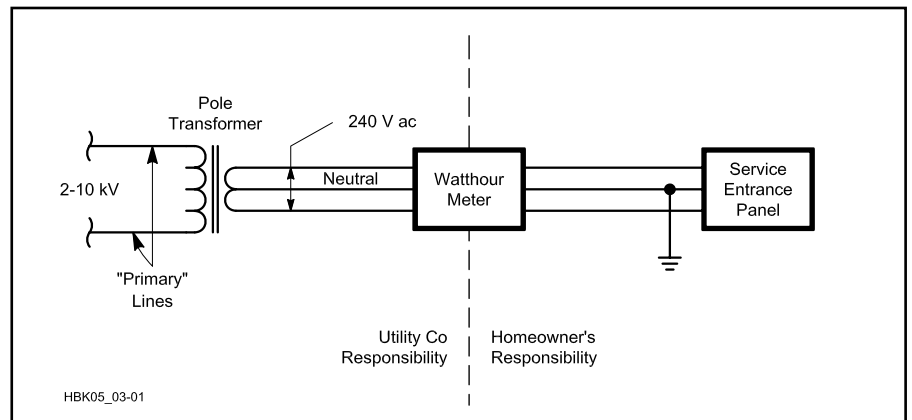

Fig 3.1 — Typical division of responsibility for maintenance of electrical power conductors and equipment. The meter is supplied by the utility company.

What Does UL Listing Mean?

CAUTION: Listing *does not* mean what most consumers expect it to mean! More often than not the listing *does not* relate to the performance of the listed product. The listing simply indicates that a sample of the device meets certain manufacturers’ construction criteria. Similar devices from the same or different manufacturers may differ significantly in overall construction and performance even though all are investigated and listed against the same UL product category

Fig 3.2 — If the switch box feeding power to your shack is equipped with a lock-out hole, use it. With a lock through the hole on the box, the power cannot be accidentally turned back on. (Photo courtesy of American ED-CO)

jobs may require drawings of planned work. Often the permit fee pays for an inspector to review the work. Considering the risk of injury or fire if critical mistakes are left uncorrected, a permit and inspection are well worth the effort. *Don’t take chances* — seek assistance from the building officials or an experienced electrician if you have *any* questions or doubts about proper wiring techniques.

Ordinary 120-V circuits are the most common source of fatal electrical accidents. Never use bare wire for exposed circuits or open-chassis construction with exposed connections! Remember that high-current, low-voltage power sources can be just as dangerous as high-voltage sources.

Never work on electrical wiring with the conductors energized! Switch off the circuit breaker or remove the fuse and take

positive steps to ensure that others do not restore the power while you are working. (Fig 3.2 illustrates one way to ensure that power will be off until you want it turned on.) Check the circuit with an ac voltmeter to be sure that it is “dead” *each time you begin work*. Before restoring power, check your work with an ohm meter: There should be good continuity between the neutral conductor (white wire, “silver” screw) and the grounding conductor (green or bare wire, green screw). An ohmmeter should indicate a closed circuit between the conductors.

There should be no continuity between the hot conductor (black wire, “brass” screw) and the grounding conductor or the neutral conductor. An ohmmeter should indicate an *open* circuit between the hot wire and either of the other two conductors.

A commercially available plug-in tester is the best way to test regular three-wire receptacles.

NATIONAL ELECTRICAL CODE

Fortunately, much has been learned about how to harness electrical energy safely. This collective experience has been codified into the *National Electrical Code*, or *NEC*. The *Code* details safety requirements for many kinds of electrical installations. Compliance with the *NEC* provides an installation that is *essentially* free from hazard, but not necessarily efficient, convenient or adequate for good service (paraphrased from *NEC* Article 90-1a and b). For example, the *NEC* requirements discussed here are *not* adequate for lightning protection and high transient voltage events. Look at “Lightning/Transient Protection” for more information. While the *NEC* is national in nature and sees wide application, it is not universal.

Local building authorities set the codes for their area of jurisdiction. They often incorporate the *NEC* in some form, while considering local issues. For example, Washington State specifically exempts telephone, telegraph, radio and television wires and equipment from conformance to electrical codes, rules and regulations. However, some local jurisdictions (city, county and so on) do impose a higher level of installation criteria, including some of the requirements exempted by the state.

Code interpretation is a complex subject, and untrained individuals should steer clear of the *NEC* itself. The *NEC* is not written to be understood by do-it-yourselfers. Therefore, the best sources of information about code compliance and acceptable practices are local building officials, engineers and practicing electricians. With that said, let’s look at a few *NEC* requirements for radio installations.

Antenna conductors — Transmitting antennas using hard-drawn copper wire: #14 for unsupported spans less than 150 ft, and #10 for longer spans. Copper-clad steel, bronze or other high-strength conductors must be #14 for spans less than 150 ft and #12 for longer spans. Open-wire transmission line conductors must be at least as large as those specified for antennas.

Lead-ins — There are several *NEC* requirements for antenna lead-in conductors. For transmitting stations, their size must be equal to or greater than that of the antenna. Lead-ins attached to buildings must be firmly mounted at least 3 inches clear of the surface of the building on non-absorbent insulators. Lead-in conductors must enter through rigid, noncombustible,

nonabsorbent insulating tubes or bushings, through an opening provided for the purpose that provides a clearance of at least 2 inches; or through a drilled windowpane. All lead-in conductors to transmitting equipment must be arranged so that accidental contact is difficult.

Lightning arrestors — Transmitting stations are required to have a means of draining static charges from the antenna system. An antenna discharge unit (lightning arrestor) must be installed on each lead-in conductor that is not protected by a permanently and effectively grounded metallic shield, unless the antenna itself is permanently and effectively grounded. (The code exception for shielded lead-ins does *not* apply to coax, but to shields such as thin-wall conduit. Coaxial braid is neither “adequate” nor “effectively grounded” for lightning pro-

tection purposes.) An acceptable alternative to lightning arrestor installation is a switch (capable of withstanding many kilovolts) that connects the lead-in to ground when the transmitter is not in use.

Ground Conductors

Grounding conductors may be made from copper, aluminum, copper-clad steel, bronze or similar erosion-resistant materials. Insulation is not required. [Lightning and high-voltage transient events may require much larger conductors. —Ed.] The “protective grounding conductor” (main conductor running to the ground rod) must be as large as the antenna lead-in, but not smaller than #10. The “operating grounding conductor” (to bond equipment chassis together) must be at least #14. There is a “unified” grounding electrode require-

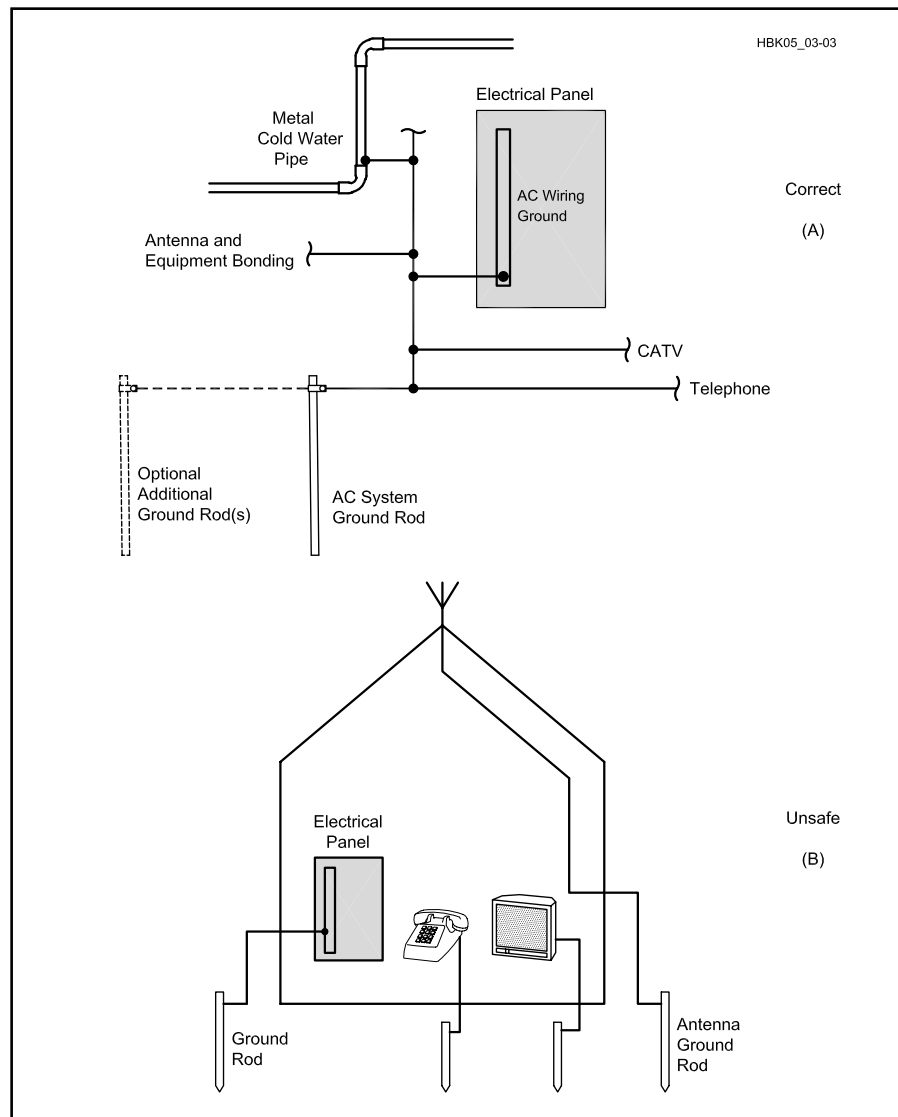

Fig 3.3 — At A, proper bonding of all grounds to electrical service panel. Installation shown at B is unsafe — the separate grounds are not bonded. This could result in a serious accident or electrical fire.

ment — it is necessary to bond *all* ground rods to the electric service entrance ground. All utilities, antennas and any separate grounding rods used must be bonded together. **Fig 3.3** shows correct (A) and incorrect (B) ways to bond ground rods. **Fig 3.4** demonstrates the importance of cor-

rectly bonding ground rods. (Note: The *NEC* requirements do not address effective RF grounds. See the **EMI/Direction Finding** chapter of this book for information about RF grounding practices.)

Additionally, the *Code* covers some information on safety inside the station.

All conductors inside the building must be at least 4 inches away from conductors of any lighting or signaling circuit except when they are separated from other conductors by conduit or insulator. Transmitters must be enclosed in metal cabinets, and the cabinets must be grounded. All metal handles and controls accessible by the operator must be grounded. Access doors must be fitted with interlocks that will automatically disconnect all voltages above 350 when the door is opened.

How Safe are Outlet Strips?

CAUTION: The switch in outlet strips is generally *not* rated for repetitive *load break* duty. Early failure and fire hazard may result from using these devices to switch loads. Misapplications are common (another bit of bad technique that has evolved from the use of personal computers), and manufacturers are all too willing to accommodate the market with marginal products that are “cheap.”

Nonindicating and poorly designed surge protection also add to the safety hazard of using power strips. Marginally rated MOVs often fail in a manner that could cause a fire hazard, especially in outlet strips that have nonmetallic enclosures.

A lockable disconnect switch or circuit breaker, as shown in Fig 3.2, is a better and safer station master switch.

Ground-Fault Circuit Interrupters

GFCIs are devices that can be used with common 120-V circuits to reduce the chance of electrocution when the path of current flow leaves the branch circuit (say, through a person’s body to another branch or ground). The *NEC* requires GFCI outlets in all wet or potentially wet locations, such as: bathrooms, kitchens, and any outdoor outlet with ground-level access, garages and unfinished basements. Any area with bare concrete floors or concrete masonry walls should be GFCI equipped. GFCIs are available as portable units, duplex outlets and as individual circuit breakers. Some early units may have been sensitive to RF radiation but this problem appears to have been solved. Ham radio shacks in potentially wet areas (basements, out buildings) should be GFCI equipped. **Fig 3.5** is a simplified diagram of a GFCI.

LIGHTNING/TRANSIENT PROTECTION

Nearly everyone recognizes the need to protect themselves from lightning. From miles away, the sight and sound of lightning boldly illustrates its destructive potential. Many people don’t realize that destructive transients from lightning and other events can reach electronic equipment from many sources, such as outside antennas, power, telephone and cable TV installations. Many hams don’t realize that the standard protection scheme of several decades, a ground rod and simple “lightning arrester” is *not* adequate.

Lightning and transient high-voltage protection follows a familiar communications scenario: identify the unwanted signal, isolate it and dissipate it. The difference here is that the unwanted signal is many megavolts at possibly 200,000 A. What can we do?

Hams *cannot* expect to design or install effective lightning protection systems, but reasonably complete protection from lightning is available in systems designed by lightning protection professionals. Hams *can* easily follow some general guidelines that will protect their stations against high-voltage events that are in-

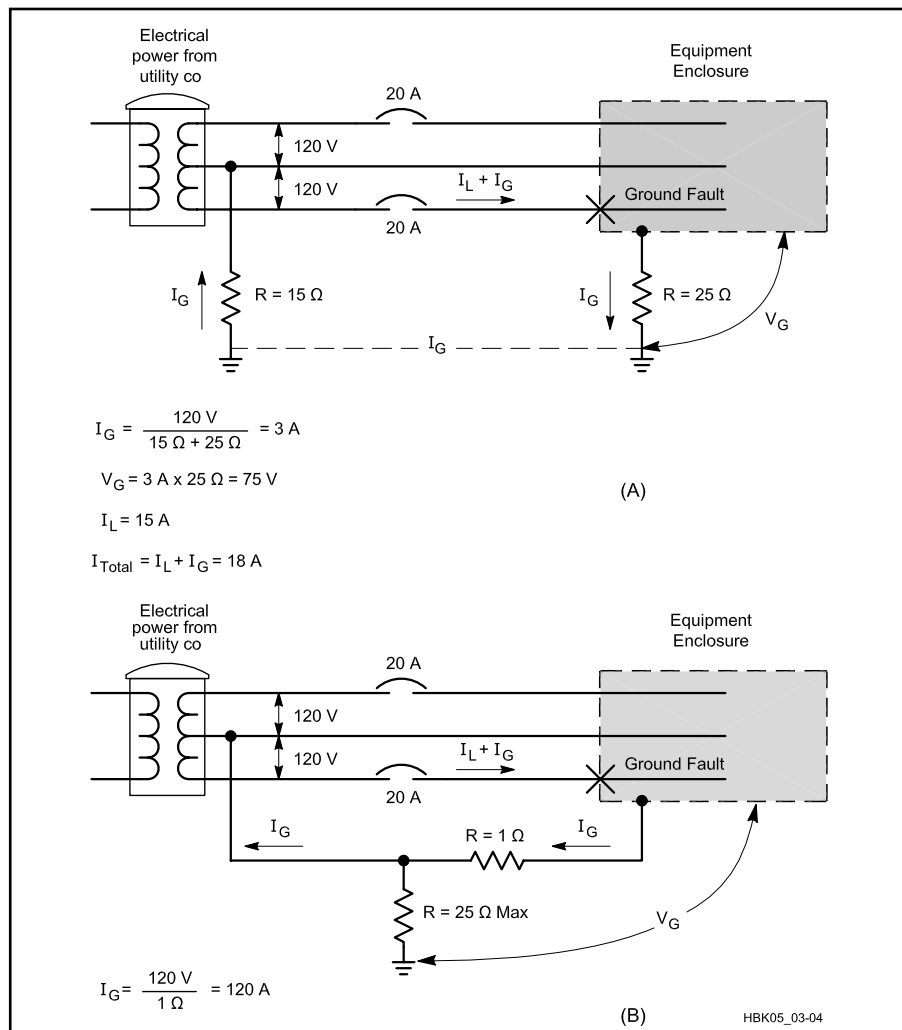

Fig 3.4 — These drawings show the importance of properly bonded ground rods. In the system shown in A, the 20-A breaker will not trip. In the system in B, the 20-A circuit breaker trips instantly. There is an equipment internal short to ground — the ground rod is properly bonded back to the power system ground. Of course, the main protection should be in a circuit ground wire in the equipment power cord itself!

duced by nearby lightning strikes or that arrive via utility lines. Let's talk about where to find professionals first, and then consider construction guidelines.

Professional Help

Start with your local government. Find

out what building codes apply in your area and have someone explain the regulations about antenna installation and safety. For more help, look in your telephone yellow pages for professional engineers, lightning protection suppliers and contractors. Companies that sell lightning-protect-

tion products may offer considerable help to apply their products to specific installations. One such source is PolyPhaser Corporation. Look under "Ground References," later in this chapter, for a partial list of PolyPhaser's publications.

Construction Guidelines

Ground rods — Ground rods should be either solid copper, copper-clad steel, hot-dipped galvanized steel or stainless steel. They should be at least 8 ft long by 1/2 inch in diameter (5/8 inch diameter for iron or steel).

Bonding Conductors — Copper strapping (or *flashing*) comes in a number of sizes; use 1 1/2 inches wide and 0.051 inches thick as a *minimum* for ground connections. Copper strap is a better lightning and RF ground than wire because straps have less inductance than wires. On the other hand, straps are more expensive than wire and more difficult to find.

Use bare copper for buried ground wires. (There are some exceptions; seek an expert's advice if your soil is corrosive.) Exposed runs above ground that are subject to physical damage may require additional protection (a conduit) to meet code requirements. Wire size depends on the application, but never use anything smaller than #6 AWG for bonding conductors. Local lightning-protection experts or building inspectors can recommend sizes for each application.

Tower and Antennas

Because a tower is usually the highest metal object on the property, it is the most likely strike target. Proper tower grounding is essential to lightning protection. The goal is to establish short multiple paths to the Earth so that the strike energy is divided and dissipated.

Connect each tower leg and each fan of metal guy wires to a separate ground rod. Space rods at least 6 ft apart. Bond the leg ground rods together with a #6 AWG or larger copper bonding conductor (form a ring around the tower base, see Fig 3.6). Connect a continuous bonding conductor between the tower ring ground and the entrance panel. Make all connections with fittings approved for grounding applications. **Do not use solder for these connections.** Solder will be destroyed in the heat of a lightning strike.

Unless the tower is also a shunt-fed antenna, use grounded metal guys. For crank-up or telescoping towers, connect the sections with strap jumpers. Because galvanized steel (which has a zinc coating) reacts with copper when combined with moisture, use stainless steel hardware between the galvanized metal and the

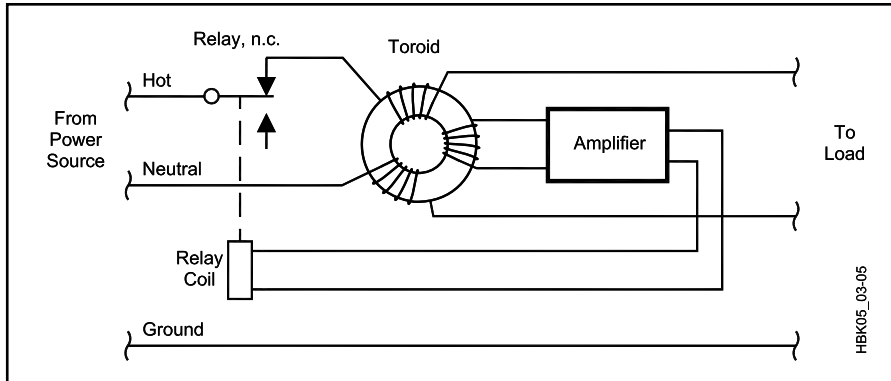

Fig 3.5 — Simplified diagram of a 120-V ac ground fault circuit interrupter (GFCI). When a stray current flows from the load (or outlet) side to ground, the toroidal current becomes unbalanced allowing detection, amplification and relay actuation to immediately cut off power to the load (and to the stray path!) GFCI units require a manual reset after tripping. GFCI's are required in wet locations (near kitchen sinks, in garages, in outdoor circuits and for construction work.) They are available as portable units or combined with over-current circuit breakers for installation in entrance panels.

About the National Electrical Code

Exactly how does the National Electrical Code become a requirement? How is it enforced?

Cities and other political subdivisions have the responsibility to act for the public safety and welfare. To address safety and fire hazards in buildings, regulations are adopted by local laws and ordinances usually including some form of permit and accompanying inspections. Because the technology for the development of general construction, mechanical and electrical codes is beyond most city building departments, model codes are incorporated by reference. There are several general building code models used in the US: Uniform, BOCA and Southern Building Codes are those most commonly adopted. For electrical issues, the *National Electrical Code* is in effect in virtually every community. City building officials will serve as "the authority having jurisdiction" and interpret the provisions of the *Code* as they apply it to specific cases.

Building codes differ from planning or zoning regulations: Building codes are directed only at safety, fire and health issues. Zoning regulations often are aimed at preservation of property values and aesthetics.

The *NEC* is part of a series of reference codes published by the National Fire Protection Association, a nonprofit organization. Published codes are regularly kept up-to-date and are developed by a series of technical committees whose makeup represents a wide consensus of opinion. The *NEC* is updated every three years.

Do I have to update my electrical wiring as code requirements are updated or changed?

Generally, no. Codes are typically applied for new construction and for renovating existing structures. Room additions, for example, might not directly trigger upgrades in the existing service panel unless the panel was determined to be inadequate. However, the wiring of the new addition would be expected to meet current codes. Prudent homeowners, however, may want to add safety features for their own value. Many homeowners, for example, have added GFCI protection to bathroom and outdoor convenience outlets.

Fig 3.6 — Schematic of a properly grounded tower. A bonding conductor connects each tower leg to a ground rod and a buried (1 ft deep) bare, tinned copper ring (dashed line), which is also connected to the station ground and then to the ac safety ground. Locate ground rods on the ring, as close as possible to their respective tower legs. All connectors should be compatible with the tower and conductor materials to prevent corrosion. See text for conductor sizes and details of lightning and voltage transient protection.

copper grounding materials.

To prevent strike energy from entering a shack via the feed line, ground the feed line *outside* the home. Ground the coax shield *to the tower* at the antenna and the base to keep the tower and line at the same potential. Several companies offer grounding blocks that make this job easy.

All grounding media at the home must be bonded together. This includes lightning-protection conductors, electrical service, telephone, antenna system grounds and underground metal pipes. Any ground rods used for lightning protection or entrance-panel grounding must be spaced at least 6 ft from each other and the electrical service or other utility grounds and then bonded to the ac system ground as required by the *NEC*.

A Radio Entrance Panel

We want to control the flow of the energy in a strike. Eliminate any possible paths for surges to enter the building. This involves routing the feed lines, rotator control cables, and so on at least 6 ft away from other nearby grounded metal objects.

Every conductor that enters the structure should have its own surge suppressor including antenna system control lines at the Radio Entrance Panel and other services where they connect to the ac system ground. They are available from a number of manufacturers, including ICE and

PolyPhaser.

Both balanced line and coax arrestors should be mounted to a secure ground connection on the *outside* of the building. The easiest way to do this is to install a large metal enclosure as a bulkhead and ground block. This bulkhead serves as the last line of lightning defense, so it's critical that it be installed properly. You can home-brew a bulkhead panel from 1/8-inch copper sheet, bent into a box shape. Position the bulkhead on the building exterior, 4 to 6 inches (minimum) away from nearby combustible materials. Install a separate ground rod for this panel and connect it to the bulkhead with a short, direct connection. Bond this ground rod to the rest of the ground system. Mount all protective devices, switches and relay disconnects on the outside face wall of the bulkhead.

Lightning Arrestors

Feed line lightning arrestors are available for both coax cable and balanced line. Most of the balanced line arrestors use a simple spark gap arrangement, but a balanced line *impulse* suppresser is available from Industrial Communication Engineers, Ltd (ICE), Indianapolis, IN.

Coaxial Cable Arrestors — DC blocking arrestors have a fixed frequency range. They present a high-impedance to lightning (less than 1 MHz) while offering a low impedance to RF.

DC continuity arrestors (gas tubes and spark gaps) can be used over a wider frequency range than those that block dc. Where the coax carries supply voltages to remote devices (such as a mast-mounted preamp or remote coax switch), dc-continuous arrestors *must* be used.

GROUNDS

As hams we are concerned with three kinds of ground, which are easily confused because we call each of them "ground." The first is the power line ground, which is required by building codes to ensure the safety of life and property surrounding electrical systems. The *NEC* requires that all grounds be *bonded* together; this is a very important safety feature as well as an *NEC* requirement. Ground systems to prevent shock hazards are generally referred to as the *dc ground* by amateurs, although *safety ground* is a more appropriate term.

The previous section discussed some of the features of a lightning protection grounding system. Additional information on lightning, surge and EMI grounding can be found in *The ARRL Antenna Book*. The *National Electrical Code* requires lightning protection ground rods to be separate from the power line safety

Suppliers of Lightning Protection Equipment

For current vendor contact information, use your favorite Internet search tool.

- Alpha Delta Communications: Coax lightning arrestors, coax switches with surge protectors.
- The Wireman: copper wire up to #4 AWG, 2-inch flat copper strap, 8-ft copper clad ground rods and 1 x 1/4-inch buss bar.
- Industrial Communication Engineers, Ltd (ICE): Coax lightning arrestors.
- PolyPhaser Corporation: Many lightning protection products for feed lines, towers, equipment, and so on.
- Rohn: Copper strap and other tower grounding products.
- Zero Surge Inc: Power line surge protector.

grounding electrodes. As discussed later, however, all grounding systems must eventually be bonded together.

An effective safety ground system is necessary for every amateur station. It provides a common reference potential for all parts of the ac system and reduces the possibility of electrical shock by ensuring that all exposed conductors remain at that (low) potential. Three-wire electrical systems effectively ground our equipment for dc and low frequencies. Unfortunately, an effective ground conductor at 60 Hz (5,000,000 m wavelength) may be an excellent antenna for a 20 m signal.

When stray RF causes interference or other problems, we need another kind of ground — a low-impedance path for RF to reach the earth or some other "ground" that dissipates, rather than radiates, the RF energy. Let's call this an *RF ground*.

In most stations, dc ground and RF ground are provided by the same system. If you install ground rods, however, bond them to each other and to the safety ground at the electrical service entrance. In older houses, water lines are sometimes used for the service entrance panel ground. It is a good idea to check that the pipes are electrically continuous from the panel to earth. (Consider that Teflon tape is often used to seal pipe joints in modern repairs.)

For decades, amateurs have been advised to bond all equipment cabinets to an RF ground located near the station. That's a good idea, but it's not easily achieved. "Near" in this use is 10 ft or less for HF operation, even less for higher frequen-

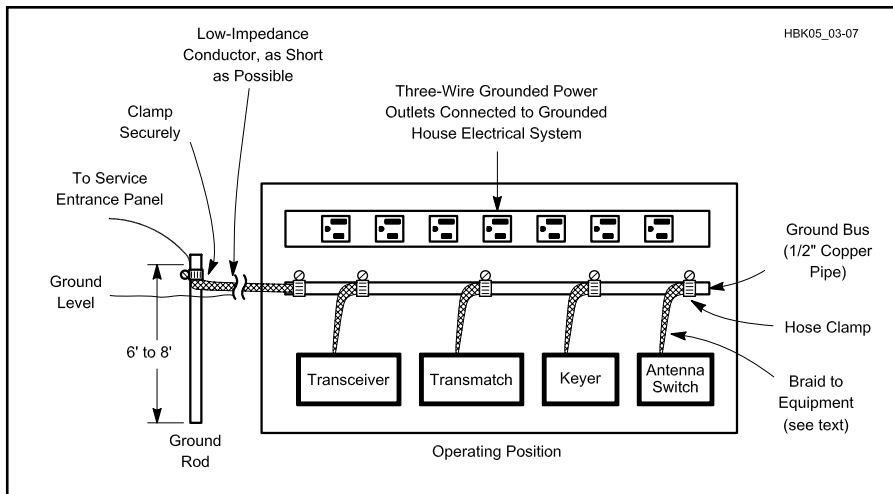

Fig 3.7 — An effective station ground bonds the chassis of all equipment together with low-impedance conductors and ties into a good earth ground. Note that the ground bus is in turn bonded to the service entrance panel. This connection should be made by a licensed electrician with #6 AWG (minimum size) copper wire.

cies. At some stations, it is very difficult to produce an effective RF ground. When levels of unwanted RF are low, an RF ground may not be needed. (See the **EMI/Direction Finding** chapter for more about RF grounds and interference.) Some think that RF grounds should be isolated from the safety ground system — *that is not true!* All grounds, including safety, RF, lightning protection and commercial communications, must be bonded together in order to protect life and property.

The first step in building an RF ground system is to bond together the chassis of all equipment in your station. Choose conductors large enough to provide a low-impedance path. The *NEC* requires that grounding conductors be as large as the largest conductor in the primary power circuit (#14 for a 15-A circuit, #12 for 20 A). Copper strap, sold as “flashing copper,” is excellent for this application. Coax braid is a popular choice; but it is not a good ground conductor unless tinned, and then it’s no longer very flexible. It is best to use commercially made copper braid ground strap that is tinned and ampacity rated — wider straps make better RF grounds. Avoid solid conductors; they tend to break.

Grounding straps can be run from equipment chassis to equipment chassis, but a more convenient approach is illustrated in **Fig 3.7**. In this installation, a 1/2-inch-

diameter copper water pipe runs the entire length of the operating bench. A wide copper ground braid runs from each piece of equipment to a stainless-steel clamp on the pipe.

After the equipment is bonded to a common ground bus, the ground bus must be wired to a good earth ground. This run should be made with a heavy conductor (copper braid is a good choice again) and should be as short and direct as possible. The earth ground usually takes one of two forms.

In most cases, the best approach is to drive one or more ground rods into the earth at the point where the conductor from the station ground bus leaves the house. The best ground rods to use are those available from an electrical supply house. These rods are generally 8 ft long and made from steel with a heavy copper plating. Do not depend on shorter, thinly plated rods sold by some home electronics suppliers, as they can quickly rust and soon become worthless.

Once the ground rod is installed, clamp the conductor from the station ground bus to it with a clamp that can be tightened securely and will not rust. Copper-plated clamps made specially for this purpose (and matching the rods) are available from electrical supply houses. Multiple ground rods reduce the electrical resistance and improve the

effectiveness of the ground system.

Building cold water supply systems were used as station grounds in years past. Connection was made via a low-impedance conductor from the station ground bus to a convenient cold water pipe, preferably somewhere near the point where the main water supply enters the house. (Hot water lines are unsuitable for grounding conductors.) Increased use of plastic plumbing both inside and outside houses is reducing the availability of this option. If you do use the cold water line, ensure that it has a good electrical connection to the earth and attach it *outside* the structure to reduce EMI. As with ground rods, ensure that the water line is also bonded to the service entrance panel.

For some installations, especially those located above the first floor, a conventional ground system such as that just described will make a fine dc ground but will not provide the necessary low-impedance path to ground for RF. The length of the conductor between the ground bus and the ultimate ground point becomes a problem. For example, the ground wire may be about 1/4 wavelength (or an odd multiple of 1/4 wavelength) long on some amateur band. A 1/4-wavelength wire acts as an impedance inverter from one end to the other. Since the grounded end is at a very low impedance, the equipment end will be at a high impedance. The likely result is RF hot spots around the station while the transmitter is in operation. In this case, this ground system may be worse (from an RF viewpoint) than no ground at all.

AN EARTH-CONTINUITY TESTER

This project was first published by the Radio Society of Great Britain (RSGB) and is reproduced here by permission. This simple ground continuity tester determines the quality of the ground (earth) connection in an Amateur Radio station installation. In the context of this discussion, the terms *ground* and *earth* are synonymous.

When using mains-powered electrical equipment, a good-quality protective earth system is very important for safety. Good earth connections are additionally important for radio operation, both for protection against lightning strikes and also for the greater effectiveness of antennas that use earth as one half of a dipole. In situations where the earth path is a *functional* earth as opposed to a *protective* earth, a simple low-voltage, low-current continuity tester or resistance meter is usually sufficient for checking earthing resistance, but for a proper test of a protective earth a high-current tester is needed, as shown in Fig 3.8. This is because a deteriorating earth connection in the form of a stranded wire where many of the strands are broken will still show a low resistance to a low-current tester but, in a fault situation when the earth path needs to pass a high current to ground and thus trigger a protective device, the high current causes the remaining strands to *burn out*, i.e., go open-circuit, before the protective device has time to operate. The protection is then nonexistent!

SAFETY STANDARDS

Recognizing this situation, the British and European safety standards for electrical safety, for example BS EN 60335-1 for

household equipment, demand that the resistance of the protective earth path between an exposed metal part and the protective earth pin is less than 0.1Ω .

The equipment needed for checking to this standard is specialized and expensive, but this simple project provides a low-cost alternative that will check resistance at 2-3 A if good-quality batteries are used. To simplify use, the circuit gives a pass/fail indication instead of a resistance value.

WHEATSTONE BRIDGE

The circuit can be considered in three parts; TEST, DETECTOR and OUTPUT INDICATOR. See the diagram in Fig 3.9 and the components list in Table 3.1. The TEST part of the circuit is based on a Wheatstone bridge, where the earth resistance path forms one of the resistance arms. See Fig 3.10 for the principle behind a Wheatstone bridge. As a consequence of the values of resistance chosen (the test leads are assumed to have a resistance of 0.1Ω), if the earth resistance is less than 0.1Ω , the voltage between the midpoints of the two halves of the Wheatstone bridge will be positive, and if it is less than 0.1Ω , it will be negative. This is fed to the detector part of the circuit. The DETECTOR is an op-amp wired as a comparator. Connected in this way, it has such a high gain that its output is roughly equal to either the positive or negative supply rail voltage, depending on whether the PD between its non-inverting and inverting inputs is positive or negative. It doesn't matter whether the PD is large or small — the output will always be at either extreme. This means there will always be a definite pass or fail indication from the

detector, no matter how large or small the output from the Wheatstone bridge. This is important, as it means correct operation of the circuit doesn't depend on the voltage of the high-current battery, particularly as it is a chemical type whose output voltage can fall dramatically when a high current is being drawn. The pass/fail voltage V_{pf} from the detector then passes to the output indicator circuit.

Fig 3.8 — Inside a completed tester. Note that in an enclosed project, the LEDs are brought out to the front panel.

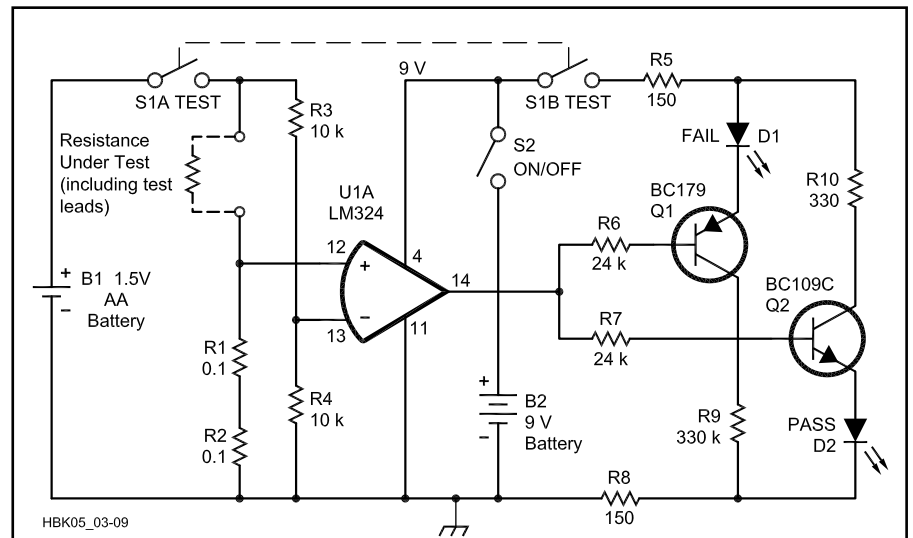

Fig 3.9 — Circuit diagram of the earth-continuity tester.

Fig 3.10 — In a conventional Wheatstone bridge circuit, the value of an unknown resistance (R_x) is determined by adjusting a variable resistor (R_V) with a calibrated scale until the reading on the voltmeter is zero. At that point $(R_x/R_1) = (R_V/R_2)$ so the value of R_x is then given by $R_x = (R_1 \times R_V)/R_2$. The advantage of this method is that, at the balance point, no current flows through the voltmeter, so the resistance of it doesn't affect the measurement. This is a sensitive method for detecting small changes in resistance, as a small change causes a large meter reading.

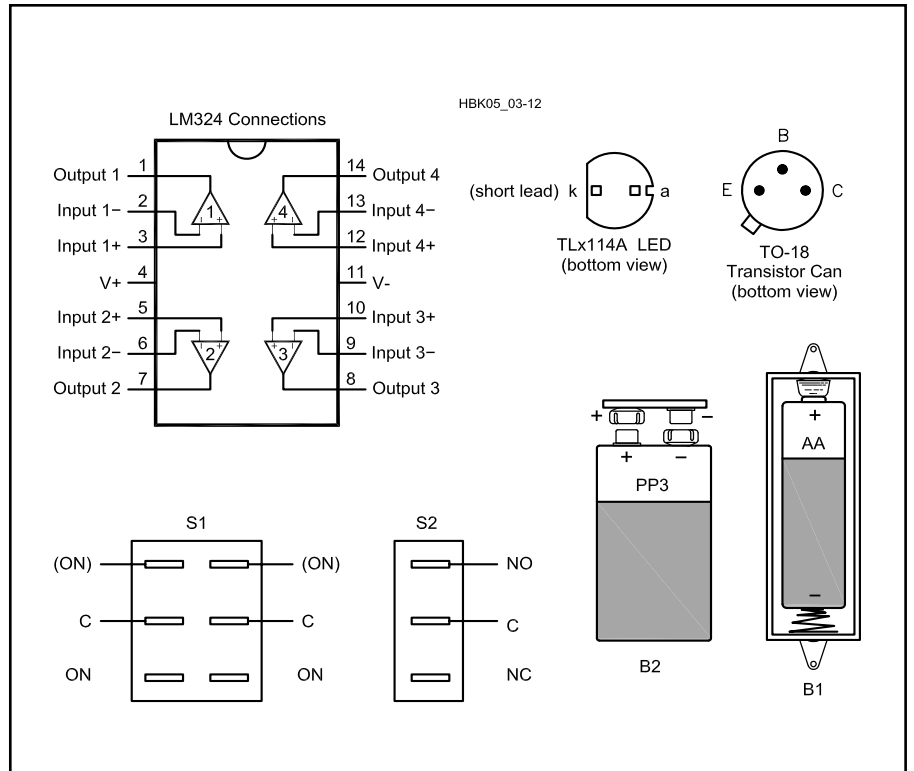

Fig 3.12 — Orientation (and pin-outs) of the batteries, U1, LEDs and transistors.

Fig 3.11 — Layout of the circuit on stripboard.

The OUTPUT INDICATOR circuit consists of two LEDs, driven by transistors to provide sufficient current, which indicate either a pass or a fail for an earth path resistance of less than or more than 0.1 Ω . Q2 is an npn transistor that switches on when its input is high, while Q1 is a pnp type that switches on when its input is low. A separate supply voltage is needed for the op-amp and LED circuit, since the test battery voltage will drop under a heavy load current.

Because the output of the op-amp does not swing completely to the positive and negative supply rails, measures need to be taken to ensure that the LED driver transistors switch off correctly.

Construction

A suitable stripboard layout is shown in Fig 3.11, and Fig 3.12 shows how to identify and orientate several of the components. Use thick wire for the test leads!

How To Use It

Using flying leads with suitable connectors, eg, alligator clips, connect the circuit to each end of the earth path to be tested. This would usually be the mains plug earth pin and any metal part meant to be earthed. Then press the test button. Release the test switch as soon as a pass/fail indicator lights (certainly within 5 to 10 seconds, to lengthen battery life and prevent possible overheating of R1 and R2).

Safety Notice

The project described here may be used to test the resistance of appliance earth connections, but it is *not* intended to conform to any *legal* requirements for the testing of electrical safety. The RSGB, ARRL and the author accept no responsibility for any accident or injury caused by its use. *Never* use on mains equipment plugged into the mains —

the connection to the mains plug earth pin mentioned in the previous paragraph implies that the plug is free. — *Ed*

STATION POWER

Amateur Radio stations generally require a 120-V ac power source. (In residential systems voltages from 110 V through 125 V are considered equivalent, as are those from 220 V through 250 V.) 120-V ac is converted to the proper ac or dc levels required for the station equipment. Power supplies should accommodate the measured voltage range at each station. (The measured voltage usually varies by hour, day, season and location.) Power supply theory is covered in the **Power Supplies** chapter. If your station is located in a room with electrical outlets, you're in luck. If your station is located in the basement, an attic or other area without a convenient 120-V source, you may need to have a new line run to your operating position.

Stations with high-power amplifiers should have a 240-V ac power source in addition to the 120-V supply. Some amplifiers may be powered from 120 V, but they require current levels that may exceed the limits of standard house wiring. For safety, and for the best possible voltage regulation in the equipment, it is advisable to install a separate 240 or 120-V line with an appropriate current rating if you use an amplifier.

The usual line running to baseboard outlets is rated at 15 A, although 20-A outlets may be installed in newer houses. This may or may not be enough current to power your station. To determine how much current your station requires, check the ratings for each piece of gear. Usually, the manufacturer will specify the required current at 120 V; if the power consumption is rated in watts, divide that rating by

120 V to get amperes. If the total current required for your station is near 12 ($0.8 \times 15 = 12$ A), you need to install another circuit. Keep in mind that other rooms may be powered from the same branch of the electrical system, so the power consumption of any equipment connected to other outlets on the branch must be taken into account. Whenever possible, power your station from a separate, heavy-duty line run directly to the distribution panel through a disconnect switch or circuit breaker that can be locked in the off position.

If you decide to install a separate heavy-duty 120-V line or a 240-V line, consult the power company for local requirements. In some areas, a licensed electrician must perform this work. Others may require a special building permit. Even if you are allowed to do the work yourself, it might need inspection by a licensed electrician. Go through the system and get the necessary permits and inspections! Faulty wiring can destroy your possessions and take away your loved ones. Many fire insurance policies are void if there is unapproved wiring in the structure.

If you decide to do the job yourself, work closely with local building officials. Most home-improvement centers sell books to guide do-it-yourself wiring projects. If you have any doubts about doing the work yourself, get a licensed electrician to do the installation.

Three-Wire 120-V Power Cords

Most metal-cased electrical tools and appliances are equipped with three-conductor power cords. Two of the conductors carry power to the device, while the third conductor is connected to the case or frame. Fig 3.13 shows two commonly used connectors.

When both plug and receptacle are prop-

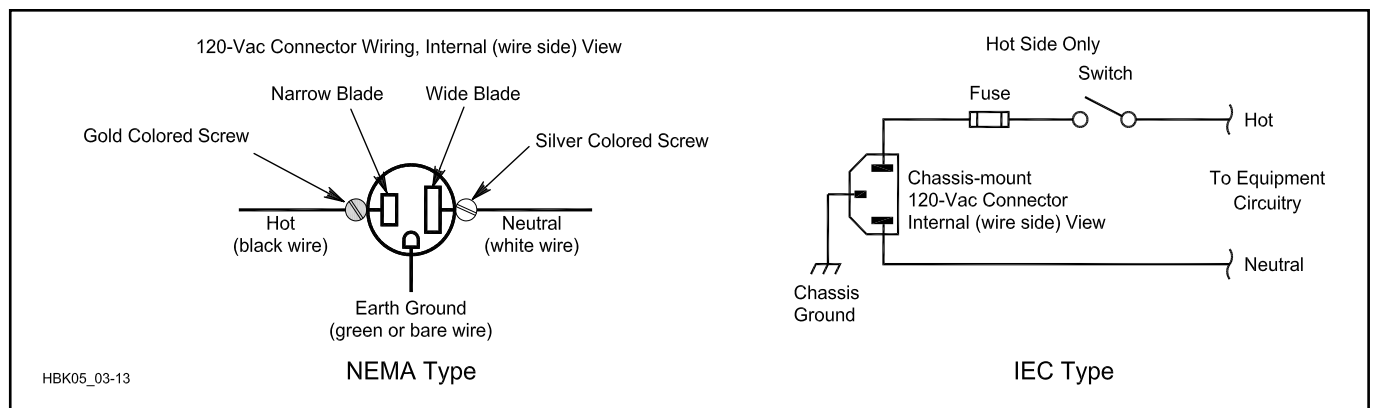

Fig 3.13 — 120-V ac chassis connector wiring.

FCC RF-Exposure Regulations

FCC regulations control the amount of RF exposure that can result from your station's operation (§§97.13, 97.503, 1.1307 (b)(c)(d), 1.1310 and 2.1093). The regulations set limits on the maximum permissible exposure (MPE) allowed from operation of transmitters in all radio services. They also require that certain types of stations be evaluated to determine if they are in compliance with the MPEs specified in the rules. The FCC has also required that five questions on RF environmental safety practices be added to Novice, Technician and General license examinations.

These rules went into effect on January 1, 1998 for new stations or stations that file a 610 application with the FCC. Other existing stations have until September 1, 2000 to be in compliance with the rules.

THE RULES

Maximum Permissible Exposure (MPE)

All radio stations regulated by the FCC must comply with the requirements for MPEs, even QRP stations running only a few watts or less. The MPEs vary with frequency, as shown in **Table A**. MPE limits are specified in maximum electric and magnetic fields for frequencies below 30 MHz, in power density for frequencies above 300 MHz and all three ways for frequencies from 30 to 300 MHz. For compliance purposes, all of these limits must be considered *separately*. If any one is exceeded, the station is not in compliance.

The regulations control human exposure to RF fields, not the strength of RF fields. There is no limit to how strong a field can be as long as no one is being exposed to it, although FCC regulations require that amateurs use

the minimum necessary power at all times (§97.311 [a]).

Environments

The FCC has defined two exposure environments — *controlled* and *uncontrolled*. A controlled environment is one in which the people who are being exposed are aware of that exposure and can take steps to minimize that exposure, if appropriate. In an uncontrolled environment, the people being exposed are not normally aware of the exposure. The uncontrolled environment limits are more stringent than the controlled environment limits.

Although the controlled environment is usually intended as an occupational environment, the FCC has determined that it generally applies to amateur operators and members of their immediate households. In most cases, controlled-environment limits can be applied to your home and property to which you can control physical access. The uncontrolled environment is intended for areas that are accessible by the general public, such as your neighbors' properties.

The MPE levels are based on average exposure. An averaging time of 6 minutes is used for controlled exposure; an averaging period of 30 minutes is used for uncontrolled exposure.

Station Evaluations

The FCC requires that certain amateur stations be evaluated for compliance with the MPEs. Although an amateur can have someone else do the evaluation, it

Table A — (From §1.1310) Limits for Maximum Permissible Exposure (MPE)

(A) Limits for Occupational/Controlled Exposure

Frequency Range (MHz)	Electric Field Strength (V/m)	Magnetic Field Strength (A/m)	Power Density (mW/cm ²)	Averaging Time (minutes)
0.3-3.0	614	1.63	(100)*	6
3.0-30	1842/f	4.89/f	(900/f ²)*	6
30-300	61.4	0.163	1.0	6
300-1500	—	—	f/300	6
1500-100,000	—	—	5	6

f = frequency in MHz

* = Plane-wave equivalent power density (see Note 1).

(B) Limits for General Population/Uncontrolled Exposure

Frequency Range (MHz)	Electric Field Strength (V/m)	Magnetic Field Strength (A/m)	Power Density (mW/cm ²)	Averaging Time (minutes)
0.3-1.34	614	1.63	(100)*	30
1.34-30	824/f	2.19/f	(180/f ²)*	30
30-300	27.5	0.073	0.2	30
300-1500	—	—	f/1500	30
1500-100,000	—	—	1.0	30

f = frequency in MHz

* = Plane-wave equivalent power density (see Note 1).

Note 1: This means the equivalent far-field strength that would have the E or H-field component calculated or measured. It does not apply well in the near field of an antenna. The equivalent far-field power density can be found in the near or far field regions from the relationships: $P_d = |E_{total}|^2 / 3770 \text{ mW/cm}^2$ or from $P_d = H_{total}^2 \times 37.7 \text{ mW/cm}^2$.

is not difficult for hams to evaluate their own stations. The ARRL book *RF Exposure and You* contains extensive information about the regulations and a large chapter of tables that show compliance distances for specific antennas and power levels. Generally, hams will use these tables to evaluate their stations. Some of these tables have been included in the FCC's information — *OET Bulletin 65* and its *Supplement B*. If hams choose, however, they can do more extensive calculations, use a computer to model their antenna and exposure, or make actual measurements.

Categorical Exemptions

Some types of amateur stations do not need to be evaluated, but these stations must still comply with the MPE limits. The station licensee remains responsible for ensuring that the station meets these requirements.

The FCC has exempted these stations from the evaluation requirement because their output power, operating mode and frequency are such that they are presumed to be in compliance with the rules.

Stations using power equal to or less than the levels in **Table B** do not have to be evaluated. For the 100-W HF ham station, for example, an evaluation would be required *only* on 12 and 10 meters.

Hand-held radios and vehicle-mounted mobile radios that operate using a push-to-talk (PTT) button are also categorically exempt from performing the routine evaluation. Repeater stations that use less than 500 W ERP or those with antennas not mounted on buildings, if the antenna is at least 10 meters off the ground, also do not need to be evaluated.

Correcting Problems

Most hams are already in compliance with the MPE requirements. Some amateurs, especially those using indoor antennas or high-power, high-duty-cycle modes such as a RTTY bulletin station and specialized stations for moonbounce operations and the like may need to make adjustments to their station or operation to be in compliance.

The FCC permits amateurs considerable flexibility in complying with these regulations. As an example, hams can adjust their operating frequency, mode or power to comply with the MPE limits. They can also adjust their operating habits or control the direction their antenna is pointing.

Table B — Power Thresholds for Routine Evaluation of Amateur Radio Stations

Wavelength Band	Evaluation Required if Power* (watts) Exceeds:
	MF
160 m	500
	HF
80 m	500
75 m	500
40 m	500
30 m	425
20 m	225
17 m	125
15 m	100
12 m	75
10 m	50
VHF (all bands)	50
	UHF
70 cm	70
33 cm	150
23 cm	200
13 cm	250
SHF (all bands)	250
EHF (all bands)	250
Repeater stations (all bands)	<i>non-building-mounted antennas:</i> height above ground level to lowest point of antenna < 10 m <i>and</i> power > 500 W ERP <i>building-mounted antennas:</i> power > 500 W ERP

*Transmitter power = Peak-envelope power input to antenna. For repeater stations **only**, power exclusion based on ERP (effective radiated power).

More Information

This discussion offers only an overview of this topic; additional information can be found in *RF Exposure and You* and on *ARRLWeb* at www.arrl.org/news/rfsafety/. *ARRLWeb* has links to the FCC Web site, with *OET Bulletin 65* and *Supplement B* and links to software that hams can use to evaluate their stations.

erly wired, the three-contact polarized plug connects the equipment to the system ground. This grounds the chassis or frame of the appliance and prevents the possibility of electrical shock to the user. Most commercially manufactured test equipment and ac-operated amateur equipment is supplied with these three-wire cords. Unfortunately, the ground wire is sometimes improperly installed. Before

connecting any new equipment, check for continuity from case to ground pin with an ohmmeter. If there is no continuity, have the equipment repaired before use. Use such equipment only with properly installed three-wire outlets. If your house does not have such outlets, consult with an electrician or local building officials to learn about safe alternatives.

Equipment with plastic cases is often

“double insulated” and fed with a two-wire cord. Such equipment is safe because both conductors are completely insulated from the user. Nonetheless, there is still a hazard if, say, a double insulated drill were used to drill an improperly grounded case of a transmitter that was still plugged in. Remember, all insulation is prey to age, damage and wear that may erode its initial protection.

Safe Homebrewing

Since Amateur Radio began, building equipment in home workshops has been a major part of an amateur's activity. In fact, in the early days, building equipment with your hands was the *only* option available. While times and interests change, home construction of radio equipment and related accessories remains very popular and enjoyable. Building your own gear need not be hazardous if you become familiar with the hazards, learn how to perform the necessary functions and follow some basic safe practices including the ones listed below.

Consider your State of Mind... when working on projects or troubleshooting (especially where high voltage is present). Some activities require a lot of concentration. As we grow older, this may be a challenge for some of us. Put another way, if we aren't able to be highly alert, we should put off doing hazardous work until we are better able to focus on the hazards.

Read instructions carefully...and follow them. The manufacturers of tools are the most knowledgeable about how to use their products safely. Tap their knowledge by carefully reading all operating instructions and warnings. Avoiding injuries with power tools requires safe tool design as well as proper operation by the user. Keep the instructions in a place where you can refer to them in the future.

Keep your tools in good condition. Al-

ways take care of your investment. Store tools in a way to prevent damage or use by untrained persons (young children, for example). Keep the cutting edges of saws, chisels and drill bits sharp. Protect metal surfaces from corrosion. Frequently inspect the cords and plugs of electrical equipment and make any necessary repairs. If you find that your power cord is becoming frayed, do not delay its repair. Often the best solution is to buy a replacement cord with a molded connector already attached.

Protect yourself. Use of drills, saws, grinders and other wood- or metal-working equipment can release small fragments that could cause serious eye damage. Always wear safety glasses or goggles when doing work that might present a flying object hazard. If you use hammers, wire-cutters, chisels and other hand tools, you will also need the protection that safety eyewear offers. Dress appropriately — loose clothing (or even hair) can be caught in exposed rotating equipment such as drill presses.

Take your time. If you hurry, not only will you make more mistakes and possibly spoil the appearance of your new equipment, you won't have time to think things through. Always plan ahead. Do not work with shop tools if you can't concentrate on what you are doing.

Know what to do in an emergency. Despite your best efforts to be careful, acci-

dents may still occur from time to time. Ensure that everyone in your household knows basic first aid procedures and understands how to summon help in an emergency. They should also know where to find and how to safely shut down electrical power in your shack and shop. Keep your shop neat and orderly, with everything in its place. Do not store an excessive amount of flammable materials. Keep clutter off the floor so no one will trip or lose their footing. Exemplary housekeeping is contagious — set a good example for everyone!

Soldering. Soldering requires a certain degree of practice and, of course, the right tools. What potential hazards are involved?

- Since the solder used for virtually all electronic components is a lead-tin alloy, the first thing in most people's mind is lead, a well-known health hazard. There are two primary ways lead might enter our bodies when soldering: we could breathe lead fumes into our lungs or we could ingest (swallow) lead or lead-contaminated food. Inhalation of lead fumes is extremely unlikely because the temperatures ordinarily used in electronic soldering are far below those needed to vaporize lead. But since lead is soft and we may tend to handle it with our fingers, contaminating our food is a real possibility. For this reason, wash your hands carefully after any soldering (or touching of solder connections).
- Generally, solder used for electronic components contains a flux, often a rosin material. When heated the flux flows freely and emits a vapor in the form of a light gray smoke-like plume. This flux vapor, which often contains aldehydes, is a strong irritant and can cause potentially serious problems to persons who may have respiratory sensitivity conditions including those who suffer from asthma. In most cases it is relatively easy to use a small fan to move the flux vapor away from your eyes and face. Open a window, if there is one, to provide additional air exchange. In extreme cases use an organic vapor cartridge respirator.
- Although it is fairly obvious, be careful when soldering not to burn yourself. A soldering iron stand is helpful.
- Solvents are often used to remove excess flux after the parts have cooled to room temperature. Minimize skin contact with solvents by wearing molded gloves that are resistant to the solvent.

RF Burns!

There's a lot of talk about hazards of RF radiation, but most people don't think about RF burns. Happily, most ham shacks offer little exposure to RF current. Transmitters are enclosed, coaxial cable is the most common feed line, and antennas are located well out of reach.

Some people have experienced a mild tingling on their lips while operating with a metal microphone — a gentle reminder of "RF in the shack." When first licensed in 1963, I learned a stronger lesson. Lightbulbs were often used as dummy loads then: they give a nice visual indication of output power, but provide a poor load for the transmitter (not 50 Ω). Also, you can work a lot of people on such a "dummy" antenna. (Don't try this with a modern solid-state transmitter; the mismatch could be fatal to the radio!)

While tuning my Viking Adventurer one day, I bumped the lit bulb and it fell off the table. I prevented a broken lightbulb by catching it — with my finger across the cable ends that were soldered to the bulb. 50-W of RF went through my finger tip and cauterized a path about $\frac{3}{16} \times \frac{1}{8}$ inch. It was an extremely painful burn; I would rather have broken the bulb. To avoid RF burns, insulate or enclose any exposed RF conductors and keep your antennas out of reach. Ground mounted vertical antennas that carry more than a few watts should be enclosed by an insulator such as a PVC pipe slipped over the radiator or an 8-ft-high fence around the antenna base.

— Bob Schetgen, KU7G, QEX Managing Editor

RF Radiation and Electromagnetic Field Safety

Amateur Radio is basically a safe activity. In recent years, however, there has been considerable discussion and concern about the possible hazards of electromagnetic radiation (EMR), including both RF energy and power-frequency (50-60 Hz) electromagnetic (EM) fields. FCC regulations set limits on the maximum permissible exposure (MPE) allowed from the operation of radio transmitters. These regulations do not take the place of RF-safety practices, however. This section deals with the topic of RF safety.

This section was prepared by members of the ARRL RF Safety Committee and coordinated by Dr. Robert E. Gold, WBØKIZ. It summarizes what is now known and offers safety precautions based on the research to date.

All life on Earth has adapted to survive in an environment of weak, natural, low-frequency electromagnetic fields (in addition to the Earth's static geomagnetic field). Natural low-frequency EM fields come from two main sources: the sun, and thunderstorm activity. But in the last 100 years, man-made fields at much higher intensities and with a very different spectral distribution have altered this natural EM background in ways that are not yet fully understood. Researchers continue to look at the effects of RF exposure over a wide range of frequencies and levels.

Both RF and 60-Hz fields are classified as *nonionizing radiation*, because the frequency is too low for there to be enough photon energy to ionize atoms. (*Ionizing radiation*, such as X-rays, gamma rays and even some ultraviolet radiation has enough energy to knock electrons loose from their atoms. When this happens, positive and negative ions are formed.) Still, at sufficiently high power densities, EMR poses certain health hazards. It has been known since the early days of radio that RF energy can cause injuries by heating body tissue. (Anyone who has ever touched an improperly grounded radio chassis or energized antenna and received an *RF burn* will agree that this type of injury can be quite painful.) In extreme cases, RF-induced heating in the eye can result in cataract formation, and can even cause blindness. Excessive RF heating of the reproductive organs can cause sterility. Other health problems also can result from RF heating. These heat-related health hazards are called *thermal effects*. A microwave oven is a positive application of this thermal effect.

There also have been observations of changes in physiological function in the presence of RF energy levels that are too

low to cause heating. These functions return to normal when the field is removed. Although research is ongoing, no harmful health consequences have been linked to these changes.

In addition to the ongoing research, much else has been done to address this issue. For example, FCC regulations set limits on exposure from radio transmitters. The Institute of Electrical and Electronics Engineers, the American National Standards Institute and the National Council for Radiation Protection and Measurement, among others, have recommended voluntary guidelines to limit human exposure to RF energy. The ARRL has established the RF Safety Committee, consisting of concerned medical doctors and scientists, serving voluntarily to monitor scientific research in the fields and to recommend safe practices for radio amateurs.

THERMAL EFFECTS OF RF ENERGY

Body tissues that are subjected to *very high* levels of RF energy may suffer serious heat damage. These effects depend on the frequency of the energy, the power density of the RF field that strikes the body and factors such as the polarization of the wave.

At frequencies near the body's natural resonant frequency, RF energy is absorbed more efficiently, and an increase in heating occurs. In adults, this frequency usually is about 35 MHz if the person is grounded, and about 70 MHz if insulated from the ground. Individual body parts may be resonant at different frequencies. The adult head, for example, is resonant around 400 MHz, while a baby's smaller head resonates near 700 MHz. Body size thus determines the frequency at which most RF energy is absorbed. As the frequency is moved farther from resonance, less RF heating generally occurs. *Specific absorption rate (SAR)* is a term that describes the rate at which RF energy is absorbed in tissue.

Maximum permissible exposure (MPE) limits are based on whole-body SAR values, with additional safety factors included as part of the standards and regulations. This helps explain why these safe exposure limits vary with frequency. The MPE limits define the maximum electric and magnetic field strengths or the plane-wave equivalent power densities associated with these fields, that a person may be exposed to without harmful effect — and with an acceptable safety factor. The regulations assume that a person exposed to a specified (safe) MPE level also

will experience a safe SAR.

Nevertheless, thermal effects of RF energy should not be a major concern for most radio amateurs, because of the power levels we normally use and the intermittent nature of most amateur transmissions. Amateurs spend more time listening than transmitting, and many amateur transmissions such as CW and SSB use low-duty-cycle modes. (With FM or RTTY, though, the RF is present continuously at its maximum level during each transmission.) In any event, it is rare for radio amateurs to be subjected to RF fields strong enough to produce thermal effects, unless they are close to an energized antenna or unshielded power amplifier. Specific suggestions for avoiding excessive exposure are offered later in this chapter.

ATHERMAL EFFECTS OF EMR

Research about possible health effects resulting from exposure to the lower level energy fields, the athermal effects, has been of two basic types: epidemiological research and laboratory research.

Scientists conduct laboratory research into biological mechanisms by which EMR may affect animals including humans. Epidemiologists look at the health patterns of large groups of people using statistical methods. These epidemiological studies have been inconclusive. By their basic design, these studies do not demonstrate cause and effect, nor do they postulate mechanisms of disease. Instead, epidemiologists look for associations between an environmental factor and an observed pattern of illness. For example, in the earliest research on malaria, epidemiologists observed the association between populations with high prevalence of the disease and the proximity of mosquito infested swamplands. It was left to the biological and medical scientists to isolate the organism causing malaria in the blood of those with the disease, and identify the same organisms in the mosquito population.

In the case of athermal effects, some studies have identified a weak association between exposure to EMF at home or at work and various malignant conditions including leukemia and brain cancer. A larger number of equally well-designed and performed studies, however, have found no association. A risk ratio of between 1.5 and 2.0 has been observed in positive studies (the number of observed cases of malignancy being 1.5 to 2.0 times the "expected" number in the population). Epidemiologists generally regard a risk ratio of 4.0 or greater to be indicative of a strong association between the cause and

effect under study. For example, men who smoke one pack of cigarettes per day increase their risk for lung cancer tenfold compared to nonsmokers, and two packs per day increases the risk to more than 25 times the nonsmokers' risk.

Epidemiological research by itself is rarely conclusive, however. Epidemiology only identifies health patterns in groups — it does not ordinarily determine their cause. And there are often confounding factors: Most of us are exposed to many different environmental hazards that may affect our health in various ways. Moreover, not all studies of persons likely to be exposed to high levels of EMR have yielded the same results.

There also has been considerable laboratory research about the biological effects of EMR in recent years. For example, some separate studies have indicated that even fairly low levels of EMR might alter the human body's circadian rhythms, affect the manner in which T lymphocytes function in the immune system and alter the nature of the electrical and chemical signals communicated through the cell membrane and between cells, among other things. Although these studies are intriguing, they do not demonstrate any effect of these low-level fields on the overall organism.

Much of this research has focused on low-frequency magnetic fields, or on RF fields that are keyed, pulsed or modulated at a low audio frequency (often below 100 Hz). Several studies suggested that humans and animals could adapt to the presence of a steady RF carrier more readily than to an intermittent, keyed or modulated energy source.

The results of studies in this area, plus speculations concerning the effect of various types of modulation, were and have remained somewhat controversial. None of the research to date has demonstrated that low-level EMR causes adverse health effects.

Given the fact that there is a great deal of ongoing research to examine the health consequences of exposure to EMF, the American Physical Society (a national group of highly respected scientists) issued a statement in May 1995 based on its review of available data pertaining to the possible connections of cancer to 60-Hz EMF exposure. This report is exhaustive and should be reviewed by anyone with a serious interest in the field. Among its general conclusions were the following:

1. The scientific literature and the reports of reviews by other panels show no consistent, significant link between cancer and power line fields.

2. No plausible biophysical mecha-

nisms for the systematic initiation or promotion of cancer by these extremely weak 60-Hz fields have been identified.

3. While it is impossible to prove that no deleterious health effects occur from exposure to any environmental factor, it is necessary to demonstrate a consistent, significant, and causal relationship before one can conclude that such effects do occur.

In a report dated October 31, 1996, a committee of the National Research Council of the National Academy of Sciences has concluded that no clear, convincing evidence exists to show that residential exposures to electric and magnetic fields (EMFs) are a threat to human health.

A National Cancer Institute epidemiological study of residential exposure to magnetic fields and acute lymphoblastic leukemia in children was published in the *New England Journal of Medicine* in July 1997. The exhaustive, seven-year study concludes that if there is any link at all, it is far too weak to be concerned about.

Readers may want to follow this topic as further studies are reported. Amateurs should be aware that exposure to RF and ELF (60 Hz) electromagnetic fields at all power levels and frequencies has not been fully studied under all circumstances. "Prudent avoidance" of any avoidable EMR is always a good idea. Prudent avoidance doesn't mean that amateurs should be fearful of using their equipment. Most amateur operations are well within the MPE limits. If any risk does exist, it will almost surely fall well down on the list of causes that may be harmful to your health (on the other end of the list from your automobile). It does mean, however, that hams should be aware of the potential for exposure from their stations, and take whatever reasonable steps they can take to minimize their own exposure and the exposure of those around them.

Safe Exposure Levels

How much EM energy is safe? Scientists and regulators have devoted a great deal of effort to deciding upon safe RF-exposure limits. This is a very complex problem, involving difficult public health and economic considerations. The recommended safe levels have been revised downward several times over the years — and not all scientific bodies agree on this question even today. An Institute of Electrical and Electronics Engineers (IEEE) standard for recommended EM exposure limits was published in 1991 (see Bibliography). It replaced a 1982 American National Standards Institute (ANSI) standard. In the new standard, most of the permitted exposure levels were revised downward (made more stringent), to better

reflect the current research. The new IEEE standard was adopted by ANSI in 1992.

The IEEE standard recommends frequency-dependent and time-dependent maximum permissible exposure levels. Unlike earlier versions of the standard, the 1991 standard recommends different RF exposure limits in *controlled environments* (that is, where energy levels can be accurately determined and everyone on the premises is aware of the presence of EM fields) and in *uncontrolled environments* (where energy levels are not known or where people may not be aware of the presence of EM fields). FCC regulations also include controlled/occupational and uncontrolled/general population exposure environments.

The graph in **Fig 3.14** depicts the 1991 IEEE standard. It is necessarily a complex graph, because the standards differ not only for controlled and uncontrolled environments but also for electric (E) fields and magnetic (H) fields. Basically, the lowest E-field exposure limits occur at frequencies between 30 and 300 MHz. The lowest H-field exposure levels occur at 100-300 MHz. The ANSI standard sets the maximum E-field limits between 30 and 300 MHz at a power density of 1 mW/cm² (61.4 V/m) in controlled environments — but at one-fifth that level (0.2 mW/cm² or 27.5 V/m) in uncontrolled environments. The H-field limit drops to 1 mW/cm² (0.163 A/m) at 100-300 MHz in controlled environments and 0.2 mW/cm² (0.0728 A/m) in uncontrolled environments. Higher power densities are permitted at frequencies below 30 MHz (below 100 MHz for H fields) and above 300 MHz, based on the concept that the body will not be resonant at those frequencies and will therefore absorb less energy.

In general, the 1991 IEEE standard requires averaging the power level over time periods ranging from 6 to 30 minutes for power-density calculations, depending on the frequency and other variables. The ANSI exposure limits for uncontrolled environments are lower than those for controlled environments, but to compensate for that the standard allows exposure levels in those environments to be averaged over much longer time periods (generally 30 minutes). This long averaging time means that an intermittently operating RF source (such as an Amateur Radio transmitter) will show a much lower power density than a continuous-duty station — for a given power level and antenna configuration.

Time averaging is based on the concept that the human body can withstand a greater rate of body heating (and thus, a higher level of RF energy) for a short

Fig 3.14 — 1991 RF protection guidelines for body exposure of humans. It is known officially as the “IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz.”

time than for a longer period. Time averaging may not be appropriate, however, when considering nonthermal effects of RF energy.

The IEEE standard excludes any transmitter with an output below 7 W because such low-power transmitters would not be able to produce significant whole-body heating. (Recent studies show that hand-held transceivers often produce power densities in excess of the IEEE standard within the head.)

There is disagreement within the scientific community about these RF exposure guidelines. The IEEE standard is still intended primarily to deal with thermal effects, not exposure to energy at lower levels. A small but significant number of researchers now believe athermal effects also should be taken into consideration. Several European countries and localities in the United States have adopted stricter standards than the recently updated IEEE standard.

Another national body in the United States, the National Council for Radiation Protection and Measurement (NCRP), also has adopted recommended exposure guidelines. NCRP urges a limit of 0.2 mW/cm² for nonoccupational exposure in the 30-300 MHz range. The NCRP guideline differs from IEEE in two notable ways: It takes into account the effects of modulation on an RF carrier, and it does not exempt transmitters with outputs below 7 W.

The FCC MPE regulations are based on parts of the 1992 IEEE/ANSI standard and

recommendations of the National Council for Radiation Protection and Measurement (NCRP). The MPE limits under the regulations are slightly different than the IEEE/ANSI limits. Note that the MPE levels apply to the FCC rules put into effect for radio amateurs on January 1, 1998. These MPE requirements do not reflect and include all the assumptions and exclusions of the IEEE/ANSI standard.

Cardiac Pacemakers and RF Safety

It is a widely held belief that cardiac pacemakers may be adversely affected in their function by exposure to electromagnetic fields. Amateurs with pacemakers may ask whether their operating might endanger themselves or visitors to their shacks who have a pacemaker. Because of this, and similar concerns regarding other sources of electromagnetic fields, pacemaker manufacturers apply design methods that for the most part shield the pacemaker circuitry from even relatively high EM field strengths.

It is recommended that any amateur who has a pacemaker, or is being considered for one, discuss this matter with his or her physician. The physician will probably put the amateur into contact with the technical representative of the pacemaker manufacturer. These representatives are generally excellent resources, and may have data from laboratory or “in the field” studies with specific model pacemakers.

One study examined the function of a

modern (dual chamber) pacemaker in and around an Amateur Radio station. The pacemaker generator has circuits that receive and process electrical signals produced by the heart, and also generate electrical signals that stimulate (pace) the heart. In one series of experiments, the pacemaker was connected to a heart simulator. The system was placed on top of the cabinet of a 1-kW HF linear amplifier during SSB and CW operation. In another test, the system was placed in close proximity to several 1 to 5-W 2-meter hand-held transceivers. The test pacemaker was connected to the heart simulator in a third test, and then placed on the ground 9 meters below and 5 meters in front of a three-element Yagi HF antenna. No interference with pacemaker function was observed in these experiments.

Although the possibility of interference cannot be entirely ruled out by these few observations, these tests represent more severe exposure to EM fields than would ordinarily be encountered by an amateur — with an average amount of common sense. Of course prudence dictates that amateurs with pacemakers, who use hand-held VHF transceivers, keep the antenna as far as possible from the site of the implanted pacemaker generator. They also should use the lowest transmitter output required for adequate communication. For high power HF transmission, the antenna should be as far as possible from the operating position, and all equipment should be properly grounded.

LOW-FREQUENCY FIELDS

Although the FCC doesn't regulate 60-Hz fields, some recent concern about EMR has focused on low-frequency energy rather than RF. Amateur Radio equipment can be a significant source of low-frequency magnetic fields, although there are many other sources of this kind of energy in the typical home. Magnetic fields can be measured relatively accurately with inexpensive 60-Hz meters that are made by several manufacturers.

Table 3.2 shows typical magnetic field intensities of Amateur Radio equipment and various household items. Because these fields dissipate rapidly with distance, "prudent avoidance" would mean staying perhaps 12 to 18 inches away from most Amateur Radio equipment (and 24 inches from power supplies with 1-kW RF amplifiers).

DETERMINING RF POWER DENSITY

Unfortunately, determining the power density of the RF fields generated by an amateur station is not as simple as measuring low-frequency magnetic fields. Although sophisticated instruments can be used to measure RF power densities quite accurately, they are costly and require frequent recalibration. Most amateurs don't have access to such equipment, and the inexpensive field-strength meters that we do have are not suitable for measuring RF power density.

Table 3.3 shows a sampling of measurements made at Amateur Radio stations by the Federal Communications Commission and the Environmental Protection Agency in 1990. As this table indicates, a good antenna well removed from inhabited areas poses no hazard under any of the IEEE/ANSI guidelines. However, the FCC/EPA survey also indicates that amateurs must be careful about using indoor or attic-mounted antennas, mobile antennas, low directional arrays or any other antenna that is close to inhabited areas, especially when moderate to high power is used.

Ideally, before using any antenna that is in close proximity to an inhabited area, you should measure the RF power density. If that is not feasible, the next best option is make the installation as safe as possible by observing the safety suggestions listed in **Table 3.4**.

It also is possible, of course, to calculate the probable power density near an antenna using simple equations. Such calculations have many pitfalls. For one, most of the situations where the power density would be high enough to be of concern are in the near field. In the near field, ground interactions and other variables produce power densities that cannot

be determined by simple arithmetic. In the far field, conditions become easier to predict with simple calculations.

The boundary between the near field and the far field depends on the wavelength of the transmitted signal and the physical size and configuration of the antenna. The boundary between the near field and the far field of an antenna can be as much as several wavelengths from the antenna.

Computer antenna-modeling programs are another approach you can use. *MININEC* or other codes derived from *NEC* (Numerical Electromagnetics Code) are suitable for estimating RF magnetic and electric fields around amateur antenna systems.

These models have limitations. Ground interactions must be considered in estimating near-field power densities, and the "correct ground" must be modeled. Computer modeling is generally not sophisticated enough to predict "hot spots" in the near field — places where the field intensity may be far higher than would be ex-

pected, due to reflections from nearby objects. In addition, "nearby objects" often change or vary with weather or the season, so the model so laboriously crafted may not be representative of the actual situation, by the time it is running on the computer.

Intensely elevated but localized fields often can be detected by professional measuring instruments. These "hot spots" are often found near wiring in the shack, and metal objects such as antenna masts or equipment cabinets. But even with the best instrumentation, these measurements also may be misleading in the near field.

One need not make precise measurements or model the exact antenna system, however, to develop some idea of the relative fields around an antenna. Computer modeling using close approximations of the geometry and power input of the antenna will generally suffice. Those who are familiar with *MININEC* can estimate their power densities by computer modeling, and those who have access to profes-

Table 3.2

Typical 60-Hz Magnetic Fields Near Amateur Radio Equipment and AC-Powered Household Appliances

Values are in milligauss.

Item	Field	Distance
Electric blanket	30-90	Surface
Microwave oven	10-100	Surface
	1-10	12"
IBM personal computer	5-10	Atop monitor
	0-1	15" from screen
Electric drill	500-2000	At handle
Hair dryer	200-2000	At handle
HF transceiver	10-100	Atop cabinet
	1-5	15" from front
1-kW RF amplifier	80-1000	Atop cabinet
	1-25	15" from front

(Source: measurements made by members of the ARRL RF Safety Committee)

Table 3.3

Typical RF Field Strengths Near Amateur Radio Antennas

A sampling of values as measured by the Federal Communications Commission and Environmental Protection Agency, 1990

Antenna Type	Freq (MHz)	Power (W)	E Field (V/m)	Location
Dipole in attic	14.15	100	7-100	In home
Discone in attic	146.5	250	10-27	In home
Half sloper	21.5	1000	50	1 m from base
Dipole at 7-13 ft	7.14	120	8-150	1-2 m from earth
Vertical	3.8	800	180	0.5 m from base
5-element Yagi at 60 ft	21.2	1000	10-20	In shack
			14	12 m from base
3-element Yagi at 25 ft	28.5	425	8-12	12 m from base
Inverted V at 22-46 ft	7.23	1400	5-27	Below antenna
Vertical on roof	14.11	140	6-9	In house
			35-100	At antenna tuner
Whip on auto roof	146.5	100	22-75	2 m antenna
			15-30	In vehicle
			90	Rear seat
5-element Yagi at 20 ft	50.1	500	37-50	10 m antenna

Table 3.4**RF Awareness Guidelines**

These guidelines were developed by the ARRL RF Safety Committee, based on the FCC/EPA measurements of Table 3.2 and other data.

- Although antennas on towers (well away from people) pose no exposure problem, make certain that the RF radiation is confined to the antennas' radiating elements themselves. Provide a single, good station ground (earth), and eliminate radiation from transmission lines. Use good coaxial cable or other feed line properly. Avoid serious imbalance in your antenna system and feed line. For high-powered installations, avoid end-fed antennas that come directly into the transmitter area near the operator.
 - No person should ever be near any transmitting antenna while it is in use. This is especially true for mobile or ground-mounted vertical antennas. Avoid transmitting with more than 25 W in a VHF mobile installation unless it is possible to first measure the RF fields inside the vehicle. At the 1-kW level, both HF and VHF directional antennas should be at least 35 ft above inhabited areas. Avoid using indoor and attic-mounted antennas if at all possible. If open-wire feeders are used, ensure that it is not possible for people (or animals) to come into accidental contact with the feed line.
 - Don't operate high-power amplifiers with the covers removed, especially at VHF/UHF.
 - In the UHF/SHF region, never look into the open end of an activated length of waveguide or microwave feed-horn antenna or point it toward anyone. (If you do, you may be exposing your eyes to more than the maximum permissible exposure level of RF radiation.) Never point a high-gain, narrow-bandwidth antenna (a paraboloid, for instance) toward people. Use caution in aiming an EME (moonbounce) array toward the horizon; EME arrays may deliver an effective radiated power of 250,000 W or more.
 - With hand-held transceivers, keep the antenna away from your head and use the lowest power possible to maintain communications. Use a separate microphone and hold the rig as far away from you as possible. This will reduce your exposure to the RF energy.
 - Don't work on antennas that have RF power applied.
 - Don't stand or sit close to a power supply or linear amplifier when the ac power is turned on. Stay at least 24 inches away from power transformers, electrical fans and other sources of high-level 60-Hz magnetic fields.
-

sional power-density meters can make useful measurements.

While our primary concern is ordinarily the intensity of the signal radiated by an antenna, we also should remember that there are other potential energy sources to be considered. You also can be exposed to RF radiation directly from a power amplifier if it is operated without proper shielding. Transmission lines also may radiate a significant amount of energy under some conditions. Poor microwave waveguide joints or improperly assembled connectors are another source of incidental radiation.

FURTHER RF EXPOSURE SUGGESTIONS

Potential exposure situations should be taken seriously. Based on the FCC/EPA measurements and other data, the "RF awareness" guidelines of Table 3.4 were developed by the ARRL RF Safety Committee. A longer version of these guidelines, along with a complete list of references, appeared in a *QST* article by Ivan Shulman, MD, WC2S ("Is Amateur Radio Hazardous to Our Health?" *QST*, Oct 1989, pp 31-34).

In addition, the ARRL has published a book, *RF Exposure and You*, that is helping hams comply with the FCC's RF-exposure regulations. The ARRL also maintains an RF-exposure news page on its Web site. See www.arrl.org/news/rfsafety. This site contains reprints of selected *QST* articles on RF exposure and links to the FCC and other useful sites.

Other Hazards in the Ham Shack

CHEMICALS

We can't seem to live without the use of chemicals, even in the electronics age. A number of substances are used everyday by amateurs without causing ill effects. A sensible approach is to become knowledgeable of the hazards associated with the chemicals we use in our shack and then treat them with respect.

A few key suggestions:

- Read the information that accompanies the chemical and follow the manufacturer's recommended safety practices. If you would like more information than is printed on the label, ask for a material safety data sheet.
- Store chemicals properly away from sunlight and sources of heat. Provide security so they won't fall off the shelf. Secure them so that children and un-

trained persons will not gain access.

- Always keep containers labeled so there is no confusion about the contents. Use the container in which the chemical was purchased.
- Handle chemicals carefully to avoid spills.
- Clean up any spills or leaks promptly but don't overexpose yourself in the process. Never dispose of chemicals in household sinks or drains. Instead, contact your local waste plant operator or fire department to determine the proper disposal procedures for your area. Many communities have household hazardous waste collection programs. Of course, the best solution is to only buy the amount of chemical that you will need, and use it all if possible. Always label any waste chemicals, especially if they are no longer in their

original containers. Oil-filled capacitors and transformers were once commonly filled with oil containing PCB's. Never dispose of any such items that may contain PCB's in landfills.

- Always use recommended personal protective equipment (such as gloves, face shield, splash goggles and aprons).
- If corrosives (acids or caustics) are splashed on you *immediately* rinse with cold water for a minimum of 15 minutes to flush the skin thoroughly. If splashed in the eyes, direct a gentle stream of cold water into the eyes for at least 15 minutes. Gently lift the eyelids so trapped liquids can be flushed completely. Start flushing before removing contaminated clothing. Seek professional medical assistance. It is unwise to work alone since people splashed with chemicals need

- the calm influence of another person.
- Food and chemicals don't mix. Keep food, drinks and cigarettes *away* from areas where chemicals are used and don't bring your chemicals to places where you eat.

Table 3.5 summarizes the uses and hazards of chemicals used in the ham shack. It includes preventive measures that can minimize risk.

ERGONOMICS

Ergonomics is a term that loosely means

“fitting the work to the person.” If tools and equipment are designed about what people can accommodate, the results will be much more satisfactory. For example, in the 1930s research was done in telephone equipment manufacturing plants because use of long-nosed pliers for wiring switchboards required considerable force at the end of the hand's range of motion. A simple tool redesign resolved this issue. Considerable attention has been focused on ergonomics in recent years because we have come to realize that long

periods of time spent in unnatural positions can lead to repetitive-motion illness. Much of this attention has been focused on people whose job tasks have required them to operate video display terminals (VDTs). While most Amateur Radio operators do not devote as much time to their hobby as they might in a full-time job, it does make sense to consider comfort and flexibility when choosing furniture and arranging it in the shack or workshop. Adjustable height chairs are available with air cylinders to serve as a shock absorber.

Table 3.5
Properties and Hazards of Chemicals often used in the Shack or Workshop

<i>Generic Chemical Name</i>	<i>Purpose or Use</i>	<i>Hazards</i>	<i>Ways to Minimize Risks</i>
Lead-tin solder	Bonding electrical components	<ul style="list-style-type: none"> • Lead exposure (mostly from hand contact) • Flux exposure (inhalation) 	<ul style="list-style-type: none"> • Always wash hands after soldering or touching solder. • Use good ventilation.

Footrests might come in handy if the chair is so high that your feet cannot support your lower leg weight. The height of tables and keyboards often is not adjustable.

Placement of VDT screens should take into consideration the reflected light coming from windows. It is always wise to build into your sitting sessions time to walk around and stimulate blood circulation. Your muscles are less likely to stiffen, while the flexibility in your joints can be enhanced by moving around.

Selection of hand tools is another area where there are choices to make that may affect how comfortable you will be while working in your shack. Look for screwdrivers with pliable grips. Take into account how heavy things are before picking them up — your back will thank you.

ENERGIZED CIRCUITS

Working with energized circuits can be very hazardous since our senses cannot directly detect dangerous voltages. The first thing we should ask ourselves when faced with troubleshooting, aligning or other “live” procedures is, “Is there a way to reduce the hazard of electrical shock?” Here are some ways of doing just that.

1. If at all possible, troubleshoot with an ohmmeter. With a reliable schematic diagram and careful consideration of how various circuit conditions may reflect resistance readings, it will often be unnecessary to do live testing.

2. Keep a fair distance from energized circuits. What is considered “good practice” in terms of distance? The *National Electrical Code* specifies minimum working space about electric equipment in Sections 110-16 and 110-34, depending on the voltage level. The principle here is that a person doing live work needs adequate space so they are not forced to be dangerously close to energized equipment.

3. If you need to measure the voltage of a circuit, install the voltmeter with the power safely off, back up, and only then energize the circuit. Remove the power before disconnecting the meter.

4. If you are building equipment that has hinged or easily removable covers that could expose someone to an energized circuit, install interlock switches that safely remove power in the event that the enclosure was opened with the power still on. Interlock switches are generally not used if tools are required to open the enclosure.

5. Never assume that a circuit is at zero potential even if the power is switched off and the power cable disconnected. Capacitors can retain a charge for a considerable period of time. Bleeder resistors should be installed, but don't assume they have bled off the voltage. Instead, after power is re-

High-Voltage Hazards

What happens when someone receives an electrical shock?

Electrocutions (fatal electric shocks) usually are caused by the heart ceasing to beat in its normal rhythm. This condition, called ventricular fibrillation, causes the heart muscles to quiver and stop working in a coordinated pattern, in turn preventing the heart from pumping blood.

The current flow that results in ventricular fibrillation varies between individuals but may be in the range of 100 mA to 500 mA. At higher current levels the heart may have less tendency to fibrillate but serious damage would be expected. Studies have shown 60-Hz alternating current to be more hazardous than dc currents. Emphasis is placed on application of cardiopulmonary resuscitation (CPR), as this technique can provide mechanical flow of some blood until paramedics can “restart” the heart's normal beating pattern. Defibrillators actually apply a carefully controlled dc voltage to “shock” the heart back into a normal heartbeat. It doesn't always work but it's the best procedure available.

What are the most important factors associated with severe shocks?

You may have heard that the current that flows through the body is the most important factor, and this is generally true. The path that current takes through the body affects the outcome to a large degree. While simple application of Ohm's Law tells us that the higher the voltage applied with a fixed resistance, the greater the current that will flow. Most electrical shocks involve skin contact. Skin, with its layer of dead cells and often fatty tissues, is a fair insulator. Nonetheless, as voltage increases the skin will reach a point where it breaks down. Then the lowered resistance of deeper tissues allows a greater current to flow. This is why electrical codes refer to the term “high voltage” as a voltage above 600 V.

How little a voltage can be lethal?

This depends entirely on the resistance of the two contact points in the circuit, the internal resistance of the body, and the path the current travels through the body. Historically, reports of fatal shocks suggest that as little as 24 V *could* be fatal under extremely adverse conditions. To add some perspective, one standard used to prevent serious electrical shock in hospital operating rooms limits leakage flow from electronic instruments to only 50 μ A due to the use of electrical devices and related conductors inside the patient's body.

moved and disconnected use a “shorting stick” to ground all exposed conductors and ensure that voltage is not present. Avoid using screwdrivers, as this brings the amateur too close to the circuit and could ruin the screwdriver's blade.

6. If you must hold a probe to take a measurement, always keep one hand in your pocket. As mentioned in the sidebar on the effects of high voltages, the worst path current could take through your body is from hand to hand since the flow would pass through the chest cavity.

7. Make sure someone is in the room with you and that they know how to remove the power safely. If they grab you with the power still on they will be shocked as well.

8. Test equipment probes and their leads must be in very good condition and rated for the conditions they will encounter.

9. Be wary of the hazards of “floating” (ungrounded) test equipment. A number of options are available to avoid this hazard. Contact your test equipment

manufacturer for suggested procedures.

10. Ground-fault circuit interrupters can offer additional protection for stray currents that flow through the ground on 120-V circuits. Know their limitations. They cannot offer protection for the plate supply voltages in linear amplifiers, for example.

11. Older radio equipment containing ac/dc power supplies have their own hazards. If working on these live, use an isolation transformer, as the chassis may be connected directly to the hot or neutral power conductor.

12. Be aware of electrolytic capacitors that might fail if used outside their intended applications.

13. Replace fuses only with those having proper ratings.

SUMMARY

The ideas presented in this chapter are intended to reinforce the concept that ham radio, like many other activities in

modern life, does have certain risks. But by understanding the hazards and how to deal effectively with them, the risk can be minimized. Common-sense measures can go a long way to help us prevent accidents. Traditionally, amateurs are inventors, and experimenting is a major part of our nature. But reckless chance-taking is never wise, especially when our health and well-being is involved. A healthy attitude toward doing things the right way will help us meet our goals and

expectations.

Chapter 4

Electrical Fundamentals

DC Circuits and Resistance Glossary

Alternating current — A flow of charged particles through a conductor, first in one direction, then in the other direction.

Ampere — A measure of flow of charged particles per unit time. One ampere represents one coulomb of charge flowing past a point in one second.

Atom — The smallest particle of matter that makes up an element. Consists of protons and neutrons in the central area called the nucleus, with electrons surrounding this central region.

Coulomb — A unit of measure of a

quantity of electrically charged particles. One coulomb is equal to 6.25×10^{18} electrons.

Direct current — A flow of charged particles through a conductor in one direction only.

EMF — Electromotive Force is the term used to define the force of attraction between two points of different charge potential. Also called voltage.

Energy — Capability of doing work. It is usually measured in electrical terms as the number of watts of power consumed during a specific period of time, such as

watt-seconds or kilowatt-hours.

Joule — Measure of a quantity of energy. One joule is defined as one newton (a measure of force) acting over a distance of one meter.

Ohm — Unit of resistance. One ohm is defined as the resistance that will allow one ampere of current when one volt of EMF is impressed across the resistance.

Power — Power is the rate at which work is done. One watt of power is equal to one volt of EMF, causing a current of one ampere through a resistor.

Volt — A measure of electromotive force.

Introduction

The DC Circuits and Resistance section of this chapter was written by Roger Taylor, K9ALD.

The atom is the primary building block of the universe. The main parts of the atom include protons, electrons and neutrons. Protons have a positive electrical charge, electrons a negative charge and neutrons have no electrical charge. All atoms are electrically neutral, so they have the same number of electrons as protons. If an atom loses electrons, so it has more protons than electrons, it has a net positive charge. If an atom gains electrons, so it has more electrons than protons, it has a negative charge. Particles with a positive or negative charge are called ions. Free electrons are also called ions, because they have a negative charge.

When there are a surplus number of positive ions in one location and a surplus

number of negative ions (or electrons) in another location, there is an attractive force between the two collections of particles. That force tries to pull the collections together. This attraction is called electromotive force, or EMF.

If there is no path (conductor) to allow electric charge to flow between the two locations, the charges cannot move together and neutralize one another. If a conductor is provided, then electric current (usually electrons) will flow through the conductor.

Electrons move from the negative to the positive side of the voltage, or EMF source. *Conventional current* has the opposite direction, from positive to negative. This comes from an arbitrary decision made by Benjamin Franklin in the 18th century. The conventional current direction is important in establishing the

proper polarity sign for many electronics calculations. Conventional current is used in much of the technical literature. The arrows in semiconductor schematic symbols point in the direction of conventional current, for example.

To measure the quantities of charge, current and force, certain definitions have been adopted. Charge is measured in *coulombs*. One coulomb is equal to 6.25×10^{18} electrons (or protons). Charge flow is measured in *amperes*. One ampere represents one coulomb of charge flowing past a point in one second. Electromotive force is measured in *volts*. One volt is defined as the potential force (electrical) between two points for which one ampere of current will do one *joule* (measure of energy) of work flowing from one point to another. (A joule of work per second represents a power of one watt.)

Voltage can be generated in a variety of ways. Chemicals with certain characteristics can be combined to form a battery. Mechanical motion such as friction (static electricity, lightning) and rotating conductors in a magnetic field (generators) can also produce voltage.

Any conductor between points at different voltages will allow current to pass between the points. No conductor is perfect or lossless, however, at least not at normal temperatures. Charged particles such as electrons resist being moved and it requires energy to move them. The amount of resistance to current is measured in *ohms*.

OHM'S LAW

One ohm is defined as the amount of resistance that allows one ampere of current to flow between two points that have a potential difference of one volt. Thus, we get Ohm's Law, which is:

$$R = \frac{E}{I} \quad (1)$$

where:

- R = resistance in ohms,
- E = potential or EMF in volts and
- I = current in amperes.

Transposing the equation gives the other common expressions of Ohm's Law as:

$$E = I \times R \quad (2)$$

and

$$I = \frac{E}{R} \quad (3)$$

All three forms of the equation are used often in radio work. You must remember that the quantities are in volts, ohms and amperes; other units cannot be used in the equations without first being converted. For example, if the current is in milliamperes you must first change it to the equivalent fraction of an ampere before substituting the value into the equations.

The following examples illustrate the use of Ohm's Law. The current through a 20000-Ω resistance is 150 mA. See **Fig 4.1**. What is the voltage? To find voltage, use equation 2 ($E = I \times R$). Convert the current from milliamperes to amperes. Divide by 1000 mA / A (or multiply by 10^{-3} A / mA) to make this conversion. (Notice the conversion factor of 1000 does not limit the number of significant figures in the calculated answer.)

$$I = \frac{150 \text{ mA}}{1000 \frac{\text{mA}}{\text{A}}} = 0.150 \text{ A}$$

Then:

$$E = 0.150 \text{ A} \times 20000 \text{ } \Omega = 3000 \text{ V}$$

When 150 V is applied to a circuit, the current is measured at 2.5 A. What is the resistance of the circuit? In this case R is the unknown, so we will use equation 1:

$$R = \frac{E}{I} = \frac{150 \text{ V}}{2.5 \text{ A}} = 60 \text{ } \Omega$$

No conversion was necessary because the voltage and current were given in volts and amperes.

How much current will flow if 250 V is applied to a 5000-Ω resistor? Since I is unknown,

$$I = \frac{E}{R} = \frac{250 \text{ V}}{5000 \text{ } \Omega} = 0.05 \text{ A}$$

It is more convenient to express the current in mA, and $0.05 \text{ A} \times 1000 \text{ mA} / \text{A} = 50 \text{ mA}$.

RESISTANCE AND CONDUCTANCE

Suppose we have two conductors of the same size and shape, but of different materials. The amount of current that will flow when a given EMF is applied will vary with the resistance of the material. The lower the resistance, the greater the current for a given EMF. The *resistivity* of a material is the resistance, in ohms, of a cube of the material measuring one centimeter on each edge. One of the best conductors is copper, and in making resistance calculations it is frequently convenient to compare the resistance of the material under consideration with that of a copper conductor of the same size and shape. **Table 4.1** gives the ratio of the resistivity of various conductors to the resistivity of copper.

The longer the physical path, the higher the resistance of that conductor. For direct current and low-frequency alternating currents (up to a few thousand hertz) the resistance is inversely proportional to the cross-sectional area of the path the current must travel; that is, given two conductors of the same material and having the same length, but differing in cross-sectional

Fig 4.1 — A simple circuit consisting of a battery and a resistor.

Table 4.1

Relative Resistivity of Metals

Material	Resistivity Compared to Copper
Aluminum (pure)	1.60
Brass	3.7-4.90
Cadmium	4.40
Chromium	1.80
Copper (hard-drawn)	1.03
Copper (annealed)	1.00
Gold	1.40
Iron (pure)	5.68
Lead	12.80
Nickel	5.10
Phosphor bronze	2.8-5.40
Silver	0.94
Steel	7.6-12.70
Tin	6.70
Zinc	3.40

tional area, the one with the larger area will have the lower resistance.

RESISTANCE OF WIRES

The problem of determining the resistance of a round wire of given diameter and length—or its converse, finding a suitable size and length of wire to provide a desired amount of resistance—can easily be solved with the help of the copper wire table given in the **Component Data and References** chapter. This table gives the resistance, in ohms per 1000 ft, of each standard wire size. For example, suppose you need a resistance of 3.5 Ω, and some #28 wire is on hand. The wire table in the **Component Data and References** chapter shows that #28 wire has a resistance of 66.17 Ω / 1000 ft. Since the desired resistance is 3.5 Ω, the required wire length is:

$$\begin{aligned} \text{Length} &= \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} = \frac{3.5 \text{ } \Omega}{\frac{66.17 \text{ } \Omega}{1000 \text{ ft}}} \\ &= \frac{3.5 \text{ } \Omega \times 1000 \text{ ft}}{66.17 \text{ } \Omega} = 53 \text{ ft} \quad (4) \end{aligned}$$

As another example, suppose that the resistance of wire in a circuit must not exceed 0.05 Ω and that the length of wire required for making the connections totals 14 ft. Then:

$$\begin{aligned} \frac{R_{\text{WIRE}}}{1000 \text{ ft}} &< \frac{R_{\text{MAXIMUM}}}{\text{Length}} = \frac{0.05 \text{ } \Omega}{14.0 \text{ ft}} \quad (5) \\ &= 3.57 \times 10^{-3} \frac{\text{ } \Omega}{\text{ft}} \times \frac{1000 \text{ ft}}{1000 \text{ ft}} \\ \frac{R_{\text{WIRE}}}{1000 \text{ ft}} &< \frac{3.57 \text{ } \Omega}{1000 \text{ ft}} \end{aligned}$$

Find the value of $R_{\text{WIRE}} / 1000 \text{ ft}$ that is less than the calculated value. The wire table shows that #15 is the smallest size

having a resistance less than this value. (The resistance of #15 wire is given as $3.1810 \Omega / 1000 \text{ ft.}$) Select any wire size larger than this for the connections in your circuit, to ensure that the total wire resistance will be less than 0.05Ω .

When the wire in question is not made of copper, the resistance values in the wire table should be multiplied by the ratios shown in Table 4.1 to obtain the resulting resistance. If the wire in the first example were made from nickel instead of copper, the length required for 3.5Ω would be:

$$\text{Length} = \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} \quad (6)$$

$$= \frac{3.5 \Omega}{\frac{66.17 \Omega}{1000 \text{ ft}} \times 5.1}$$

$$= \frac{3.5 \Omega \times 1000 \text{ ft}}{66.17 \Omega \times 5.1}$$

$$\text{Length} = \frac{3500 \text{ ft}}{337.5} = 10.37 \text{ ft}$$

TEMPERATURE EFFECTS

The resistance of a conductor changes with its temperature. The resistance of practically every metallic conductor increases with increasing temperature. Carbon, however, acts in the opposite way; its resistance decreases when its temperature rises. It is seldom necessary to consider temperature in making resistance calculations for amateur work. The temperature effect is important when it is necessary to maintain a constant resistance under all conditions, however. Special materials that have little or no change in resistance over a wide temperature range are used in that case.

RESISTORS

A package of material exhibiting a certain amount of resistance, made up into a single unit is called a resistor. Different resistors having the same resistance value may be considerably different in physical size and construction (see Fig 4.2). Cur-

Fig 4.2 — Examples of various resistors. At the top left is a small 10-W wirewound resistor. A single in-line package (SIP) of resistors is at the top right. At the top center is a small PC-board-mount variable resistor. A tiny surface-mount (chip) resistor is also shown at the top. Below the variable resistor is a 1-W carbon composition resistor and then a ½-W composition unit. The dog-bone-shaped resistors at the bottom are ½-W and ¼-W film resistors. The ¼-inch-ruled graph paper background provides a size comparison. The inset photo shows the chip resistor with a penny for size comparison.

rent through a resistance causes the conductor to become heated; the higher the resistance and the larger the current, the greater the amount of heat developed. Resistors intended for carrying large currents must be physically large so the heat can be radiated quickly to the surrounding air. If the resistor does not dissipate the heat quickly, it may get hot enough to melt or burn.

The amount of heat a resistor can safely dissipate depends on the material, surface area and design. Typical carbon resistors used in amateur electronics ($1/8$ to 2-W resistors) depend primarily on the surface area of the case, with some heat also being carried off through the connecting leads. Wirewound resistors are usually used for higher power levels. Some have finned cases for better convection cooling and/or metal cases for better conductive cooling.

In some circuits, the resistor value may be critical. In this case, precision resistors are used. These are typically wirewound, or carbon-film devices whose values are carefully controlled during manufacture.

In addition, special material or construction techniques may be used to provide temperature compensation, so the value does not change (or changes in a precise manner) as the resistor temperature changes. There is more information about the electrical characteristics of real resistors in the **Real-World Component Characteristics** chapter.

CONDUCTANCE

The reciprocal of resistance ($1/R$) is *conductance*. It is usually represented by the symbol G. A circuit having high conductance has low resistance, and vice versa. In radio work, the term is used chiefly in connection with electron-tube and field-effect transistor characteristics. The unit of conductance is the siemens, abbreviated S. A resistance of 1Ω has a conductance of 1 S, a resistance of 1000 Ω has a conductance of 0.001 S, and so on. A unit frequently used in connection with electron devices is the μS or one millionth of a siemens. It is the conductance of a 1-M Ω resistance.

Series and Parallel Resistances

Very few actual electric circuits are as simple as Fig 4.1. Commonly, resistances are found connected in a variety of ways. The two fundamental methods of connecting resistances are shown in Fig 4.3. In part A, the current flows from the source of EMF (in the direction shown by the ar-

row) down through the first resistance, R1, then through the second, R2 and then back to the source. These resistors are connected in series. The current everywhere in the circuit has the same value.

In part B, the current flows to the common connection point at the top of the two

resistors and then divides, one part of it flowing through R1 and the other through R2. At the lower connection point these two currents again combine; the total is the same as the current into the upper common connection. In this case, the two resistors are connected in parallel.

RESISTORS IN PARALLEL

In a circuit with resistances in parallel, the total resistance is less than that of the lowest resistance value present. This is because the total current is always greater than the current in any individual resistor. The formula for finding the total resistance of resistances in parallel is:

$$R = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} + \dots} \quad (7)$$

where the dots indicate that any number of resistors can be combined by the same method. For only two resistances in parallel (a very common case) the formula becomes:

$$R = \frac{R_1 \times R_2}{R_1 + R_2} \quad (8)$$

Example: If a 500- Ω resistor is connected in parallel with one of 1200 Ω , what is the total resistance?

$$R = \frac{R_1 \times R_2}{R_1 + R_2} = \frac{500 \Omega \times 1200 \Omega}{500 \Omega + 1200 \Omega}$$

$$R = \frac{600000 \Omega^2}{1700 \Omega} = 353 \Omega$$

KIRCHHOFF'S FIRST LAW (KIRCHHOFF'S CURRENT LAW)

Suppose three resistors (5.00 k Ω , 20.0 k Ω and 8.00 k Ω) are connected in parallel as shown in **Fig 4.4**. The same EMF, 250 V, is applied to all three resistors. The current in each can be found from

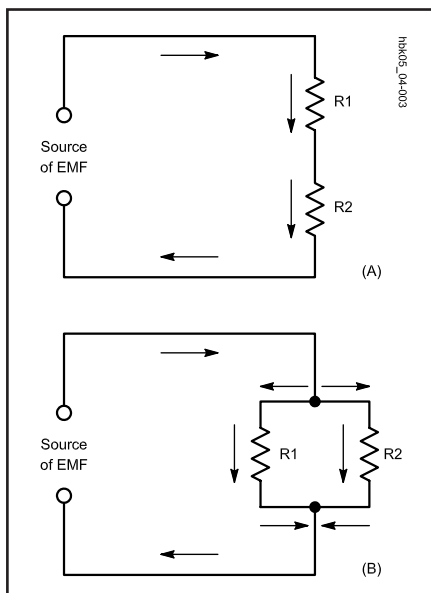

Fig 4.3 — Resistors connected in series at A, and in parallel at B.

Fig 4.4 — An example of resistors in parallel. See text for calculations.

Ohm's Law, as shown below. The current through R1 is I1, I2 is the current through R2 and I3 is the current through R3.

For convenience, we can use resistance in k Ω , which gives current in milliamperes.

$$I_1 = \frac{E}{R_1} = \frac{250 \text{ V}}{5.00 \text{ k}\Omega} = 50.0 \text{ mA}$$

$$I_2 = \frac{E}{R_2} = \frac{250 \text{ V}}{20.0 \text{ k}\Omega} = 12.5 \text{ mA}$$

$$I_3 = \frac{E}{R_3} = \frac{250 \text{ V}}{8.00 \text{ k}\Omega} = 31.2 \text{ mA}$$

Notice that the branch currents are inversely proportional to the resistances. The 20000- Ω resistor has a value four times larger than the 5000- Ω resistor, and has a current one quarter as large. If a resistor has a value twice as large as another, it will have half as much current through it when they are connected in parallel.

The total circuit current is:

$$I_{\text{TOTAL}} = I_1 + I_2 + I_3 \quad (9)$$

$$I_{\text{TOTAL}} = 50.0 \text{ mA} + 12.5 \text{ mA} + 31.2 \text{ mA}$$

$$I_{\text{TOTAL}} = 93.7 \text{ mA}$$

This example illustrates Kirchhoff's Current Law: The current flowing into a node or branching point is equal to the sum of the individual currents leaving the node or branching point. The total resistance of the circuit is therefore:

$$R = \frac{E}{I} = \frac{250 \text{ V}}{93.7 \text{ mA}} = 2.67 \text{ k}\Omega$$

You can verify this calculation by combining the three resistor values in parallel, using equation 7.

RESISTORS IN SERIES

When a circuit has a number of resistances connected in series, the total resistance of the circuit is the sum of the individual resistances. If these are numbered R1, R2, R3 and so on, then:

$$R_{\text{TOTAL}} = R_1 + R_2 + R_3 + R_4 \dots \quad (10)$$

where the dots indicate that as many resistors as necessary may be added.

Example: Suppose that three resistors are

Fig 4.5 — An example of resistors in series. See text for calculations.

connected to a source of EMF as shown in **Fig 4.5**. The EMF is 250 V, R1 is 5.00 k Ω , R2 is 20.0 k Ω and R3 is 8.00 k Ω . The total resistance is then

$$R_{\text{TOTAL}} = R_1 + R_2 + R_3$$

$$R = 5.00 \text{ k}\Omega + 20.0 \text{ k}\Omega + 8.00 \text{ k}\Omega$$

$$R = 33.0 \text{ k}\Omega.$$

The current in the circuit is then

$$I = \frac{E}{R} = \frac{250 \text{ V}}{33.0 \text{ k}\Omega} = 7.58 \text{ mA}$$

(We need not carry calculations beyond three significant figures; often, two will suffice because the accuracy of measurements is seldom better than a few percent.)

KIRCHHOFF'S SECOND LAW (KIRCHHOFF'S VOLTAGE LAW)

Ohm's Law applies in any portion of a circuit as well as to the circuit as a whole. Although the current is the same in all three of the resistances in the example of Fig 4.5, the total voltage divides between them. The voltage appearing across each resistor (the voltage drop) can be found from Ohm's Law.

Example: If the voltage across R1 is called E1, that across R2 is called E2 and that across R3 is called E3, then

$$E = IR_1 = 0.00758 \text{ A} \times 5000 \Omega = 37.9 \text{ V}$$

$$E = IR_2 = 0.00758 \text{ A} \times 20000 \Omega = 152 \text{ V}$$

$$E = IR_3 = 0.00758 \text{ A} \times 8000 \Omega = 60.6 \text{ V}$$

Notice here that the voltage drop across each resistor is directly proportional to the resistance. The 20000- Ω resistor value is four times larger than the 5000- Ω resistor, and the voltage drop across the 20000- Ω resistor is four times larger. A resistor that has a value twice as large as another will have twice the voltage drop across it when they are connected in series.

Kirchhoff's Voltage Law accurately describes the situation in the circuit: The sum of the voltages in a closed current loop is zero. The resistors are power sinks, while the battery is a power source. It is common to assign a + sign to power sources and a

– sign to power sinks. This means the voltages across the resistors have the opposite sign from the battery voltage. Adding all the voltages yields zero. In the case of a single voltage source, algebraic manipulation implies that the sum of the individual voltage drops in the circuit must be equal to the applied voltage.

$$E_{TOTAL} = E1 + E2 + E3 \quad (11)$$

$$E_{TOTAL} = 37.9 \text{ V} + 152 \text{ V} + 60.6 \text{ V}$$

$$E_{TOTAL} = 250 \text{ V}$$

(Remember the significant figures rule for addition.)

In problems such as this, when the current is small enough to be expressed in milliamperes, considerable time and trouble can be saved if the resistance is expressed in kilohms rather than in ohms. When the resistance in kilohms is substituted directly in Ohm's Law, the current will be milliamperes, if the EMF is in volts.

RESISTORS IN SERIES-PARALLEL

A circuit may have resistances both in parallel and in series, as shown in Fig 4.6A. The method for analyzing such a circuit is as follows: Consider R2 and R3 to be the equivalent of a single resistor, R_{EQ} whose value is equal to R2 and R3 in parallel.

$$R_{EQ} = \frac{R2 \times R3}{R2 + R3} = \frac{20000 \Omega \times 8000 \Omega}{20000 \Omega + 8000 \Omega}$$

$$= \frac{1.60 \times 10^8 \Omega^2}{28000 \Omega}$$

$$R_{EQ} = 5710 \Omega = 5.71 \text{ k}\Omega$$

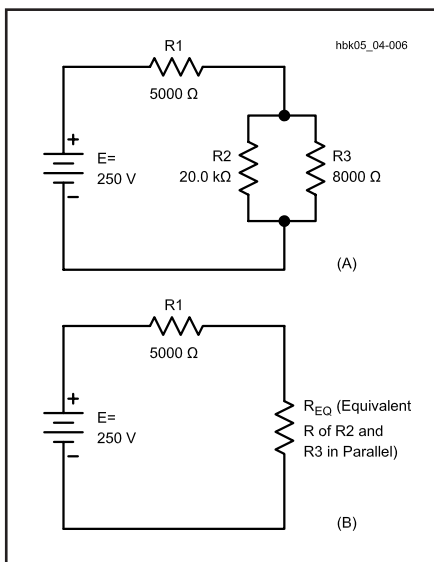

Fig 4.6 — At A, an example of resistors in series-parallel. The equivalent circuit is shown at B. See text for calculations.

This resistance in series with R1 forms a simple series circuit, as shown in Fig 4.6B. The total resistance in the circuit is:

$$R_{TOTAL} = R1 + R_{EQ} = 5.00 \text{ k}\Omega + 5.71 \text{ k}\Omega$$

$$R_{TOTAL} = 10.71 \text{ k}\Omega$$

The current is:

$$I = \frac{E}{R} = \frac{250 \text{ V}}{10.71 \text{ k}\Omega} = 23.3 \text{ mA}$$

The voltage drops across R1 and R_{EQ} are:

$$E1 = I \times R1 = 23.3 \text{ mA} \times 5.00 \text{ k}\Omega = 117 \text{ V}$$

$$E2 = I \times R_{EQ} = 23.3 \text{ mA} \times 5.71 \text{ k}\Omega = 133 \text{ V}$$

with sufficient accuracy. These two voltage drops total 250 V, as described by Kirchhoff's Current Law. E2 appears across both R2 and R3 so,

$$I2 = \frac{E2}{R2} = \frac{133 \text{ V}}{20.0 \text{ k}\Omega} = 6.65 \text{ mA}$$

$$I3 = \frac{E3}{R3} = \frac{133 \text{ V}}{8.00 \text{ k}\Omega} = 16.6 \text{ mA}$$

where:

I2 = current through R2 and

I3 = current through R3.

The sum of I2 and I3 is equal to 23.3 mA, conforming to Kirchhoff's Voltage Law.

THEVENIN'S THEOREM

Thevenin's Theorem is a useful tool for simplifying electrical networks. Thevenin's Theorem states that any two-terminal network of resistors and voltage or current sources can be replaced by a single voltage source and a series resistor. Such a transformation can simplify the calculation of current through a parallel branch. Thevenin's Theorem can be readily applied to the circuit of Fig 4.6A, to find the current through R3.

In this example, R1 and R2 form a voltage divider circuit, with R3 as the load (Fig 4.7A). The current drawn by the load (R3) is simply the voltage across R3, divided by its resistance. Unfortunately, the value of R2 affects the voltage across R3, just as the presence of R3 affects the potential appearing across R2. Some means of separating the two is needed; hence the Thevenin-equivalent circuit.

The voltage of the Thevenin-equivalent battery is the open-circuit voltage, measured when there is no current from either terminal A or B. Without a load connected between A and B, the total current through the circuit is (from Ohm's Law):

$$I = \frac{E}{R1 + R2} \quad (12)$$

and the voltage between terminals A and B (E_{AB}) is:

$$E_{AB} = I \times R2 \quad (13)$$

By substituting the first equation into the second, we can find a simplified expression for E_{AB} :

$$E_{AB} = \frac{R2}{R1 + R2} \times E \quad (14)$$

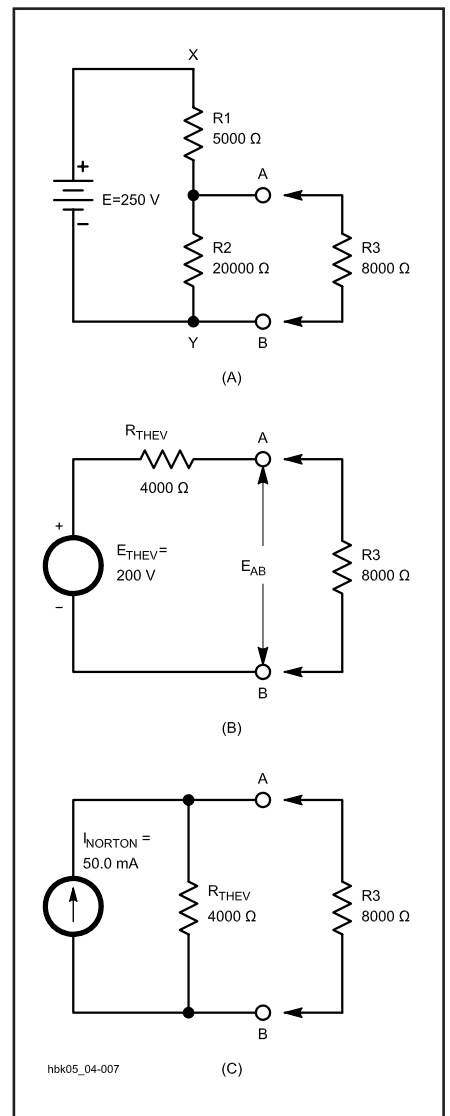

Fig 4.7 — Equivalent circuits for the circuit shown in Fig 4.6. A shows the load resistor (R3) looking into the circuit. B shows the Thevenin-equivalent circuit, with a resistor and a voltage source in series. C shows the Norton-equivalent circuit, with a resistor and current source in parallel.

Using the values in our example, this becomes:

$$E_{AB} = \frac{20.0 \text{ k}\Omega}{25.0 \text{ k}\Omega} \times 250 \text{ V} = 200 \text{ V}$$

when nothing is connected to terminals A or B. With no current drawn, E is equal to E_{AB} .

The Thevenin-equivalent resistance is the total resistance between terminals A and B. The ideal voltage source, by definition, has zero internal resistance. Assuming the battery to be a close approximation of an ideal source, put a short between points X and Y in the circuit of Fig 4.7A. R1 and R2 are then effectively placed in parallel, as viewed from terminals A and B. The Thevenin-equivalent resistance is then:

$$R_{THEV} = \frac{R1 \times R2}{R1 + R2} \quad (15)$$

$$R_{THEV} = \frac{5000 \Omega \times 20000 \Omega}{5000 \Omega + 20000 \Omega}$$

$$R_{THEV} = \frac{1.00 \times 10^8 \Omega^2}{25000 \Omega} = 4000 \Omega$$

This gives the Thevenin-equivalent circuit as shown in Fig 4.7B. The circuits of Figures 4.7A and 4.7B are equivalent as far as R3 is concerned.

Once R3 is connected to terminals A and

B, there will be current through R_{THEV} , causing a voltage drop across R_{THEV} and reducing E_{AB} . The current through R3 is equal to

$$I3 = \frac{E_{THEV}}{R_{TOTAL}} = \frac{E_{THEV}}{R_{THEV} + R3} \quad (16)$$

Substituting the values from our example:

$$I3 = \frac{200 \text{ V}}{4000 \Omega + 8000 \Omega} = 16.7 \text{ mA}$$

This agrees with the value calculated earlier.

NORTON'S THEOREM

Norton's Theorem is another tool for analyzing electrical networks. Norton's Theorem states that any two-terminal network of resistors and current or voltage sources can be replaced by a single current source and a parallel resistor. Norton's Theorem is to current sources what Thevenin's Theorem is to voltage sources. In fact, the Thevenin resistance calculated previously is also used as the Norton equivalent resistance.

The circuit just analyzed by means of Thevenin's Theorem can be analyzed just as easily by Norton's Theorem. The equivalent Norton circuit is shown in Fig 4.7C. The current I_{SC} of the equivalent current source is the short-circuit current

through terminals A and B. In the case of the voltage divider shown in Fig 4.7A, the short-circuit current is:

$$I_{SC} = \frac{E}{R1} \quad (17)$$

Substituting the values from our example, we have:

$$I_{SC} = \frac{E}{R1} = \frac{250 \text{ V}}{5000 \Omega} = 50.0 \text{ mA}$$

The resulting Norton-equivalent circuit consists of a 50.0-mA current source placed in parallel with a 4000- Ω resistor. When R3 is connected to terminals A and B, one-third of the supply current flows through R3 and the remainder through R_{THEV} . This gives a current through R3 of 16.7 mA, again agreeing with previous conclusions.

A Norton-equivalent circuit can be transformed into a Thevenin-equivalent circuit and vice versa. The equivalent resistor stays the same in both cases; it is placed in series with the voltage source in the case of a Thevenin-equivalent circuit and in parallel with the current source in the case of a Norton-equivalent circuit. The voltage for a Thevenin-equivalent source is equal to the no-load voltage appearing across the resistor in the Norton-equivalent circuit. The current for a Norton-equivalent source is equal to the short-circuit current provided by the Thevenin source.

Power and Energy

Regardless of how voltage is generated, energy must be supplied if current is drawn from the voltage source. The energy supplied may be in the form of chemical energy or mechanical energy. This energy is measured in joules. One joule is defined from classical physics as the amount of energy or work done when a force of one newton (a measure of force) is applied to an object that is moved one meter in the direction of the force.

Power is another important concept. In the USA, power is often measured in horsepower in mechanical systems. We use the metric power unit of watts in electrical systems, however. In metric countries, mechanical power is usually expressed in watts also. One watt is defined as the use (or generation) of one joule of energy per second. One watt is also defined as one volt of potential pushing one ampere of current through a resistance. Thus,

$$P = I \times E \quad (18)$$

where:

P = power in watts

I = current in amperes

E = EMF in volts.

When current flows through a resistance, the electrical energy is turned into heat. Common fractional and multiple units for power are the milliwatt (one thousandth of a watt) and the kilowatt (1000 W).

Example: The plate voltage on a transmitting vacuum tube is 2000 V and the plate current is 350 mA. (The current must be changed to amperes before substitution in the formula, and so is 0.350 A.) Then:

$$P = I \times E = 2000 \text{ V} \times 0.350 \text{ A} = 700 \text{ W}$$

By substituting the Ohm's Law equivalent for E and I, the following formulas are obtained for power:

$$P = \frac{E^2}{R} \quad (19)$$

and

$$P = I^2 \times R \quad (20)$$

These formulas are useful in power calculations when the resistance and either the current or voltage (but not both) are known.

Example: How much power will be converted to heat in a 4000- Ω resistor if the potential applied to it is 200 V? From equation 19,

$$P = \frac{E^2}{R} = \frac{40000 \text{ V}^2}{4000 \Omega} = 10.0 \text{ W}$$

As another example, suppose a current

of 20 mA flows through a 300-Ω resistor. Then:

$$P = I^2 \times R = 0.020^2 \text{ A}^2 \times 300 \Omega$$

$$P = 0.00040 \text{ A}^2 \times 300 \Omega$$

$$P = 0.12 \text{ W}$$

Note that the current was changed from milliamperes to amperes before substitution in the formula.

Electrical power in a resistance is turned into heat. The greater the power, the more rapidly the heat is generated. Resistors for radio work are made in many sizes, the smallest being rated to dissipate (or carry safely) about $\frac{1}{16}$ W. The largest resistors commonly used in amateur equipment will dissipate about 100 W. Large resistors, such as those used in dummy-load antennas, are often cooled with oil to increase their power-handling capability.

If you want to express power in horsepower instead of watts, the following relationship holds:

$$1 \text{ horsepower} = 746 \text{ W} \quad (21)$$

This formula assumes lossless transformation; practical efficiency is taken up shortly. This formula is especially useful if you are working with a system that converts electrical energy into mechanical energy, and vice versa, since mechanical power is often expressed in horsepower, in the US.

This discussion relates to direct current in resistive circuits. See the **AC Theory and Reactive Components** section of this chapter for a discussion about power in ac circuits, including reactive circuits.

GENERALIZED DEFINITION OF RESISTANCE

Electrical energy is not always turned into heat. The energy used in running a motor, for example, is converted to mechanical motion. The energy supplied to a radio transmitter is largely converted into radio waves. Energy applied to a loudspeaker is changed into sound waves. In each case, the energy is converted to other forms and can be completely accounted for. None of the energy *just disappears!* This is a statement of the Law of Conservation of Energy. When a device converts energy from one form to another, we often say it *dissipates* the energy, or power. (Power is energy divided by time.) Of course the device doesn't really "use up" the energy, or make it disappear, it just converts it to another form. Proper operation of electrical devices often requires that the power must be supplied at a specific ratio of voltage to current. These fea-

The Ohm's Law and Power Circle

During the first semester of my *Electrical Power Technology* program, one of the first challenges issued by our dedicated instructor—Roger Crerie—to his new freshman students was to identify and develop 12 equations or formulas that could be used to determine voltage, current, resistance and power. Ohm's Law is expressed as

$$R = \frac{E}{I}$$

and it provided three of these equation forms while the basic equation relating power to current and voltage ($P = I \times E$) accounted for another three. With six known equations, it was just a matter of applying mathematical substitution for his students to develop the remaining six. Together, these 12 equations compose the

circle or *wheel* of voltage (E), current (I), resistance (R) and power (P) shown in Fig A. Just as Roger's previous students had learned at the Worcester Industrial Technical Institute (Worcester, Massachusetts), our Class of '82 now held the basic electrical formulas needed to proceed in our studies or professions. As can be seen in Fig A, we can determine any one of these four electrical quantities by knowing the value of any two others. You may want to keep this page bookmarked for your reference. You'll probably be using many of these formulas as the years go by—this has certainly been my experience—Dana G. Reed, W1LC, ARRL Handbook Editor

Fig A—Electrical formulas.

tures are characteristics of resistance, so it can be said that any device that "dissipates power" has a definite value of resistance.

This concept of resistance as something that absorbs power at a definite voltage-to-current ratio is very useful; it permits substituting a simple resistance for the load or power-consuming part of the device receiving power, often with considerable simplification of calculations. Of course, every electrical device has some resistance of its own in the more narrow sense, so a part of the energy supplied to it is converted to heat in that resistance even though the major part of the energy may be converted to another form.

EFFICIENCY

In devices such as motors and vacuum tubes, the objective is to convert the supplied energy (or power) into some form other than heat. Therefore, power converted to heat is considered to be a loss, because it is not useful power. The efficiency of a device is the useful power output (in its converted form) divided by the power input to the device. In a vacuum-tube transmitter, for example, the objective is to convert power from a dc source into ac power at some radio frequency. The ratio of the RF power output to the dc input is the efficiency of the tube. That is:

$$\text{Eff} = \frac{P_O}{P_I} \quad (22)$$

where:

Eff = efficiency (as a decimal)

P_O = power output (W)

P_I = power input (W).

Example: If the dc input to the tube is 100 W, and the RF power output is 60 W, the efficiency is:

$$\text{Eff} = \frac{P_O}{P_I} = \frac{60 \text{ W}}{100 \text{ W}} = 0.6$$

Efficiency is usually expressed as a percentage — that is, it tells what percent of the input power will be available as useful output. To calculate percent efficiency, just multiply the value from equation 22 by 100%. The efficiency in the example above is 60%.

Suppose a mobile transmitter has an RF power output of 100 W with 52% efficiency at 13.8 V. The vehicle's alternator system charges the battery at a 5.0-A rate at this voltage. Assuming an alternator efficiency of 68%, how much horsepower must the engine produce to operate the transmitter and charge the battery? Solution: To charge the battery, the alternator

must produce $13.8 \text{ V} \times 5.0 \text{ A} = 69 \text{ W}$. The transmitter dc input power is $100 \text{ W} / 0.52 = 190 \text{ W}$. Therefore, the total electrical power required from the alternator is $190 + 69 = 260 \text{ W}$. The engine load then is:

$$P_1 = \frac{P_O}{\text{Eff}} = \frac{260 \text{ W}}{0.68} = 380 \text{ W}$$

We can convert this to horsepower using the formula given earlier to convert between horsepower and watts:

$$380 \text{ W} \times \frac{1 \text{ horsepower}}{746 \text{ W}} = 0.51 \text{ horsepower}$$

ENERGY

When you buy electricity from a power company, you pay for electrical energy, not power. What you pay for is the *work*

that electricity does for you, not the rate at which that work is done. Work is equal to power multiplied by time. The common unit for measuring electrical energy is the watt-hour, which means that a power of 1 W has been used for one hour. That is:

$$\text{W hr} = P T$$

where:

W hr = energy in watt-hours

P = power in watts

T = time in hours.

Actually, the watt-hour is a fairly small energy unit, so the power company bills you for kilowatt-hours of energy used. Another energy unit that is sometimes useful is the watt-second (joule).

Energy units are seldom used in amateur practice, but it is obvious that a small amount of power used for a long time can

eventually result in a power bill that is just as large as if a large amount of power had been used for a very short time.

One practical application of energy units is to estimate how long a radio (such as a hand-held unit) will operate from a certain battery. For example, suppose a fully charged battery stores 900 mA hr of energy, and a radio draws 30 mA on receive. You might guess that the radio will receive 30 hrs with this battery, assuming 100% efficiency. You shouldn't expect to get the full 900 mA hr out of the battery, and you will probably spend some of the time transmitting, which will also reduce the time the battery will last. The **Real-World Component Characteristics** and **Power Supplies** chapters include additional information about batteries and their charge/discharge cycles.

Circuits and Components

SERIES AND PARALLEL CIRCUITS

Passive components (resistors for dc circuits) can be used to make voltage and current dividers and limiters to obtain a desired value. For instance, in **Fig 4.8A**, two resistors are connected in series to provide a voltage divider. As long as the device connected at point A has a much higher resistance than the resistors in the divider, the voltage will be approximately the ratio of the resistances. Thus, if $E = 10 \text{ V}$, $R_1 = 5 \Omega$ and $R_2 = 5 \Omega$, the voltage at point A will be 5 V measured on a high-impedance voltmeter. A good rule of thumb is that the load at point A should be at least ten times the value of the highest resistor in the divider to get reasonably close to the voltage you want. As the load resistance gets closer to the value of the divider, the current drawn by the load affects the division and causes changes from the desired value. If you need precise voltage division from fixed resistors and know the value of the load resistance, you can use Kirchhoff's Laws and Thevenin's Theorem (explained earlier) to calculate exact values.

Similarly, resistors can be used, as shown in **Fig 4.8B**, to make current dividers. Suppose you had two LEDs (light emitting diodes) and wanted one to glow twice as brightly as the other. You could use one resistor with twice the value of the other for the dimmer LED. Thus, approximately two-thirds of the current would flow through one LED and one-third through the other (neglecting any effect of the 0.7-V drop across the diode).

Resistors can also be used to limit the current through a device from a fixed voltage source. A typical example is shown in **Fig 4.8C**. Here a high-voltage source feeds a battery in a battery charger. This is typical of nickel cadmium chargers. The high resistor value limits the current that can possibly flow through the battery to a value that is low enough so it will not damage the battery.

SWITCHES

Switches are used to start or stop a signal (current) flowing in a particular circuit. Most switches are mechanical devices, although the same effect may be achieved with solid-state devices. Relays are switches that are controlled by another electrical signal rather than manual or mechanical means.

Switches come in many different forms and a wide variety of ratings. The most important ratings are the voltage and current handling capabilities. The voltage rating usually includes both the breakdown rating and the interrupt rating. Normally, the interrupt rating is the lower value, and therefore the one given on (for) the switch. The current rating includes both the current carrying capacity and the interrupt capability.

Most power switches are rated for alternating current use. Because ac voltage goes through zero with each cycle, switches can successfully interrupt much more alternating current than direct current without arcing. A switch that has a 10-A ac current rating may arc and dam-

Fig 4.8 — This circuit shows a resistive voltage divider at A, a resistive current divider at B, and a current-limiting resistor at C.

Fig 4.9 — Schematic diagrams of various types of switches. A is an SPST, B is an SPDT, and C is an SPDT switch with a center-off position.

age the contacts if used to turn off more than an ampere or two of dc.

Switches are normally designated by the number of *poles* (circuits controlled) and *positions* (circuit path choices). The simplest switch is the on-off switch, which is a single-pole, single-throw (SPST) switch as shown in **Fig 4.9A**. The off position does not direct the current to another circuit. The next step would be to change the current path to another path. This would be a single-pole, double-throw (SPDT) switch as shown in **Fig 4.9B**. Adding an off position would give a single-pole, double-throw, center-off switch as shown in **Fig 4.9C**.

Several such switches can be “ganged” to the same mechanical activator to provide double pole, triple pole or even more, separate control paths all activated at once. Switches can be activated in a variety of ways. The most common methods include lever, push button and rotary switches. Samples of these are shown in **Fig 4.10**. Most switches stay in the position set, but some are spring loaded so they only stay in the desired position while held there. These are called momentary switches.

Switches typically found in the home are usually rated for 125 V ac and 15 to 20 A. Switches in cars are usually rated for 12 V dc and several amperes. The breakdown voltage rating of a switch, which is usually higher than the interrupt rating, primarily depends on the insulating material surrounding the contacts and the separation between the contacts. Plastic or phenolic material normally provides both structural support and insulation. Ceramic material may be used to provide better insulation, particularly in rotary (wafer) switches.

The current carrying capacity of the switch depends on the contact material and size and on the pressure between the contacts. It is primarily determined from the

Fig 4.10 — This photo shows examples of various styles of switches. The ¼-inch-ruled graph paper background provides for size comparison.

allowable contact temperature rise. On larger ac switches, or most dc switches, the interrupt capability may be lower than the current carrying value.

Rotary/wafer switches can provide very complex switching patterns. Several poles (separate circuits) can be included on each wafer. Many wafers may be stacked on the same shaft. Not only may many different circuits be controlled at once, but by wiring different poles/positions on different wafers together, a high degree of circuit switching logic can be developed. Such switches can select different paths as they are turned and can also “short” together successive contacts to connect numbers of components or paths. They can also be designed to either break one contact before making another, or to short two contacts together before disconnecting the first one (make before break) to eliminate arcing or perform certain logic functions.

In choosing a switch for a particular task, consideration should be given to function, voltage and current ratings, ease of use, availability and cost. If a switch is to be operated frequently, a slightly higher cost for a better-quality switch is usually less costly over the long run. If signal noise or contact corrosion is a potential problem, (usually in low-current signal applications) it is best to get gold plated contacts. Gold does not oxidize or corrode, thus providing surer contact, which can be particularly important at very low signal levels. Gold plating will not hold up under high-current-interrupt applications, however.

FUSES

Fuses self-destruct to protect circuit wiring or equipment. The fuse element that melts is a carefully shaped piece of soft metal, usually mounted in a cartridge of some kind. The element is designed to safely carry a given amount of current and to melt at a current value that is a certain

percentage over the rated value. The melting value depends on the type of material, the shape of the element and the heat dissipation capability of the cartridge and holder, among other factors. Some fuses (Slo-blo) are designed to carry an overload for a short period of time. They typically are used in motor starting and power-supply circuits that have a large inrush current when first started. Other fuses are designed to blow very quickly to protect delicate instruments and solid-state circuits. A replacement fuse should have the same current rating and the same characteristics as the fuse it replaces. **Fig 4.11** shows a variety of fuse types and sizes.

The most important fuse rating is the nominal current rating that it will safely carry. Next most important are the timing characteristics, or how quickly it opens under a given current overload. A fuse also has a voltage rating, both a value in volts and whether it is expected to be used in ac or dc circuits. While you should never substitute a fuse with a higher current rating than the one it replaces, you can use a fuse with a higher voltage rating. There is no danger in replacing a 12-V, 2-A fuse with a 250-V, 2-A unit.

Fuses fail for several reasons. The most obvious reason is that a problem develops in the circuit, which causes too much current to flow. In this case, the circuit problem needs to be fixed. A fuse may just fail eventually, particularly when cycled on and off near its current rating. A kind of metal fatigue sets in, and eventually the fuse goes. A fuse can also blow because of a momentary power surge, or even turning something on and off several times quickly when there is a large inrush current. In these cases it is only necessary to replace the fuse with the same type and value. Never substitute a fuse with a larger current rating. You may cause permanent

Fig 4.11 — These photos show examples of various styles of fuses. The ¼-inch-ruled graph paper background provides a size comparison.

damage (maybe even a fire) to the wiring or circuit elements if/when there is an internal problem in the equipment.

RELAYS

Relays are switches that are driven by an electrical signal, usually through a magnetic coil. An armature that moves when current is applied pushes the switch contacts together, or pulls them apart. Many such contacts can be connected to the same armature, allowing many circuits to be controlled by a single signal. Usually, relays have only two positions (opening some contacts and closing others) although there are special cases.

Like switches, relays have specific voltage and current ratings for the contacts. These may be far different from the voltage and current of the coil that drives the relay. That means a small signal voltage might control very large values of voltage and/or current. Relay contacts (and housings) may be designed for ac, dc or RF signals. The control voltages are usually 12 V dc or 125 V ac for most amateur

(A)

(B)

(C)

Fig 4.12 — These photos show examples of various styles and sizes of relays. Photo A shows a large reed relay, and a small reed relay in a package the size of a DIP IC. The contacts and coil can clearly be seen in the open-frame relay. Photo B shows a relay inside a plastic case. Photo C shows a four-position relay with SMA coaxial connectors. The ¼-inch-ruled graph paper background provides a size comparison.

applications, but the coils may be designed to be “current sensing” and operate when the current through the coil exceeds a specific value. Fig 4.12 shows some typical relays found in amateur equipment. Relays with 24- and 28-V coils are also common.

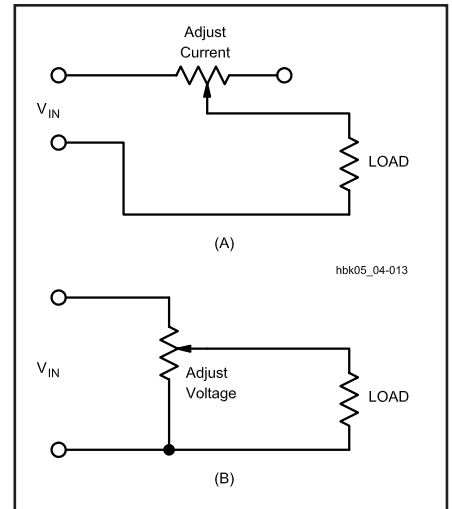

Fig 4.13 — Various uses of potentiometers.

Coaxial relays are specially designed to handle RF signals and to maintain a characteristic impedance to match certain values of coaxial-cable impedance. They typically are used to switch an antenna between a receiver and transmitter or between a linear amplifier and a transceiver.

POTENTIOMETERS

Potentiometer is a big name for a variable resistor. They are commonly used as volume controls on radios, televisions and stereos. A typical potentiometer is a circular pattern of resistive material, usually a carbon compound, that has a wiper on a shaft moving across the material. For higher power applications, the resistive material may be wire, wound around a core. As the wiper moves along the material, more resistance is introduced between the wiper and one of the fixed contacts on the material. A potentiometer may be used primarily to control current, voltage or resistance in a circuit. Fig 4.13 shows several circuits to demonstrate various uses. Fig 4.14 shows several different types of potentiometers.

Typical specifications for a potentiometer include maximum resistance, power dissipation, voltage and current ratings, number of turns (or degrees) the shaft can rotate, type and size of shaft, mounting arrangements and resistance “taper.”

Not all potentiometers have a *linear* taper. That is, the resistance may not be the same for a given number of degrees of shaft rotation along different portions of the resistive material. A typical use of a potentiometer with a nonlinear taper is as

Fig 4.14 — This photo shows examples of different styles of potentiometers. The $\frac{1}{4}$ -inch-ruled graph paper background provides a size comparison.

a volume control. Since the human ear has a logarithmic response to sound, a volume control may actually change the volume (resistance) much more near one end of the potentiometer than the other (for a given amount of rotation) so that the “perceived” change in volume is about the same for a similar change in the control. This is commonly called an “audio taper” as the change in resistance per degree of rotation attempts to match the response of the human ear. The taper can be designed to match almost any desired control function for a given application. Linear and audio tapers are the most common.

AC Theory and Reactance Glossary

Admittance (Y) — The reciprocal of impedance, measured in siemens (S).

Capacitance (C) — The ability to store electrical energy in an electrostatic field, measured in farads (F). A device with capacitance is a capacitor.

Conductance (G) — The reciprocal of resistance, measured in siemens (S).

Current (I) — The rate of electron flow through a conductor, measured in amperes (A).

Flux density (B) — The number of magnetic-force lines per unit area, measured in gauss.

Frequency (f) — The rate of change of an ac voltage or current, measured in cycles per second, or hertz (Hz).

Impedance (Z) — The complex combination of resistance and reactance, measured in ohms (Ω).

Inductance (L) — The ability to store electrical energy in a magnetic field, measured in henrys (H). A device, such as a coil, with inductance is an inductor.

Peak (voltage or current) — The maximum value relative to zero that an ac voltage or current attains during any cycle.

Peak-to-peak (voltage or current) — The value of the total swing of an ac voltage or current from its peak negative value to its peak positive value, ordinarily twice

the value of the peak voltage or current.

Period (T) — The duration of one ac voltage or current cycle, measured in seconds (s).

Permeability (μ) — The ratio of the magnetic flux density of an iron, ferrite, or similar core in an electromagnet compared to the magnetic flux density of an air core, when the current through the electromagnet is held constant.

Power (P) — The rate of electrical-energy use, measured in watts (W).

Q (quality factor) — The ratio of energy stored in a reactive component (capacitor or inductor) to the energy dissipated, equal to the reactance divided by the resistance.

Reactance (X) — Opposition to alternating current by storage in an electrical field (by a capacitor) or in a magnetic field (by an inductor), measured in ohms (Ω).

Resistance (R) — Opposition to current by conversion into other forms of energy, such as heat, measured in ohms (Ω).

Resonance — Ordinarily, the condition in an ac circuit containing both capacitive and inductive reactance in which the reactances are equal.

RMS (voltage or current) — Literally, “root mean square,” the square root of the

average of the squares of the instantaneous values for one cycle of a waveform. A dc voltage or current that will produce the same heating effect as the waveform. For a sine wave, the RMS value is equal to 0.707 times the peak value of ac voltage or current.

Susceptance (B) — The reciprocal of reactance, measured in siemens (S).

Time constant (τ) — The time required for the voltage in an RC circuit or the current in an RL circuit to rise from zero to approximately 63.2% of its maximum value or to fall from its maximum value 63.2% toward zero.

Toroid — Literally, any donut-shaped solid; most commonly referring to ferrite or powdered-iron cores supporting inductors and transformers.

Transducer — Any device that converts one form of energy to another; for example an antenna, which converts electrical energy to electromagnetic energy or a speaker, which converts electrical energy to sonic energy.

Transformer — A device consisting of at least two coupled inductors capable of transferring energy through mutual inductance.

Voltage (E) — Electromotive force or electrical pressure, measured in volts (V).

AC Theory and Reactive Components

AC IN CIRCUITS

A circuit is a complete conductive route for electrons to follow from a source, through a load and back to the source. If the source permits the electrons to flow in only one direction, the current is *dc* or *direct current*. If the source permits the current periodically to change direction, the current is *ac* or *alternating current*. **Fig 4.15** illustrates the two types of circuits. Drawing A shows the source as a battery, a typical dc source. Drawing B shows a more abstract source symbol to indicate ac. In an ac circuit, not only does the current change direction periodically; the voltage also periodically reverses. The rate of reversal may range from a few times per second to many billions per second.

Graphs of current or voltage, such as Fig 4.15, begin with a horizontal axis that represents time. The vertical axis represents the amplitude of the current or the voltage, whichever is graphed. Distance above the zero line means a greater positive amplitude; distance below the zero line means a greater negative amplitude. Positive and negative simply designate the opposing directions in which current may flow in an

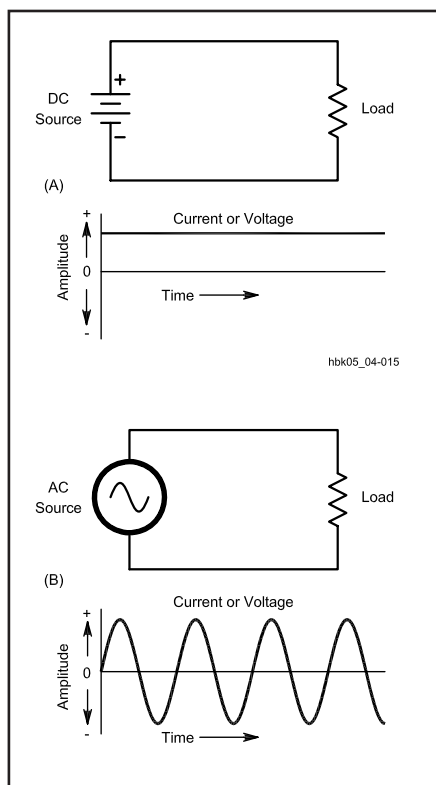

Fig 4.15 — Basic circuits for direct and alternating currents. With each circuit is a graph of the current, constant for the dc circuit, but periodically changing direction in the ac circuit.

alternating current circuit or the opposing directions of force of an ac voltage.

If the current and voltage never change direction, then from one perspective, we have a dc circuit, even if the level of dc constantly changes. **Fig 4.16** shows a current that is always positive with respect to 0. It varies periodically in amplitude, however. Whatever the shape of the variations, the current can be called *pulsating dc*. If the current periodically reaches 0, it can be called *intermittent dc*. From another perspective, we may look at intermittent and pulsating dc as a combination of an ac and a dc current. Special circuits can separate the two currents into ac and dc com-

Fig 4.16 — A pulsating dc current (A) and its resolution into an ac component (B) and a dc component (C).

Fig 4.17 — Two ac waveforms of similar frequencies ($f_1 = 1.5 f_2$) and amplitudes form a composite wave. Note the points where the positive peaks of the two waves combine to create high composite peaks: this is the phenomenon of beats. The beat note frequency is $1.5f - f = 0.5f$ and is visible in the drawing.

ponents for separate analysis or use. There are also circuits that combine ac and dc currents and voltages for many purposes.

We can combine ac and dc voltages and currents. Different ac voltages and currents also form combinations. Such combinations will result in complex waveforms. A *waveform* is the pattern of amplitudes reached by the voltage or current as measured over time. **Fig 4.17** shows two ac waveforms fairly close in frequency, and their resultant combination. **Fig 4.18** shows two ac waveforms dissimilar in both frequency and wavelength, along with the resultant combined waveform. Note the similarities (and the differences) between the resultant waveform in Fig 4.18 and the combined ac-dc waveform in Fig 4.16.

Alternating currents may take on many useful wave shapes. **Fig 4.19** shows a few that are commonly used in practical circuits and in test equipment. The square

Fig 4.18 — Two ac waveforms of widely different frequencies and amplitudes form a composite wave in which one wave appears to ride upon the other.

Fig 4.19 — Some common ac waveforms: square, triangle, ramp and sine.

wave is vital to digital electronics. The triangular and ramp waves — sometimes called “sawtooth” waves — are especially useful in timing circuits. The sine wave is both mathematically and practically the foundation of all other forms of ac; the other forms can usually be reduced to (and even constructed from) a particular collection of sine waves.

There are numerous ways to generate alternating currents: with an ac power generator (an *alternator*), with a transducer (for example, a microphone) or with an electronic circuit (for example, an RF oscillator). The basis of the sine wave is circular motion, which underlies the most usual methods of generating alternating current. The circular motion of the ac generator may be physical or mechanical, as in an alternator. Currents in the resonant circuit of an oscillator may also produce sine waves without mechanical motion.

Fig 4.20 demonstrates the relationship of the current (and voltage) amplitude to relative positions of a circular rotation through one complete revolution of 360°. Note that the current is zero at point 1. It rises to its maximum value at a point 90° from point 1, which is point 3. At a point 180° from point 1, which is point 4, the current level falls back to zero. Then the current begins to rise again. The direction of the current after point 4 and prior to its return to point 1, however, is opposite the direction of current from point 1 to point 4. Point 2 illustrates one of the innumerable intermediate values of current throughout the cycle.

Tracing the rise and fall of current over a linear time line produces the curve accompanying the circle in Fig 4.20. The curve is *sinusoidal* or a *sine wave*. The amplitude of the current varies as the sine of the angle made by the circular movement with respect to the zero point. The sine of 90° is 1, and 90° is also the point of maximum current (along with 270°). The sine of 45° (point 2) is 0.707, and the value of current at the 45° point of rotation is

Fig 4.20 — The relationship of circular motion and the resultant graph of ac current or voltage. The curve is sinusoidal, a sine wave.

0.707 times the maximum current. Similar considerations apply to the variation of ac voltage over time.

FREQUENCY AND PERIOD

With a continuously rotating generator, alternating current will pass through many equal cycles over time. Select an arbitrary point on any one cycle and use it as a marker. For this example, the positive peak will work as an unambiguous marker. The number of times per second that the current (or voltage) reaches this positive peak in any one second is called the *frequency* of the ac. In other words, frequency expresses the *rate* at which current (or voltage) cycles occur. The unit of frequency is *cycles per second*, or *hertz*—abbreviated Hz (after the 19th century radio-phenomena pioneer, Heinrich Hertz).

The length of any cycle in units of time is the *period* of the cycle, as measured from and to equivalent points on succeeding cycles. Mathematically, the period is simply the inverse of the frequency. That is,

$$\text{Frequency (f) in Hz} = \frac{1}{\text{Period (T) in seconds}} \quad (23)$$

and

$$\text{Period (T) in seconds} = \frac{1}{\text{Frequency (f) in Hz}} \quad (24)$$

Example: What is the period of a 400-hertz ac current?

$$T = \frac{1}{f} = \frac{1}{400 \text{ Hz}} = 0.00250 \text{ s} = 2.5 \text{ ms}$$

The frequency of alternating currents used in Amateur Radio circuits varies from a few hertz, or cycles per second, to thousands of millions of hertz. Likewise, the period of alternating currents amateurs use ranges from significant fractions of a second down to nanoseconds or smaller. In order to express units of frequency, time and almost everything else in electronics compactly, a standard system of prefixes is used. In magnitudes of 1000 or 10³, frequency is measurable in hertz, in kilohertz (1000 hertz or kHz), in megahertz (1 million hertz or MHz), gigahertz (1 billion hertz or GHz) and even in tera-hertz (1 trillion hertz or THz). For units smaller than one, as in the measurement of period, the basic unit seconds can become milliseconds (1 thousandth of a second or ms), microseconds (1 millionth of a second or μs), nanoseconds (1 billionth of a second or ns) and picoseconds (1 trillionth of a second or ps).

The uses of ac in Amateur Radio cir-

cuits are many and varied. Most can be cataloged by reference to ac frequency ranges used in circuits. For example, ac power used in the home, office and factory is ordinarily 60 Hz in the United States and Canada. In Great Britain and much of Europe, ac power is 50 Hz. For special purposes, ac power has been generated up to about 400 Hz.

Sonic and ultrasonic applications of ac run from about 20 Hz up to several MHz. Audio work makes use of the lower end of the sonic spectrum, with communications audio focusing on the range from about 300 to 3000 Hz. High-fidelity audio uses ac circuits capable of handling 20 Hz to at least 20 kHz. Ultrasonics — used in medicine and industry — makes use of ac circuits above 20 kHz.

Amateur Radio circuits include both power- and sonic-frequency-range circuits. Radio communication and other electronics work, however, require ac circuits capable of operation with frequencies up to the gigahertz range. Some of the applications include signal sources for transmitters (and for circuits inside receivers); industrial induction heating; diathermy; microwaves for cooking, radar and communication; remote control of appliances, lighting, model planes and boats and other equipment; and radio direction finding and guidance.

AC IN CIRCUITS AND TRANSDUCED ENERGY

Alternating currents are often loosely classified as audio frequency (AF) and radio frequency (RF). Although these designations are handy, they actually represent something other than the electrical energy of ac circuits: They designate special forms of energy that we find useful.

Audio or *sonic* energy is the energy imparted by the mechanical movement of a medium, which can be air, metal, water or even the human body. Sound that humans can hear normally requires the movement of air between 20 Hz and 20 kHz, although the human ear loses its ability to detect the extremes of this range as we age. Some animals, such as elephants, can apparently detect air vibrations well below 20 Hz, while others, such as dogs and cats, can detect air vibrations well above 20 kHz.

Electrical circuits do not directly produce air vibrations. Sound production requires a *transducer*, a device to transform one form of energy into another form of energy; in this case electrical energy into sonic energy. The speaker and the microphone are the most common audio transducers. There are numerous ultrasonic transducers for various applications.

Likewise, converting electrical energy

into radio signals also requires a transducer, usually called an *antenna*. In contrast to RF alternating currents in circuits, RF *energy* is a form of electromagnetic energy. The frequencies of electromagnetic energy run from 3 kHz to above 10^{12} GHz. They include radio, infrared, visible light, ultraviolet and a number of energy forms of greatest interest to physicists and astronomers. **Table 4.2** provides a brief glimpse at the total spectrum of electromagnetic energy.

All electromagnetic energy has one thing in common: it travels, or *propagates*, at the speed of light. This speed is approximately 300000000 (or 3.00×10^8) meters per second in a vacuum. Electromagnetic-energy waves have a length uniquely associated with each possible frequency. The wavelength (λ) is simply the speed of propagation divided by the frequency (f) in hertz.

$$f(\text{Hz}) = \frac{3.00 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{\lambda(\text{m})} \quad (25)$$

and

$$\lambda(\text{m}) = \frac{3.00 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{f(\text{Hz})} \quad (26)$$

Example: What is the frequency of an 80.0-m RF wave?

$$f(\text{Hz}) = \frac{3.00 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{\lambda(\text{m})}$$

$$= \frac{3.00 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{80.0 \text{ m}}$$

$$f(\text{Hz}) = 3.75 \times 10^6 \text{ Hz}$$

We could use a similar equation to calculate the wavelength of a sound wave in air, but we would have to use the speed of sound instead of the speed of light in the numerator of the equation. The speed of propagation of the mechanical movement of air that we call sound varies considerably with air temperature and altitude. The speed of sound at sea level is about 331 m/s at 0°C and 344 m/s at 20°C.

To calculate the frequency of an electromagnetic wave directly in kilohertz, change the speed constant to 300,000 (3.00×10^5) km/s.

$$f(\text{kHz}) = \frac{3.00 \times 10^5 \left(\frac{\text{km}}{\text{s}} \right)}{\lambda(\text{m})} \quad (27)$$

and

$$\lambda(\text{m}) = \frac{3.00 \times 10^5 \left(\frac{\text{km}}{\text{s}} \right)}{f(\text{kHz})} \quad (28)$$

For frequencies in megahertz, use:

$$f(\text{MHz}) = \frac{300 \left(\frac{\text{Mm}}{\text{s}} \right)}{\lambda(\text{m})} \quad (29)$$

and

$$\lambda(\text{m}) = \frac{300 \left(\frac{\text{Mm}}{\text{s}} \right)}{f(\text{MHz})} \quad (30)$$

You would normally just drop the units that go with the speed of light constant to make the equation look simpler.

Example: What is the wavelength of an RF wave whose frequency is 4.0 MHz?

$$\lambda(\text{m}) = \frac{300}{f(\text{MHz})} = \frac{300}{4.0 \text{ MHz}} = 75 \text{ m}$$

At higher frequencies, circuit elements act like transducers. This property can be put to use, but it can also cause problems for some circuit operations. Therefore, wavelength calculations are of some importance in designing ac circuits for those frequencies.

Within the part of the electromagnetic-

energy spectrum of most interest to radio applications, frequencies have been classified into groups and given names. **Table 4.3** provides a reference list of these classifications. To a significant degree, the frequencies within each group exhibit similar properties. For example, HF or high frequencies, from 3 to 30 MHz, all exhibit *skip* or ionospheric refraction that permits regular long-range radio communications. This property also applies occasionally both to MF (medium frequencies) and to VHF (very high frequencies).

Despite the close relationship between RF electromagnetic energy and RF ac circuits, it remains important to distinguish the two. To the ac circuit producing or amplifying a 15-kHz alternating current, the ultimate transformation and use of the electrical energy may make no difference to the circuit's operation. By choosing the right transducer, one can produce either an audio tone or a radio signal — or both. Such was the accidental fate of many horizontal oscillators and amplifiers in early television sets; they found ways to vibrate parts audibly and to radiate electromagnetic energy.

PHASE

When tracing a sine-wave curve of an ac voltage or current, the horizontal axis represents time. We call this the *time domain* of the sine wave. Events to the right take place later; events to the left occur earlier. Although time is measurable in parts of a second, it is more convenient

Table 4.2
Key Regions of the Electromagnetic Energy Spectrum

Region Name	Frequency Range
Radio frequencies	3.0×10^3 Hz to 3.0×10^{11} Hz
Infrared	3.0×10^{11} Hz to 4.3×10^{14} Hz
Visible light	4.3×10^{14} Hz to 7.5×10^{14} Hz
Ultraviolet	7.5×10^{14} Hz to 6.0×10^{16} Hz
X-rays	6.0×10^{16} Hz to 3.0×10^{19} Hz
Gamma rays	3.0×10^{19} Hz to 5.0×10^{20} Hz
Cosmic rays	5.0×10^{20} Hz to 8.0×10^{21} Hz

Table 4.3
Classification of the Radio Frequency Spectrum

Abbreviation	Classification	Frequency Range
VLF	Very low frequencies	3 to 30 kHz
LF	Low frequencies	30 to 300 kHz
MF	Medium frequencies	300 to 3000 kHz
HF	High frequencies	3 to 30 MHz
VHF	Very high frequencies	30 to 300 MHz
UHF	Ultrahigh frequencies	300 to 3000 MHz
SHF	Superhigh frequencies	3 to 30 GHz
EHF	Extremely high frequencies	30 to 300 GHz

Fig 4.21 — An ac cycle is divided into 360° that are used as a measure of time or phase.

Fig 4.22 — When two waves of the same frequency start their cycles at slightly different times, the time difference or phase difference is measured in degrees. In this drawing, wave B starts 45° (one-eighth cycle) later than wave A, and so lags 45° behind A.

Fig 4.23 — Two important special cases of phase difference: In the upper drawing, the phase difference between A and B is 90°; in the lower drawing, the phase difference is 180°.

to treat each cycle as a complete time unit that we divide into 360°. The conventional starting point for counting degrees is the zero point as the voltage or current begins the positive half cycle. The essential elements of an ac cycle appear in **Fig 4.21**.

The advantage of treating the ac cycle in this way is that many calculations and measurements can be taken and recorded in a manner that is independent of frequency. The positive peak voltage or current occurs at 90° along the cycle. Relative to the starting point, 90° is the *phase* of the ac at that point. Thus, a complete description of an ac voltage or current involves reference to three properties: frequency, amplitude and phase.

Phase relationships also permit the comparison of two ac voltages or currents at the same frequency, as **Fig 4.22** demonstrates. Since B crosses the zero point in the positive direction after A has already done so, there is a *phase difference* between the two waves. In the example, B lags A by 45°, or A leads B by 45°. If A and B occur in the same circuit, their composite waveform will also be a sine wave at an intermediate phase angle relative to each. Adding any number of sine waves of the same frequency always results in a sine wave at that frequency.

Fig 4.22 might equally apply to a voltage and a current measured in the same ac circuit. Either A or B might represent the voltage; that is, in some instances voltage will lead the current and in others voltage will lag the current.

Two important special cases appear in **Fig 4.23**. In Part A, line B lags 90° behind line A. Its cycle begins exactly one quarter cycle later than the A cycle. When one wave is passing through zero, the other

just reaches its maximum value.

In Part B, lines A and B are 180° *out of phase*. In this case, it does not matter which one is considered to lead or lag. Line B is always positive while line A is negative, and vice versa. If the two waveforms are of two voltages or two currents in the same circuit and if they have the same amplitude, they will cancel each other completely.

MEASURING AC VOLTAGE, CURRENT AND POWER

Measuring the voltage or current in a dc circuit is straightforward, as **Fig 4.24A** demonstrates. Since the current flows in only one direction, for a resistive load, the voltage and current have constant values until the circuit components change.

Fig 4.24B illustrates a perplexing problem encountered when measuring voltages and currents in ac circuits. The current and voltage continuously change direction and value. Which values are meaningful? In fact, several values of constant sine-wave voltage and current in ac circuits are important to differing applications and concerns.

Instantaneous Voltage and Current

Fig 4.25 shows a sine wave of some arbitrary frequency and amplitude with respect to either voltage or current. The instantaneous voltage (or current) at point A on the curve is a function of three factors: the maximum value of voltage (or current) along the curve (point B), the frequency of the wave, and the time elapsed in seconds or fractions of a second. Thus,

$$E_{inst} = E_{max} \sin (2\pi ft) \theta \quad (31)$$

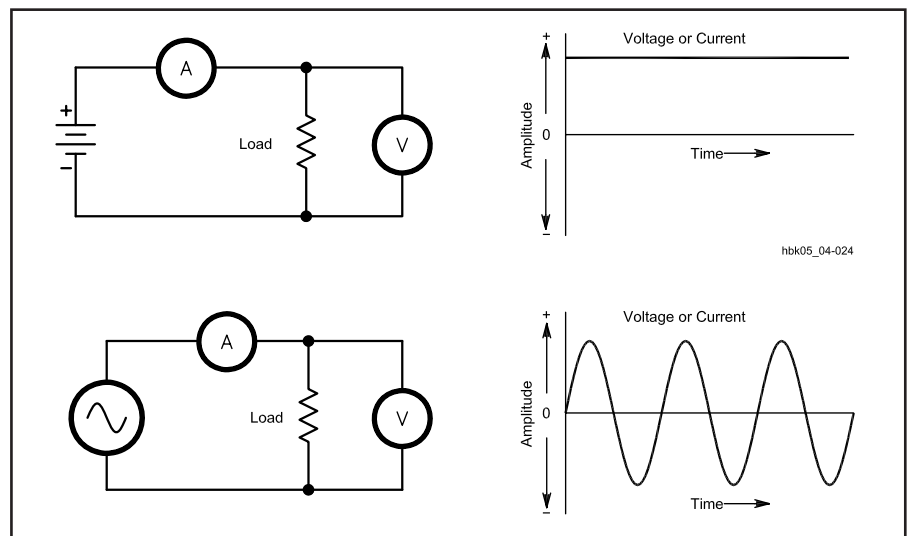

Fig 4.24 — Voltage and current measurements in dc and ac circuits.

Fig 4.25 — Two cycles of a sine wave to illustrate instantaneous, peak, and peak-to-peak ac voltage and current values.

Considering just one sine wave, independent of frequency, the instantaneous value of voltage (or current) becomes

$$E_{inst} = E_{max} \sin \theta \quad (32)$$

where θ is the angle in degrees through which the voltage has moved over time after the beginning of the cycle.

Example: What is the instantaneous value of voltage at point D in Fig 4.25, if the maximum voltage value is 120 V and the angular travel is 60.0° ?

$$\begin{aligned} E_{inst} &= 120 \text{ V} \times \sin 60.0^\circ \\ &= 120 \times 0.866 = 104 \text{ V} \end{aligned}$$

Peak and Peak-to-Peak Voltage and Current

The most important instantaneous voltages and currents are the maximum or peak values reached on each positive and negative half cycle of the sine wave. In Fig 4.25, points B and C represent the positive and negative peaks of voltage or current. Peak (pk) values are especially important with respect to component ratings, which the voltage or current in a circuit must not exceed without danger of component failure.

The peak power in an ac circuit is simply the product of the peak voltage and the peak current, or

$$P_{pk} = E_{pk} \times I_{pk} \quad (33)$$

The span from points B to C in Fig 4.25 represents the largest voltage or current swing of the sine wave. Designated the *peak-to-peak* (P-P) voltage (or current), this span is equal to twice the peak value of the voltage (or current). Thus,

$$E_{P-P} = 2E_{pk} \quad (34)$$

Amplifying devices often specify their input limits in terms of peak-to-peak voltages. Operational amplifiers, which have almost unlimited gain potential, often require input-level limiting to prevent the output signals from distorting if they exceed the peak-to-peak output rating of the devices.

RMS Voltages and Currents

The *root mean square* or *RMS* values of voltage and current are the most common values encountered in electronics. Sometimes called the *effective* values of ac voltage and current, they are based upon equating the values of ac and dc power required to heat a resistive element to exactly the same temperature. The peak ac power required for this condition is twice the dc power needed. Therefore, the aver-

age ac power equivalent to a corresponding average dc power is half the peak ac power.

$$P_{ave} = \frac{P_{pk}}{2} \quad (35)$$

Since a circuit with a constant resistance is linear — that is, raising or lowering the voltage will raise or lower the current proportionally — the voltage and current values needed to arrive at average ac power are related to their peak values by the factor.

$$E_{RMS} = \frac{E_{pk}}{\sqrt{2}} = \frac{E_{pk}}{1.414} = E_{pk} \times 0.707 \quad (36)$$

$$I_{RMS} = \frac{I_{pk}}{\sqrt{2}} = \frac{I_{pk}}{1.414} = I_{pk} \times 0.707 \quad (37)$$

In the time domain of a sine wave, the RMS values of voltage and current occur at the 45° , 135° , 225° and 315° points along the cycle shown in Fig 4.26. (The sine of 45° is approximately 0.707.) The absolute instantaneous value of voltage or current is greater than the RMS value for half the cycle and less than the RMS value for half the cycle.

The RMS values of voltage and current get their name from the means used to derive their value relative to peak voltage and current. Square the individual values of all the instantaneous values of voltage or current in a single cycle of ac. Take the average of these squares and then find the square root of the average. This *root mean square* procedure produces the RMS value of voltage or current.

If the RMS voltage is the peak voltage divided by the $\sqrt{2}$, then the peak voltage must be the RMS voltage multiplied by

Fig 4.26 — The relationships between RMS, average, peak, and peak-to-peak values of ac voltage and current.

Table 4.4**Conversion Factors for AC Voltage or Current**

From	To	Multiply By
Peak	Peak-to-Peak	2
Peak-to-Peak	Peak	0.5
Peak	RMS	$1 / \sqrt{2}$ or 0.707
RMS	Peak	$\sqrt{2}$ or 1.414
Peak-to-Peak	RMS	$1 / (2 \times \sqrt{2})$ or 0.35355
RMS	Peak-to-Peak	$2 \times \sqrt{2}$ or 2.828
Peak	Average	$2 / \pi$ or 0.6366
Average	Peak	$\pi / 2$ or 1.5708
RMS	Average	$(2 \times \sqrt{2}) / \pi$ or 0.90
Average	RMS	$\pi / (2 \times \sqrt{2})$ or 1.11

Note: These conversion factors apply only to continuous pure sine waves.

the $\sqrt{2}$, or

$$E_{pk} = E_{RMS} \times 1.414$$

$$I_{pk} = I_{RMS} \times 1.414$$

Since circuit specifications will most commonly list only RMS voltage and current values, these relationships are important in finding the peak voltages or currents that will stress components.

Example: What is the peak voltage on a capacitor if the RMS voltage of a sinusoidal waveform signal across it is 300 V ac?

$$E_{pk} = 300 \text{ V} \times 1.414 = 424 \text{ V}$$

The capacitor must be able to withstand this higher voltage, plus a safety margin. The capacitor must also be rated for ac use. A capacitor rated for 1 kV dc may explode if used in this application. In power supplies that convert ac to dc and use capacitive input filters, the output voltage will approach the peak value of the ac voltage rather than the RMS value.

Example: What is the peak voltage and the peak-to-peak voltage at the usual household ac outlet, if the RMS voltage is 120 V?

$$E_{pk} = 120 \text{ V} \times 1.414 = 170 \text{ V}$$

$$(38) \quad E_{p-p} = 2 \times 170 \text{ V} = 340 \text{ V}$$

Unless otherwise specified, unlabeled ac voltage and current values found in most electronics literature are normally RMS values.

Average Values of Voltage and Current

Certain kinds of circuits respond to the *average* value of an ac waveform. Among these circuits are electrodynamic meter movements and power supplies that convert ac to dc and use heavily inductive (“choke”) input filters, both of which use the pulsating dc output of a full-wave rectifier. The average value of each ac half cycle is the *mean* of all the instantaneous values in that half cycle. Related to the peak values of voltage and current, average values are $2 / \pi$ (or 0.6366) times the peak value.

$$E_{ave} = 0.6366 E_{pk} \quad (40)$$

$$I_{ave} = 0.6366 I_{pk} \quad (41)$$

For convenience, **Table 4.4** summarizes the relationships between all of the common ac values. All of these relationships apply only to pure sine waves.

Fig 4.27 — The peak envelope voltage (PEV) for a composite waveform.

Complex Waves and Peak-Envelope Values

Complex waves, as shown earlier in Fig 4.18, differ from pure sine waves. The amplitude of the peak voltage may vary significantly from one cycle to the next. Therefore, other amplitude measures are required, especially for accurate measurement of voltage and power with single sideband (SSB) waveforms. **Fig 4.27** illustrates a multitone composite waveform with an RF ac waveform as the basis.

The RF ac waveform has a frequency many times that of the audio-frequency ac waveform with which it is usually combined in SSB operations. Therefore, the resultant waveform appears as an amplitude envelope superimposed upon the RF waveform. The *peak envelope voltage* (PEV), then, is the maximum or peak value of voltage achieved.

Peak envelope voltage permits the calculation of *peak envelope power* (PEP). The Federal Communications Commission (FCC) uses the concept of peak envelope power to set the maximum power standards for amateur transmitters. PEP is the *average* power supplied to the antenna transmission line by a transmitter during one RF cycle at the crest of the modulation envelope, taken under normal operating conditions. Since calculation of PEP requires the average power of the cycle, multiply the PEV by 0.707 to obtain the RMS value. Then calculate power by using the square of the voltage divided by the load resistance.

$$PEP = \frac{(PEV \times 0.707)^2}{R} \quad (42)$$

Capacitance and Capacitors

Without the ability to store electrical energy, radio would not be possible. One may build and hold an electrical charge in an *electrostatic field*. This phenomenon is called *capacitance*, and the devices that exhibit capacitance are called *capacitors*. See Chapter 6 for more information on practical capacitor applications and problems. **Fig 4.28** shows several schematic symbols for capacitors. Part A shows a fixed capacitor; one that has a single value of capacitance. Part B shows variable capacitors; these are adjustable over a range of values. Ordinarily, the straight line in each symbol connects to a positive voltage, while the curved line goes to a negative voltage or to ground. Some capacitor designs require rigorous adherence to polarity markings; other designs are symmetrical and non-polarized.

CHARGE AND ELECTROSTATIC ENERGY STORAGE

Suppose two flat metal plates are placed close to each other (but not touching) and are connected to a battery through a switch, as illustrated in **Fig 4.29A**. At the instant the switch is closed, electrons are attracted from the upper plate to the positive terminal of the battery, and the same number are repelled into the lower plate from the negative battery terminal. Enough electrons move into one plate and out of the other to make the voltage between the plates the same as the battery voltage.

If the switch is opened after the plates have been charged in this way, the top plate is left with a deficiency of electrons and the bottom plate with an excess. Since there is no current path between the two, the plates remain charged despite the fact that the battery no longer is connected. The charge remains due to the electrostatic field between the plates. The large number of opposite charges exert an attractive force across the small distance between plates, as illustrated in **Fig 4.29B**.

If a wire is touched between the two plates (short-circuiting them), the excess electrons on the bottom plate flow through the wire to the upper plate, restoring electrical neutrality. The plates are discharged.

These two plates represent an electrical capacitor, a device possessing the property of storing electrical energy in the electric field between its plates. During the time the electrons are moving — that is, while the capacitor is being charged or discharged — a current flows in the circuit even though the circuit apparently is broken by the gap between the capacitor

Fig 4.28 — Schematic symbol for a fixed capacitor is shown at A. The symbols for a variable capacitor are shown at B.

Fig 4.29 — A simple capacitor showing the basic charging arrangement at A, and the retention of the charge due to the electrostatic field at B.

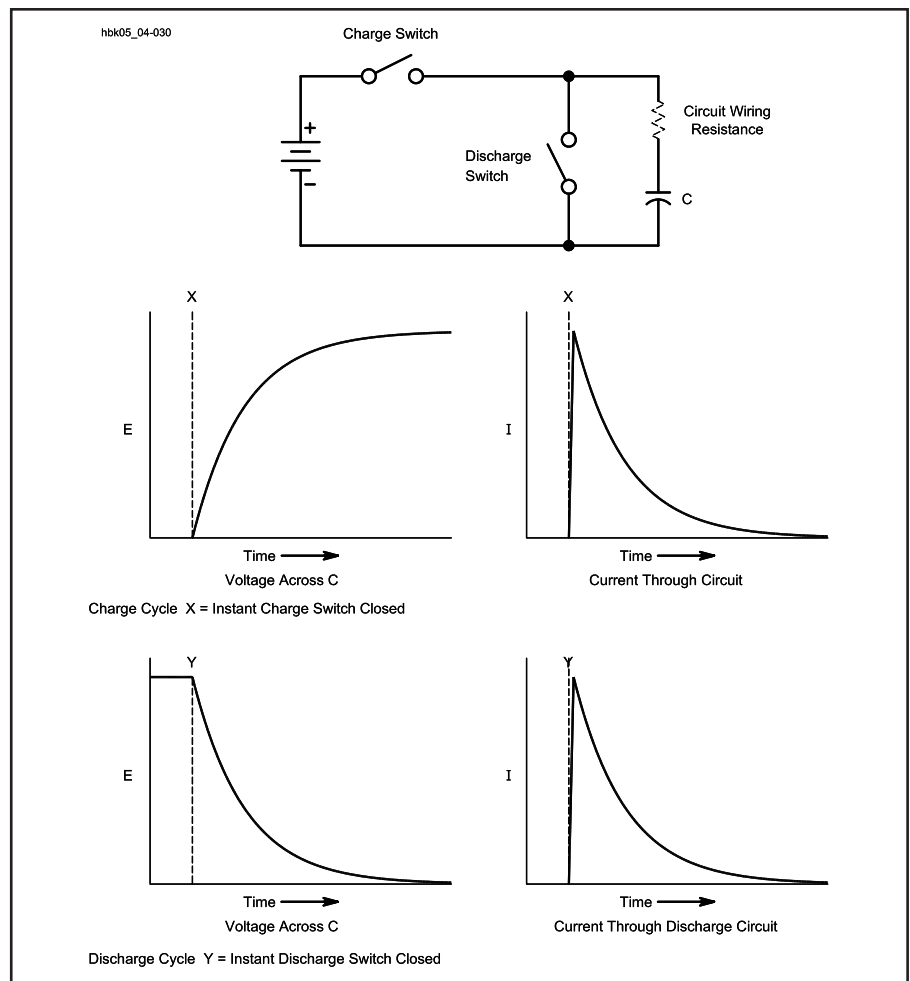

Fig 4.30 — The flow of current during the charge and discharge of a capacitor. The charge graphs assume that the charge switch is closed and the discharge switch is open. The discharge graphs assume just the opposite.

plates. The current flows only during the time of charge and discharge, however, and this time is usually very short. There can be no continuous flow of direct current through a capacitor.

Fig 4.30 demonstrates the voltage and current in the circuit, first, at the moment the switch is closed to charge the capacitor and, second, at the moment the shorting switch is closed to discharge the unit. Note that the periods of charge and discharge are very short, but that they are not zero. This finite charging and discharging time can be lengthened and will prove useful later in timing circuits.

Although dc cannot pass through a capacitor, alternating current can. As fast as one plate is charged positively by the positive excursion of the alternating current, the other plate is being charged negatively. Positive charges flowing into one plate causes a current to flow out of the other plate during one half of the cycle, resulting in a negative charge on that plate. The reverse occurs during the second half of the cycle.

The charge or quantity of electricity that can be held on the capacitor plates is proportional to the applied voltage and to the capacitance of the capacitor:

$$Q = CE \quad (43)$$

where:

- Q = charge in coulombs,
- C = capacitance in farads, and
- E = electrical potential in volts.

The energy stored in a capacitor is also a function of electrical potential and capacitance:

$$W = \frac{E^2 C}{2} \quad (44)$$

where:

- W = energy in joules (watt-seconds),
- E = electrical potential in volts (some texts use V instead of E), and
- C = capacitance in farads.

The numerator of this expression can be derived easily from the definitions for charge, capacitance, current, power and energy. The denominator is not so obvious, however. It arises because the voltage across a capacitor is not constant, but is a function of time. The average voltage over the time interval determines the energy stored. The time dependence of the capacitor voltage is a very useful property; see the section on time constants.

UNITS OF CAPACITANCE AND CAPACITOR CONSTRUCTION

A capacitor consists, fundamentally, of two plates separated by an insulator or

Table 4.5

Relative Dielectric Constants of Common Capacitor Dielectric Materials

Material	Dielectric Constant (k)	(O)rganic or (I)norganic
Vacuum	1 (by definition)	
Air	1.0006	
Ruby mica	6.5 - 8.7	
Glass (flint)	10	
Barium titanate (class I)	5 - 450	
Barium titanate (class II)	200 - 12000	
Kraft paper	≈ 2.6	O
Mineral Oil	≈ 2.23	O
Castor Oil	≈ 4.7	O
Halowax	≈ 5.2	O
Chlorinated diphenyl	≈ 5.3	O
Polyisobutylene	≈ 2.2	O
Polytetrafluoroethylene	≈ 2.1	O
Polyethylene terephthalate	≈ 3	O
Polystyrene	≈ 2.6	O
Polycarbonate	≈ 3.1	O
Aluminum oxide	≈ 8.4	
Tantalum pentoxide	≈ 28	
Niobium oxide	≈ 40	
Titanium dioxide	≈ 80	

(Adapted from: Charles A. Harper, *Handbook of Components for Electronics*, p 8-7.)

dielectric. The *larger* the plate area and the *smaller* the spacing between the plates, the *greater* the capacitance. The capacitance also depends on the kind of insulating material between the plates; it is smallest with air insulation or a vacuum. Substituting other insulating materials for air may greatly increase the capacitance.

The ratio of the capacitance with a material other than a vacuum or air between the plates to the capacitance of the same capacitor with air insulation is called the dielectric constant, or K, of that particular insulating material. The dielectric constants of a number of materials commonly used as dielectrics in capacitors are given in **Table 4.5**. For example, if a sheet of polystyrene is substituted for air between the plates of a capacitor, the capacitance will be 2.6 times greater.

The basic unit of capacitance, the ability to store electrical energy in an electrostatic field, is the farad. This unit is generally too large for practical radio work, however. Capacitance is usually measured in microfarads (abbreviated μF), nanofarads (abbreviated nF) or picofarads (pF). The microfarad is one millionth of a farad (10^{-6} F), the nanofarad is one thousandth of a microfarad (10^{-9} F) and the picofarad is one millionth of a microfarad (10^{-12} F).

In practice, capacitors often have more than two plates, the alternate plates being connected to form two sets, as shown in **Fig 4.31**. This practice makes it possible to

Fig 4.31 — A multiple-plate capacitor. Alternate plates are connected to each other.

obtain a fairly large capacitance in a small space, since several plates of smaller individual area can be stacked to form the equivalent of a single large plate of the same total area. Also, all plates except the two on the ends are exposed to plates of the other group on both sides, and so are twice as effective in increasing the capacitance.

The formula for calculating capacitance from these physical properties is:

$$C = \frac{0.2248 K A (n - 1)}{d} \quad (45)$$

where:

- C = capacitance in pF,
- K = dielectric constant of material between plates,
- A = area of one side of one plate in square inches,

d = separation of plate surfaces in inches, and
 n = number of plates.

If the area (A) is in square centimeters and the separation (d) is in centimeters, then the formula for capacitance becomes

$$C = \frac{0.0885 K A (n - 1)}{d} \quad (46)$$

If the plates in one group do not have the same area as the plates in the other, use the area of the smaller plates.

Example: What is the capacitance of 2 copper plates, each 1.50 square inches in area, separated by a distance of 0.00500 inch, if the dielectric is air?

$$C = \frac{0.2248 K A (n - 1)}{d}$$

$$C = \frac{0.2248 \times 1 \times 1.50 (2 - 1)}{0.00500}$$

$$C = 67.4 \text{ pF}$$

KINDS OF CAPACITORS AND THEIR USES

The capacitors used in radio work differ considerably in physical size, construction and capacitance. Representative kinds are shown in Fig 4.32. In variable capacitors, which are almost always constructed with air for the dielectric, one set of plates is made movable with respect to the other set so the capacitance can be varied. Fixed capacitors — those having a single, nonadjustable value of capacitance — can also be made with metal plates and with air as the dielectric.

Fixed capacitors are usually constructed from plates of metal foil with a thin solid or liquid dielectric sandwiched between, so a relatively large capacitance can be obtained in a small unit. The solid dielectrics commonly used are mica, paper and special ceramics. An example of a liquid dielectric is mineral oil. Electrolytic capacitors use aluminum-foil plates with a semiliquid conducting chemical compound between them. The actual dielectric is a very thin film of insulating material that forms on one set of plates through electrochemical action when a dc voltage is applied to the capacitor. The capacitance obtained with a given plate area in an electrolytic capacitor is very

large compared to capacitors having other dielectrics, because the film is so thin — much less than any thickness practical with a solid dielectric.

The use of electrolytic and oil-filled capacitors is confined to power-supply filtering and audio-bypass applications because their dielectrics have high losses at higher frequencies. Mica and ceramic capacitors are used throughout the frequency range from audio to several hundred megahertz.

New dielectric materials appear from time to time and represent improvements in capacitor performance. Silvered-mica capacitors, formed by spraying thin coats of silver on each side of the mica insulating sheet, improved the stability of mica capacitors in circuits sensitive to temperature changes. Polystyrene and other synthetic dielectrics, along with tantalum electrolytics, have permitted the size of capacitors to shrink per unit of capacitance.

VOLTAGE RATINGS AND BREAKDOWN

When high voltage is applied to the plates of a capacitor, considerable force is exerted on the electrons and nuclei of the dielectric. The dielectric is an insulator; its electrons do not become detached from

(A)

(B)

(C)

(D)

(E)

Fig 4.32 — Fixed-value capacitors are shown in parts A and B. Aluminum electrolytic capacitors are pictured near the center of photo A. The small tear-drop units to the left of center are tantalum electrolytic capacitors. The rectangular units are silvered-mica, polystyrene film and monolithic ceramic. At the right edge is a disc-ceramic capacitor and near the top right corner is a surface-mount capacitor. B shows a large “computer-grade” electrolytic. These have very low equivalent series resistance (ESR) and are often used as filter capacitors in switch-mode power supplies, and in series-strings for high-voltage supplies of RF power amplifiers. Parts C and D show a variety of variable capacitors, including air variable capacitors and mica compression units. Part E shows a vacuum variable capacitor such as is sometimes used in high-power amplifier circuits. The 1/4-inch-ruled graph paper backgrounds provide size comparisons.

atoms the way they do in conductors. If the force is great enough, however, the dielectric will break down. Failed dielectrics usually puncture and offer a low-resistance current path between the two plates.

The *breakdown voltage* a dielectric can withstand depends on the chemical composition and thickness of the dielectric. Breakdown voltage is not directly proportional to the thickness; doubling the thickness does not quite double the breakdown voltage. Gas dielectrics also break down, as evidenced by a spark or arc between the plates. Spark voltages are generally given with the units *kilovolts per centimeter*. For air, the spark voltage or V_s may range from more than 120 kV/cm for gaps as narrow as 0.006 cm down to 28 kV/cm for gaps as wide as 10 cm. In addition, a large number of variables enter into the actual breakdown voltage in a real situation. Among the variables are the electrode shape, the gap distance, the air pressure or density, the voltage, impurities in the air (or any other dielectric material) and the nature of the external circuit (with air, for instance, the humidity affects conduction on the surface of the capacitor plate).

Dielectric breakdown occurs at a lower voltage between pointed or sharp-edged surfaces than between rounded and polished surfaces. Consequently, the breakdown voltage between metal plates of any given spacing in air can be increased by buffing the edges of the plates. With most gas dielectrics such as air, once the voltage is removed, the arc ceases and the capacitor is ready for use again. If the plates are damaged so they are no longer smooth and polished, they may have to be polished or the capacitor replaced. In contrast, solid dielectrics are permanently damaged by dielectric breakdown, and often will totally short out and melt or explode.

A thick dielectric must be used to withstand high voltages. Since the capacitance is inversely proportional to dielectric thickness (plate spacing) for a given plate area, a high-voltage capacitor must have more plate area than a low-voltage one of the same capacitance. High-voltage, high-capacitance capacitors are therefore physically large.

Dielectric strength is specified in terms of a dielectric withstanding voltage (DWV), given in volts per mil (0.001 inch) at a specified temperature. Taking into account the design temperature range of a capacitor and a safety margin, manufacturers specify *dc working voltage* (dcwv) to express the maximum safe limits of dc voltage across a capacitor to prevent dielectric breakdown.

It is not safe to connect capacitors across an ac power line unless they are rated for such use. Capacitors with dc ratings may short the line. Several manufacturers make capacitors specifically rated for use across the ac power line.

For use with other ac signals, the peak value of ac voltage should not exceed the dc working voltage, unless otherwise specified in component ratings. In other words, the RMS value of ac should be 0.707 times the dcwv value or lower. With many types of capacitors, further derating is required as the operating frequency increases. An additional safety margin is good practice.

Any two surfaces having different electrical potentials, and which are close enough to exhibit a significant electrostatic field, constitute a capacitor. The arrangement of circuit components and leads sometimes results in the creation of unintended capacitors. This is called *stray capacitance*: It often results in the passage of signals in ways that disrupt the normal operation of a circuit. Good design minimizes stray capacitance.

Stray capacitance may have a greater affect in a high-impedance circuit because the capacitive reactance may be a greater percentage of the circuit impedance. Also, because stray capacitance often appears in parallel with the circuit, the stray capacitor may bypass more of the desired signal at higher frequencies. Stray capacitance can often adversely affect sensitive circuits.

For further information about the physical and electrical characteristics of various types of capacitors in actual use, see the **Real-World Component Characteristics** chapter.

CAPACITORS IN SERIES AND PARALLEL

When a number of capacitors are connected in parallel, as in **Fig 4.33A**, the total capacitance of the group is equal to the sum of the individual capacitances:

$$C_{\text{total}} = C_1 + C_2 + C_3 + C_4 + \dots + C_n \quad (47)$$

When two or more capacitors are connected in series, as in **Fig 4.33B**, the total capacitance is less than that of the smallest capacitor in the group. The rule for finding the capacitance of a number of series-connected capacitors is the same as that for finding the resistance of a number of parallel-connected resistors.

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots + \frac{1}{C_n}} \quad (48)$$

For only two capacitors in series, the

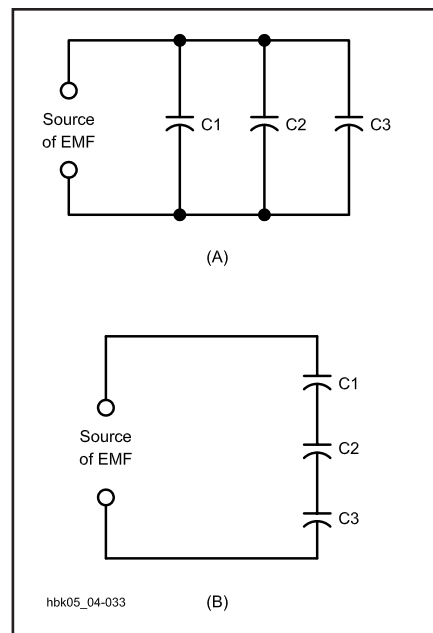

Fig 4.33 — Capacitors in parallel are shown at A, and in series at B.

formula becomes:

$$C_{\text{total}} = \frac{C_1 \times C_2}{C_1 + C_2} \quad (49)$$

The same units must be used throughout; that is, all capacitances must be expressed in either μF , nF or pF. Different units cannot be used in the same equation.

Capacitors are usually connected in parallel to obtain a larger total capacitance than is available in one unit. The largest voltage that can be applied safely to a parallel-connected group of capacitors is the voltage that can be applied safely to the one having the lowest voltage rating.

When capacitors are connected in series, the applied voltage is divided between them according to Kirchhoff's Voltage Law. The situation is much the same as when resistors are in series and there is a

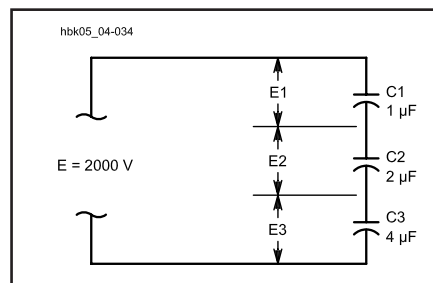

Fig 4.34 — An example of capacitors connected in series. The text shows how to find the voltage drops, E1 through E3.

voltage drop across each. The voltage that appears across each series-connected capacitor is inversely proportional to its capacitance, as compared with the capacitance of the whole group. (This assumes ideal capacitors.)

Example: Three capacitors having capacitances of 1, 2 and 4 μF , respectively, are connected in series as shown in **Fig 4.34**. The voltage across the entire series is 2000 V. What is the total capacitance? (Since this is a calculation using theoretical values to illustrate a technique, we will not follow the rules of significant figures for the calculations.)

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}}$$

$$= \frac{1}{\frac{1}{1\mu\text{F}} + \frac{1}{2\mu\text{F}} + \frac{1}{4\mu\text{F}}}$$

$$C_{\text{total}} = \frac{1}{\frac{7}{4\mu\text{F}}} = \frac{4\mu\text{F}}{7} = 0.5714\mu\text{F}$$

The voltage across each capacitor is proportional to the total capacitance divided by the capacitance of the capacitor in question. So the voltage across C1 is:

$$E_1 = \frac{0.5714\mu\text{F}}{1\mu\text{F}} \times 2000\text{ V} = 1143\text{ V}$$

Similarly, the voltages across C2 and C3 are:

$$E_2 = \frac{0.5714\mu\text{F}}{2\mu\text{F}} \times 2000\text{ V} = 571\text{ V}$$

and

$$E_3 = \frac{0.5714\mu\text{F}}{4\mu\text{F}} \times 2000\text{ V} = 286\text{ V}$$

The sum of these three voltages equals 2000 V, the applied voltage.

Capacitors may be connected in series to enable the group to withstand a larger voltage than any individual capacitor is rated to withstand. The trade-off is a decrease in the total capacitance. As shown by the previous example, the applied voltage does not divide equally between the capacitors except when all the capacitances are precisely the same. Use care to ensure that the voltage rating of any capacitor in the group is not exceeded. If you use capacitors in series to withstand a higher voltage, you should also connect an "equalizing resistor" across each capacitor. Use resistors with about 100 Ω per volt of supply voltage, and be sure they have sufficient power-handling capability for

the circuit. With real capacitors, the leakage resistance of the capacitors may have more effect on the voltage division than does the capacitance. A capacitor with a high parallel resistance will have the highest voltage across it. Adding equalizing resistors reduces this effect.

RC TIME CONSTANT

Connecting a dc voltage source directly to the terminals of a capacitor charges the capacitor to the full source voltage almost instantaneously. Any resistance added to the circuit as in **Fig 4.35A** limits the current, lengthening the time required for the voltage between the capacitor plates to build up to the source-voltage value. During this charging period, the current flowing from the source into the capacitor gradually decreases from its initial value. The increasing voltage stored in the capacitor's electric field offers increasing opposition to the steady source voltage.

While it is being charged, the voltage between the capacitor terminals is an exponential function of time, and is given by:

$$V(t) = E \left(1 - e^{-\frac{t}{RC}} \right) \quad (50)$$

where:

- V(t) = capacitor voltage in volts at time t;
- E = potential of charging source in volts;
- t = time in seconds after initiation of charging current;
- e = natural logarithmic base = 2.718;
- R = circuit resistance in ohms; and
- C = capacitance in farads.

Theoretically, the charging process is never really finished, but eventually the charging current drops to an unmeasurable value. For many purposes, it is convenient to let $t = RC$. Under this condition, the above equation becomes:

$$V(RC) = E(1 - e^{-1}) \approx 0.632 E \quad (51)$$

The product of R in ohms times C in

Fig 4.35 — An illustration of the time constant in an RC circuit.

farads is called the *time constant* of the circuit and is the time in seconds required to charge the capacitor to 63.2% of the supply voltage. (The lower-case Greek letter tau [τ] is often used to represent the time constant in electronics circuits.) After two time constants ($t = 2\tau$) the capacitor charges another 63.2% of the difference between the capacitor voltage at one time constant and the supply voltage, for a total charge of 86.5%. After three time constants the capacitor reaches 95% of the supply voltage, and so on, as illustrated in the curve of **Fig 4.36A**. After 5 RC time periods, a capacitor is considered fully charged, having reached 99.24% of the source voltage.

If a charged capacitor is discharged through a resistor, as indicated in **Fig 4.35B**, the same time constant applies for the decay of the capacitor voltage. A direct short circuit applied between the capacitor terminals would discharge the capacitor almost instantly. The resistor, R, limits the current, so the capacitor voltage decreases only as rapidly as the capacitor can discharge itself through R. A capacitor discharging through a resistance

Fig 4.36 — At A, the curve shows how the voltage across a capacitor rises, with time, when charged through a resistor. The curve at B shows the way in which the voltage decreases across a capacitor when discharging through the same resistance. For practical purposes, a capacitor may be considered charged or discharged after 5 RC periods.

exhibits the same time-constant characteristics (calculated in the same way as above) as a charging capacitor. The voltage, as a function of time while the capacitor is being discharged, is given by:

$$V(t) = E \left[e^{-\frac{t}{RC}} \right] \quad (52)$$

where t = time in seconds after initiation of discharge.

Again, by letting $t = RC$, the time constant of a discharging capacitor represents a decrease in the voltage across the capacitor of about 63.2%. After 5 time-constant periods, the capacitor is considered fully discharged, since the voltage has dropped to less than 1% of the full-charge voltage.

Time constant calculations have many uses in radio work. The following examples are all derived from practical-circuit applications.

Example 1: A 100- μF capacitor in a high-voltage power supply is shunted by a 100-k Ω resistor. What is the minimum time before the capacitor may be considered fully discharged? Since full discharge is approximately 5 RC periods,

$$\begin{aligned} t &= 5 \times RC = 5 \times 100 \times 10^3 \Omega \times 100 \times 10^{-6} \text{ F} \\ &= 50000 \times 10^{-3} \text{ seconds} \\ t &= 50.0 \text{ s} \end{aligned}$$

Note: Although waiting almost a minute for the capacitor to discharge seems safe in this high-voltage circuit, never rely solely on capacitor-discharging resistors (often called *bleeder resistors*). Be certain the power source is removed and the capacitors are totally discharged before touching any circuit components.

Example 2: Smooth CW keying without clicks requires approximately 5 ms (0.005 s) of delay in both the make and break edges of the waveform, relative to full charging and discharging of a capacitor in the circuit. What typical values might a builder choose for an RC delay circuit in a keyed voltage line? Since full charge and discharge require 5 RC periods,

$$RC = \frac{t}{5} = \frac{0.005 \text{ s}}{5} = 0.001 \text{ s}$$

Any combination of resistor and capacitor whose values, when multiplied together, equal 0.001 would do the job. A typical capacitor might be 0.05 μF . In that case, the necessary resistor would be:

$$\begin{aligned} R &= \frac{0.001 \text{ s}}{0.05 \times 10^{-6} \text{ F}} \\ &= 0.02 \times 10^6 \Omega = 20000 \Omega = 20 \text{ k}\Omega \end{aligned}$$

In practice, a builder would likely either experiment with values or use a variable resistor. The final value would be selected after monitoring the waveform on an oscilloscope.

Example 3: Many modern integrated circuit (IC) devices use RC circuits to control their timing. To match their internal circuitry, they may use a specified threshold voltage as the trigger level. For example, a certain IC uses a trigger level of 0.667 of the supply voltage. What value of capacitor and resistor would be required for a 4.5-second timing period?

First we will solve equation 50 for the time constant, RC. The threshold voltage is 0.667 times the supply voltage, so we use this value for $V(t)$.

$$\begin{aligned} V(t) &= E \left[1 - e^{-\frac{t}{RC}} \right] \\ 0.667 E &= E \left[1 - e^{-\frac{t}{RC}} \right] \\ e^{-\frac{t}{RC}} &= 1 - 0.667 \\ \ln \left[e^{-\frac{t}{RC}} \right] &= \ln(0.333) \\ -\frac{t}{RC} &= -1.10 \end{aligned}$$

We want to find a capacitor and resistor combination that will produce a 4.5 s

timing period, so we substitute that value for t .

$$RC = \frac{4.5 \text{ s}}{1.10}$$

If we select a value of 10 μF , we can solve for R.

$$R = \frac{4.1 \text{ s}}{10 \times 10^{-6} \text{ F}} = 0.41 \times 10^6 \Omega = 410 \text{ k}\Omega$$

A 1% tolerance resistor and capacitor will give good precision. You could also use a variable resistor and an accurate method to measure the time to set the circuit to a 4.5 s period.

As the examples suggest, RC circuits have numerous applications in electronics. The number of applications is growing steadily, especially with the introduction of integrated circuits controlled by part or all of a capacitor charge or discharge cycle.

ALTERNATING CURRENT IN CAPACITANCE

Everything said about capacitance and capacitors in a dc circuit applies to capacitance in an ac circuit with one major exception. Whereas a capacitor in a dc circuit will appear as an open circuit except for the brief charge and discharge periods, the same capacitor in an ac circuit will both pass and limit current. A capacitor in an ac circuit does not handle electrical energy like a resistor, however. Instead of converting the energy to heat and dissipating it, capacitors store electrical energy and return it to the circuit.

In **Fig 4.37** a sine-wave ac voltage having a maximum value of 100 is applied to a ca-

Fig 4.37 — Voltage and current phase relationships when an alternating current is applied to a capacitor.

capacitor. In the period OA, the applied voltage increases from 0 to 38; at the end of this period the capacitor is charged to that voltage. In interval AB the voltage increases to 71; that is, 33 V additional. During this interval a smaller quantity of charge has been added than in OA, because the voltage rise during interval AB is smaller. Consequently the average current during interval AB is smaller than during OA. In the third interval, BC, the voltage rises from 71 to 92, an increase of 21 V. This is less than the voltage increase during AB, so the quantity of electricity added is less; in other words, the average current during interval BC is still smaller. In the fourth interval, CD, the voltage increases only 8 V; the charge added is smaller than in any preceding interval and therefore the current also is smaller.

By dividing the first quarter cycle into a very large number of intervals, it could be shown that the current charging the capacitor has the shape of a sine wave, just as the applied voltage does. The current is largest at the beginning of the cycle and becomes zero at the maximum value of the voltage, so there is a phase difference of 90° between the voltage and the current. During the first quarter cycle the current is flowing in the normal direction through the circuit, since the capacitor is being charged. Hence the current is positive, as indicated by the dashed line in Fig 4.37.

In the second quarter cycle — that is, in the time from D to H — the voltage applied to the capacitor decreases. During this time the capacitor loses its charge. Applying the same reasoning, it is evident that the current is small in interval DE and continues to increase during each succeeding interval. The current is flowing against the applied voltage, however, because the capacitor is discharging into the circuit. The current flows in the negative direction during this quarter cycle.

The third and fourth quarter cycles repeat the events of the first and second, respectively, with this difference: the polarity of the applied voltage has reversed, and the current changes to correspond. In other words, an alternating current flows in the circuit because of the alternate charging and discharging of the capacitance. As shown in Fig 4.37, the current starts its cycle 90° before the voltage, so the current in a capacitor *leads* the applied voltage by 90°. You might find it helpful to remember the word “ICE” as a mnemonic because the current (I) in a capacitor (C) comes before voltage (E). We can also turn this statement around, to say the voltage in a capacitor *lags* the current by 90°.

CAPACITIVE REACTANCE

The quantity of electric charge that can be placed on a capacitor is proportional to

the applied voltage and the capacitance. This amount of charge moves back and forth in the circuit once each cycle; hence, the rate of movement of charge (the current) is proportional to voltage, capacitance and frequency. When the effects of capacitance and frequency are considered together, they form a quantity that plays a part similar to that of resistance in Ohm’s Law. This quantity is called *reactance*. The unit for reactance is the ohm, just as in the case of resistance. The formula for calculating the reactance of a capacitor at a given frequency is:

$$X_C = \frac{1}{2\pi f C} \quad (53)$$

where:

- X_C = capacitive reactance in ohms,
- f = frequency in hertz,
- C = capacitance in farads
- $\pi = 3.1416$

Note: In many references and texts, the symbol ω is used to represent $2\pi f$. In such references, equation 53 would read

$$X_C = \frac{1}{\omega C}$$

Although the unit of reactance is the ohm, there is no power dissipated in reactance. The energy stored in the capacitor during one portion of the cycle is simply returned to the circuit in the next.

The fundamental units for frequency and capacitance (hertz and farads) are too cumbersome for practical use in radio circuits. If the capacitance is specified in microfarads (μF) and the frequency is in megahertz (MHz), however, the reactance calculated from the previous formula retains the unit ohms.

Example: What is the reactance of a capacitor of 470 pF (0.000470 μF) at a frequency of 7.15 MHz?

$$\begin{aligned} X_C &= \frac{1}{2\pi f C} \\ &= \frac{1}{2\pi \times 7.15 \text{ MHz} \times 0.000470 \mu\text{F}} \\ &= \frac{1\Omega}{0.0211} = 47.4\Omega \end{aligned}$$

Example: What is the reactance of the same capacitor, 470 pF (0.000470 μF), at a frequency of 14.29 MHz?

$$\begin{aligned} X_C &= \frac{1}{2\pi f C} \\ &= \frac{1}{2\pi \times 14.29 \text{ MHz} \times 0.000470 \mu\text{F}} \\ &= \frac{1\Omega}{0.0422} = 23.7\Omega \end{aligned}$$

The rate of change of voltage in a sine wave increases directly with the frequency. Therefore, the current into the capacitor also increases directly with frequency. Since, for a given voltage, an increase in current is equivalent to a decrease in reactance, the reactance of any capacitor decreases proportionally as the frequency increases. Fig 4.38 traces the decrease in reactance of an arbitrary-value capacitor with respect to increasing frequency. The only limitation on the application of the graph is the physical make-up of the capacitor, which may favor low-frequency uses or high-frequency applications.

Among other things, reactance is a measure of the ability of a capacitor to limit the flow of ac in a circuit. For some purposes it is important to know the ability of a capacitor to pass current. This ability is called *susceptance*, and it corresponds to conductance in resistive circuit elements. In an ideal capacitor with no resistive losses — that is, no energy lost as heat — susceptance is simply the reciprocal of reactance. Hence,

$$B = \frac{1}{X_C} \quad (54)$$

where:

- X_C is the reactance, and
- B is the susceptance.

The unit of susceptance (and conductance and admittance) is the *siemens* (abbreviated S). In literature only a few years old, the term *mho* is also sometimes given as the unit of susceptance (as well as of conductance and admittance). The role of reactance and susceptance in current and other Ohm’s Law calculations will appear in a later section of this chapter.

Inductance and Inductors

A second way to store electrical energy is in a *magnetic field*. This phenomenon is called *inductance*, and the devices that exhibit inductance are called *inductors*. Inductance depends upon some basic underlying magnetic properties. See Chapter 6 for more information on practical inductor applications and problems.

MAGNETISM

Magnetic Fields, Flux and Flux Density

Magnetic fields are closed fields that surround a magnet, as illustrated in **Fig 4.39**. The field consists of lines of magnetic force or *flux*. It exhibits polarity, which is conventionally indicated as north-seeking and south-seeking poles, or *north* and *south poles* for short. Magnetic flux is measured in the SI unit of the weber, which is a volt second ($\text{Wb} = \text{Vs}$). In the *centimeter gram second (cgs)*

metric system units, we measure magnetic flux in maxwells ($1\text{Mx} = 10^{-8} \text{Wb}$).

The field intensity, known as the *flux density*, decreases with the square of the distance from the source. Flux density (B) is represented in gauss (G), where one gauss is equivalent to one line of force per square centimeter of area across the field ($G = \text{Mx} / \text{cm}^2$). The gauss is a *cgs* unit. In SI units, flux density is represented by the tesla (T), which is one weber per square meter ($T = \text{Wb}/\text{m}^2$).

Magnetic fields exist around two types of materials. First, certain ferromagnetic materials contain molecules aligned so as to produce a magnetic field. Lodestone, Alnico and other materials with high *retentivity* form *permanent magnets* because they retain their magnetic properties for long periods. Other materials, such as soft iron, yield temporary magnets that lose their magnetic properties rapidly.

The second type of magnetic material is an electrical conductor with a current through it. As shown in **Fig 4.40**, moving electrons are surrounded by a closed magnetic field lying in planes perpendicular to their motion. The needle of a compass placed near a wire carrying direct current will be deflected by the magnetic field around the wire. This phenomenon is one aspect of a two-way relationship: a moving magnetic field whose lines cut across a wire will induce an electrical current in the wire, and an electrical current will produce a magnetic field.

If the wire is coiled into a solenoid, the magnetic field greatly intensifies as the individual flux lines add together. **Fig 4.41** illustrates the principle by showing a coil section. Note that the resulting *electro-*

magnet has magnetic properties identical in principle to those of a permanent magnet, including poles and lines of force or flux. The strength of the magnetic field depends on several factors: the number of turns of the coil, the magnetic properties of the materials surrounding the coil (both inside and out), the length of the magnetic path and the amplitude of the current.

The magnetizing or *magnetomotive force* that produces a flux or total magnetic field is measured in gilberts (Gb). The force in gilberts equals 0.4π (approximately 1.257) times the number of turns in the coil times the current in amperes. (The SI unit of magnetomotive force is the ampere turn, abbreviated A, just like the ampere.) The magnetic field strength, H , measured in oersteds (Oe) produced by any particular magnetomotive force (measured in gilberts) is given by:

$$H = \frac{0.4\pi NI}{\ell} \quad (55)$$

where:

- H = magnetic field strength in oersteds,
- N = number of turns,
- I = dc current in amperes,
- $\pi = 3.1416$, and
- ℓ = mean magnetic path length in centimeters.

The gilbert and oersted are *cgs* units. These are given here because most amateur calculations will use these units. You may also see the preferred SI units in some literature. The SI unit of magnetic field strength is the ampere (turn) per meter.

A force is required to produce a given magnetic field strength. This implies that there is a resistance, called *reluctance*, to be overcome.

Fig 4.39 — The magnetic field and poles of a permanent magnet. The magnetic field direction is from the north to the south pole.

Fig 4.40 — The magnetic field around a conductor carrying an electrical current. If the thumb of your right hand points in the direction of the conventional current (plus to minus), your fingers curl in the direction of the magnetic field around the wire.

Core Properties: Permeability, Saturation, Reluctance, Hysteresis

The nature of the material within the coil of an electromagnet, where the lines of force are most concentrated, has the greatest effect upon the magnetic field established by the coil. All materials are compared to air. The ratio of flux density produced by a given material compared to the flux density produce by an air core is the *permeability* of the material. Suppose the coil in Fig 4.42 is wound on an iron core having a cross-sectional area of 2 square inches. When a certain current is sent through the coil, it is found that there are 80000 lines of force in the core. Since the area is 2 square inches, the magnetic flux density is 40000 lines per square inch. Now suppose that the iron core is removed and the same current is maintained in the coil. Also suppose the flux density without the iron core is found to be 50 lines per square inch. The ratio of these flux densities, iron core to air, is 40000 / 50 or 800, the core's permeability.

Permeabilities as high as 10⁶ have been attained. The three most common types of materials used in magnetic cores are these:

A. stacks of laminated steel sheets (for power and audio applications);

B. various ferrite compounds (for cores shaped as rods, toroids, beads and numerous other forms); and

C. powdered iron (shaped as slugs, toroids and other forms for RF inductors).

Brass has a permeability less than 1. A brass core inserted into a coil will decrease the inductance compared to an air core.

The permeability of silicon-steel power-transformer cores approaches

5000 in high-quality units. Powdered-iron cores used in RF tuned circuits range in permeability from 3 to about 35, while ferrites of nickel-zinc and manganese-zinc range from 20 to 15000. **Table 4.6** lists some common magnetic materials, their composition and their permeabilities. Core materials are often frequency sensitive, exhibiting excessive losses outside the frequency band of intended use.

As a measure of the ease with which a magnetic field may be established in a material as compared with air, permeability (μ) corresponds roughly to electrical conductivity. Permeability is given as:

Fig 4.43 — A typical permeability curve for a magnetic core, showing the point where saturation begins.

Fig 4.44 — A typical hysteresis curve for a magnetic core, showing the additional energy needed to overcome residual flux.

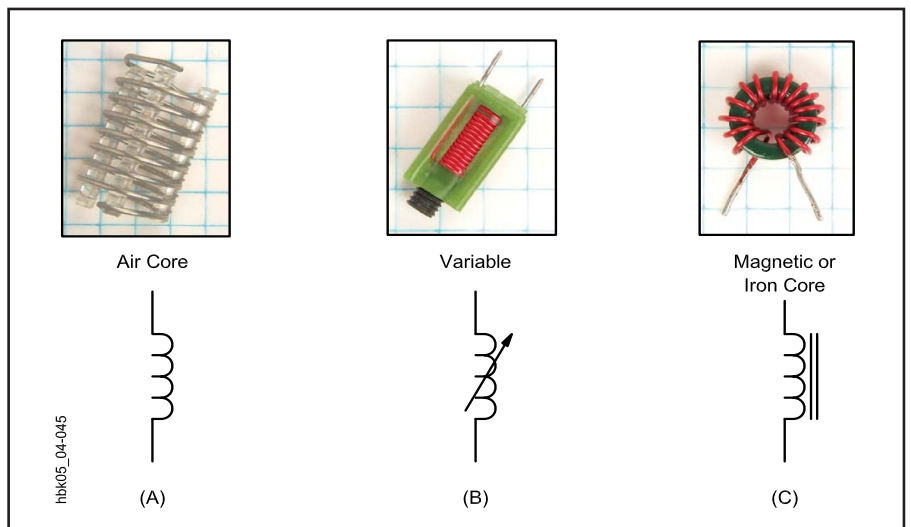

Fig 4.45 — Photos and schematic symbols for representative inductors. A, an air-core inductor; B, a variable inductor with a nonmagnetic slug and C, an inductor with a toroidal magnetic core. The 1/4-inch-ruled graph paper background provides a size comparison.

$$\mu = \frac{B}{H} \quad (56)$$

where:

B is the flux density in gauss, and

H is the magnetic field strength in oersteds.

Unlike electrical conductivity, which is independent of other electrical parameters, the permeability of a magnetic material varies with the flux density. At low flux densities (or with an air core), increasing the current through the coil will cause a proportionate increase in flux. But at very high flux densities, increasing the current beyond a certain point may cause no appreciable change in the flux. At this point, the core is said to be *saturated*. Saturation causes a rapid decrease in permeability, because it decreases the ratio of flux lines to those obtainable with the same current using an air core. **Fig 4.43** displays a typical permeability curve, showing the region of saturation. The saturation point varies with the makeup of different magnetic materials. Air and other nonmagnetic materials do not saturate and have a permeability of one. *Reluctance*, which is the reciprocal of permeability and corresponds roughly to resistance in an electrical circuit, is also one for air and other nonmagnetic cores.

The retentivity of magnetic core materials creates another potential set of losses caused by *hysteresis*. **Fig 4.44** illustrates the change of flux density (B) with a changing magnetizing force (H). From starting point A, with no residual flux, the flux reaches point B at the maximum magnetizing force. As the force decreases, so too does the flux, but it does not reach zero simultaneously with the force at point D. As the force continues in the opposite direction, it brings the flux density to point C. As the force decreases to zero, the flux once more lags behind. In effect, a reverse force is necessary to overcome the residual magnetism retained by the core material, a *coercive force*. The result is a power loss to the magnetic circuit, which appears as heat in the core material. Air cores are immune to hysteresis effects and losses.

INDUCTANCE AND DIRECT CURRENT

In an electrical circuit, any element having a magnetic field is called an *inductor*. **Fig 4.45** shows schematic-diagram symbols and photographs of a few representative inductors: an air-core inductor, a slug-tuned variable inductor with a nonmagnetic core and an inductor with a magnetic (iron) core.

The transfer of energy to the magnetic field of an inductor represents work per-

formed by the source of the voltage. Power is required for doing work, and since power is equal to current multiplied by voltage, there must be a voltage drop in the circuit while energy is being stored in the field. This voltage drop, exclusive of any voltage drop caused by resistance in the circuit, is the result of an opposing voltage induced in the circuit while the field is building up to its final value. Once the field becomes constant, the *induced voltage* or back-voltage disappears, because no further energy is being stored. The induced voltage opposes the voltage of the source and tends to prevent the current from rising rapidly when the circuit is closed. **Fig 4.46A** illustrates the situation of energizing an inductor or magnetic circuit, showing the relative amplitudes of induced voltage and the delayed rise in current to its full value.

The amplitude of the induced voltage is proportional to the rate at which the current changes (and consequently, the rate at which the magnetic field changes) and to a constant associated with the circuit itself: the *inductance* (or *self-inductance*) of the circuit. Inductance depends on the

physical configuration of the inductor. Coiling a conductor increases its inductance. In effect, the growing (or shrinking) magnetic field of each turn produces magnetic lines of force that — in their expansion (or contraction) — cut across the other turns of the coil, inducing a voltage in every other turn. The mutuality of the effect multiplies the ability of the coiled conductor to store electrical energy.

A coil of many turns will have more inductance than one of few turns, if both coils are otherwise physically similar. Furthermore, if an inductor is placed around a magnetic core, its inductance will increase in proportion to the permeability of that core, if the circuit current is below the point at which the core saturates.

The polarity of an induced voltage is always such as to oppose any change in the circuit current. This means that when the current in the circuit is increasing, work is being done against the induced voltage by storing energy in the magnetic field. Likewise, if the current in the circuit tends to decrease, the stored energy of the field returns to the circuit, and adds to the energy being supplied by the voltage

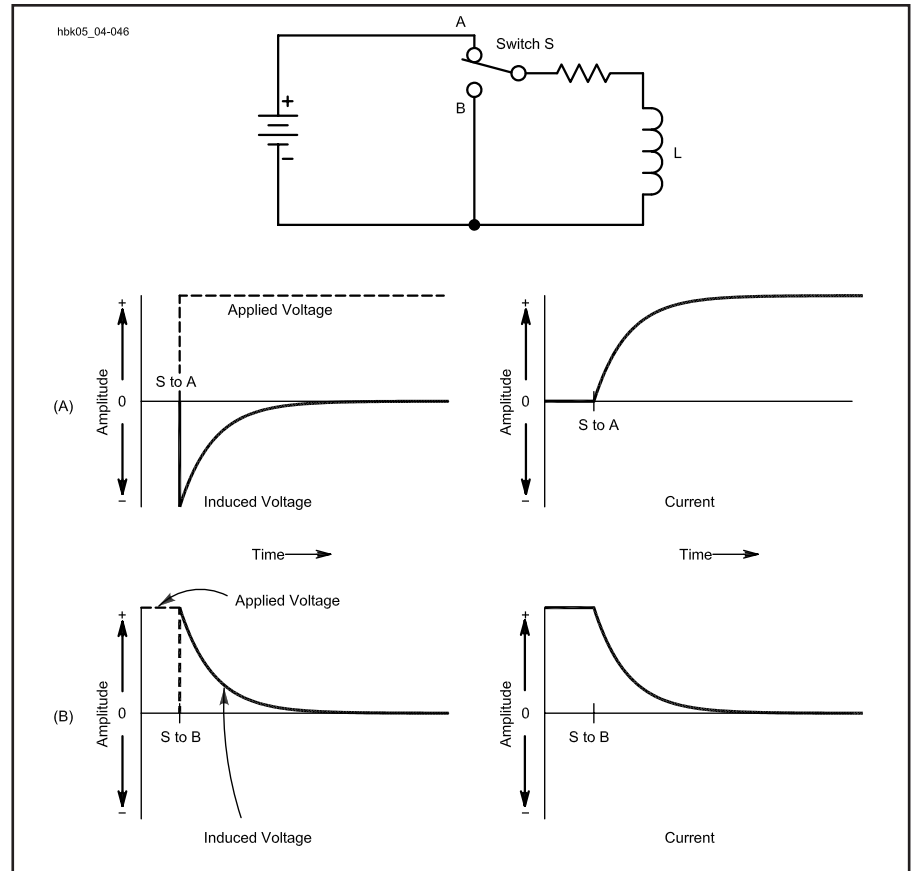

Fig 4.46 — Inductive circuit showing and graphing the generation of induced voltage and the rise of current in an inductor at A, and the decay of current as power is removed and the coil shorted at B.

source. Inductors try to maintain a constant current through the circuit. This phenomenon tends to keep the current flowing even though the applied voltage may be decreasing or be removed entirely. Fig 4.46B illustrates the decreasing but continuing flow of current caused by the induced voltage after the source voltage is removed from the circuit.

The energy stored in the magnetic field of an inductor is given by the formula:

$$W = \frac{I^2 L}{2} \quad (57)$$

where:

- W = energy in joules,
- I = current in amperes, and
- L = inductance in henrys.

This formula corresponds to the energy-storage formula for capacitors: energy storage is a function of current squared over time. As with capacitors, the time dependence of inductor current is a significant property; see the section on time constants.

The basic unit of inductance is the *henry* (abbreviated H), which equals an induced voltage of one volt when the inducing current is varying at a rate of one ampere per second. In various aspects of radio work, inductors may take values ranging from a fraction of a nanohenry (nH) through millihenrys (mH) up to about 20 H.

MUTUAL INDUCTANCE AND MAGNETIC COUPLING

Mutual Inductance

When two coils are arranged with their axes on the same line, as shown in Fig 4.47, current sent through coil 1 creates a magnetic field that cuts coil 2. Consequently, a voltage will be induced in coil 2 whenever the field strength of coil 1 is changing. This induced voltage is similar to the voltage of self-induction, but since

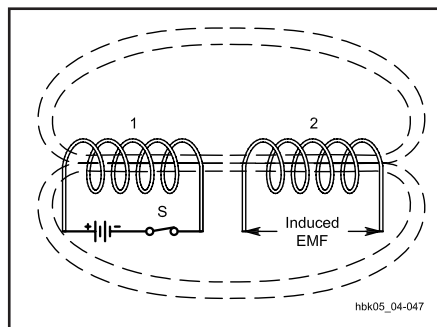

Fig 4.47 — Mutual inductance: When S is closed, current flows through coil number 1, setting up a magnetic field that induces a voltage in the turns of coil number 2.

it appears in the second coil because of current flowing in the first, it is a mutual effect and results from the *mutual inductance* between the two coils.

When all the flux set up by one coil cuts all the turns of the other coil, the mutual inductance has its maximum possible value. If only a small part of the flux set up by one coil cuts the turns of the other, the mutual inductance is relatively small. Two coils having mutual inductance are said to be *coupled*.

The ratio of actual mutual inductance to the maximum possible value that could theoretically be obtained with two given coils is called the *coefficient of coupling* between the coils. It is frequently expressed as a percentage. Coils that have nearly the maximum possible mutual inductance (coefficient = 1 or 100%) are said to be closely, or tightly, coupled. If the mutual inductance is relatively small the coils are said to be loosely coupled. The degree of coupling depends upon the physical spacing between the coils and how they are placed with respect to each other. Maximum coupling exists when they have a common axis and are as close together as possible (for example, one wound over the other). The coupling is least when the coils are far apart or are placed so their axes are at right angles.

The maximum possible coefficient of coupling is closely approached when the two coils are wound on a closed iron core. The coefficient with air-core coils may run as high as 0.6 or 0.7 if one coil is wound over the other, but will be much less if the two coils are separated. Although unity coupling is suggested by Fig 4.47, such coupling is possible only when the coils are wound on a closed magnetic core.

Unwanted Couplings: Spikes, Lightning and Other Pulses

Every conductor passing current has a magnetic field associated with it — and therefore inductance — even though the conductor is not formed into a coil. The inductance of a short length of straight wire is small, but it may not be negligible. If the current through it changes rapidly, the induced voltage may be appreciable. This is the case in even a few inches of wire with an alternating current having a frequency on the order of 100 MHz or higher. At much lower frequencies or at dc, the inductance of the same wire might be ignored because the induced voltage would seemingly be negligible.

There are many phenomena, however, both natural and man-made, which create sufficiently strong magnetic fields to induce voltages into straight wires. Many of them are brief but intense pulses of en-

ergy that act like the turning on of the switch in a circuit containing self-inductance. Because the fields created grow to very high levels rapidly, they cut across wires leading into and out of — and wires wholly within — electronic equipment, inducing unwanted voltages by mutual coupling.

Short-duration, high-level voltage spikes occur on ac and dc power lines. Because the field intensity is great, these spikes may induce voltages upon conducting elements in sensitive circuits, disrupting them and even injuring components. Lightning in the vicinity of the equipment can induce voltages on power lines and other conductive paths (even ground conductors) that lead to the equipment location. Lightning that seems a safe distance away can induce large spikes on power lines that ultimately lead to the equipment. Closer at hand, heavy equipment with electrical motors can induce significant spikes into power lines within the equipment location. Even though the power lines are straight, the powerful magnetic field of a spike source can induce damaging voltages on equipment left “plugged in” during electrical storms or during the operation of heavy equipment that inadequately filters its spikes.

Parallel-wire cables linking elements of electronic equipment consist of long wires in close proximity to each other. Signal pulses can couple both magnetically and capacitively from one wire to another. Since the magnetic field of a changing current decreases as the square of distance, separating the signal-carrying lines diminishes inductive coupling. Placing a grounded wire between signal-carrying lines reduces capacitive coupling. Unless they are well-shielded and filtered, however, the lines are still susceptible to the inductive coupling of pulses from other sources.

INDUCTORS IN RADIO WORK

Various facets of radio work make use of inductors ranging from the tiny up to the massive. Small values of inductance, as illustrated by Fig 4.48A, serve mostly in RF circuits. They may be self-supporting air-core or air-wound coils or the winding may be supported by nonmagnetic strips or a form. Phenolic, certain plastics and ceramics are the most common coil forms for air-core inductors. These inductors range in value from a few hundred μH for medium- and high-frequency circuits down to tenths of a μH for VHF and UHF work. The smallest values of inductance in radio work result from component leads. For VHF work and higher frequencies, component lead

(A)

(B)

(C)

Fig 4.48 — Part A shows small-value air-wound inductors. Part B shows some inductors with values in the range of a few millihenrys and C shows a large inductor such as might be used in audio circuits or as power-supply chokes. The 1/4-inch-ruled graph paper background provides a size comparison.

length is often critical. Circuits may fail to operate properly because leads are a little too short or too long.

It is possible to make these solenoid coils variable by inserting a slug in the center of the coil. (Slug-tuned coils normally have a ceramic, plastic or phenolic insulating form between the conductive slug and the coil winding.) If the slug material is magnetic, such as powdered iron, the inductance increases as the slug is centered along the length of the coil. If the slug is brass or some other conductive but nonmagnetic material, centering the slug will reduce the coil's inductance. This effect stems from the fact that brass has low electrical resistance and acts as an effective short-circuited one-turn secondary for the coil. (See more on transformer effects later in this chapter.)

An alternative to air-core inductors for RF work are toroidal coils wound on cores composed of powdered iron mixed with a binder to hold the material together. The availability of many types and sizes of powdered-iron cores has made these inductors popular for low-power fixed-value service. The toroidal shape concentrates the inductor's field tightly about the coil, eliminating the need in many cases for other forms of shielding to limit the interaction of the inductor's magnetic field with the fields of other inductors.

Fig 4.48B shows samples of inductors in the millihenry range. Among these inductors are multisection RF chokes designed to keep RF currents from pass-

ing beyond them to other parts of circuits. Low-frequency radio work may also use inductors in this range of values, sometimes wound with *litz* wire. Litz wire is a special version of stranded wire, with each strand insulated from the others. For audio filters, toroidal coils with values below 100 mH are useful. Resembling powdered-iron-core RF toroids, these coils are wound on ferrite or molybdenum-permalloy cores having much higher permeabilities.

Audio and power-supply inductors

appear in Fig 4.48C. Lower values of these iron-core coils, in the range of a few henrys, are useful as audio-frequency chokes. Larger values up to about 20 H may be found in power supplies, as choke filters, to suppress 120-Hz ripple. Although some of these inductors are open frame, most have iron covers to confine the powerful magnetic fields they produce.

INDUCTANCES IN SERIES AND PARALLEL

When two or more inductors are con-

Fig 4.49 — Part A shows inductances in series, and Part B shows inductances in parallel.

Fig 4.50 — Time constant of an RL circuit being energized.

nected in series (**Fig 4.49A**), the total inductance is equal to the sum of the individual inductances, provided that the coils are sufficiently separated so that coils are not in the magnetic field of one another. That is:

$$L_{\text{total}} = L_1 + L_2 + L_3 \dots + L_n \quad (58)$$

If inductors are connected in parallel (**Fig 4.49B**), and if the coils are separated sufficiently, the total inductance is given by:

$$L_{\text{total}} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \dots + \frac{1}{L_n}} \quad (59)$$

For only two inductors in parallel, the formula becomes:

$$L_{\text{total}} = \frac{L_1 \times L_2}{L_1 + L_2} \quad (60)$$

Thus, the rules for combining inductances in series and parallel are the same as those for resistances, assuming that the coils are far enough apart so that each is unaffected by another's magnetic field. When this is not so, the formulas given above will not yield correct results.

RL TIME CONSTANT

A comparable situation to an RC circuit exists when resistance and inductance are connected in series. In **Fig 4.50**, first consider L to have no resistance and also consider that R is zero. Closing S1 sends a current through the circuit. The instantaneous transition from no current to a finite value, however small, represents a rapid change in current, and a reverse voltage is developed by the self-inductance of L. The value of reverse voltage is almost equal and opposite to the applied voltage. The resulting initial current is very small.

The reverse voltage depends on the change in the value of the current and would cease to offer opposition if the current did not continue to increase. With no resistance in the circuit (which, by Ohm's Law, would lead to an infinitely large current), the current would increase forever, always growing just fast enough to keep the self-induced voltage equal to the applied voltage.

When resistance in the circuit limits the current, Ohm's Law defines the value that the current can reach. The reverse voltage generated in L must only equal the difference between E and the drop across R, because the difference is the voltage actually applied to L. This difference becomes smaller as the current approaches the final Ohm's Law value. Theoretically, the reverse voltage never quite disappears, and so the current never quite reaches the

Ohm's Law value. In practical terms, the differences become unmeasurable after a time.

The current at any time after the switch in **Fig 4.50** has been closed, can be found from:

$$I(t) = \frac{E \left[1 - e^{-\frac{tR}{L}} \right]}{R} \quad (61)$$

where:

I(t) = current in amperes at time t,
E = power supply potential in volts,
t = time in seconds after initiation of current,
e = natural logarithmic base = 2.718,
R = circuit resistance in ohms, and
L = inductance in henrys.

The time in seconds required for the current to build up to 63.2% of the maximum value is called the time constant, and is equal to L/R , where L is in henrys and R is in ohms. After each time interval equal to this constant, the circuit conducts an additional 63.2% of the remaining current. This behavior is graphed in **Fig 4.50**. As is the case with capacitors, after 5 time constants the current is considered to have reached its maximum value. As with capacitors, we often use the lower-case Greek tau (τ) to represent the time constant.

Example: If a circuit has an inductor of 5.0 mH in series with a resistor of 10 Ω , how long will it take for the current in the circuit to reach full value after power is applied? Since achieving maximum current takes approximately five time constants,

$$t = 5L/R = (5 \times 5.0 \times 10^{-3} \text{ H}) / 10 \Omega \\ = 2.5 \times 10^{-3} \text{ seconds or } 2.5 \text{ ms}$$

Note that if the inductance is increased to 5.0 H, the required time increases by a factor of 1000 to 2.5 seconds. Since the circuit resistance didn't change, the final current is the same for both cases in this example. Increasing inductance increases the time required to reach full current.

Zero resistance would prevent the circuit from ever achieving full current. All inductive circuits have some resistance, however, if only the resistance of the wire making up the inductor.

An inductor cannot be discharged in the simple circuit of **Fig 4.50** because the magnetic field collapses as soon as the current ceases. Opening S1 does not leave the inductor charged in the way that a capacitor would remain charged. The

energy stored in the magnetic field returns instantly to the circuit when S1 is opened. The rapid collapse of the field causes a very large voltage to be induced in the coil. Usually the induced voltage is many times larger than the applied voltage, because the induced voltage is proportional to the rate at which the field changes. The common result of opening the switch in such a circuit is that a spark or arc forms at the switch contacts during the instant the switch opens. When the inductance is large and the current in the circuit is high, large amounts of energy are released in a very short time. It is not at all unusual for the switch contacts to burn or melt under such circumstances. The spark or arc at the opened switch can be reduced or suppressed by connecting a suitable capacitor and resistor in series across the contacts. Such an RC combination is called a *snubber network*.

Transistor switches connected to and controlling coils, such as relay solenoids, also require protection. In most cases, a small power diode connected in reverse across the relay coil will prevent field-collapse currents from harming the transistor.

If the excitation is removed without breaking the circuit, as theoretically diagrammed in **Fig 4.51**, the current will decay according to the formula:

$$I(t) = \frac{E}{R} \left[e^{-\frac{tR}{L}} \right] \quad (62)$$

Fig 4.51 — Time constant of an RL circuit being deenergized. This is a theoretical model only, since a mechanical switch cannot change state instantaneously.

where t = time in seconds after removal of the source voltage.

After one time constant the current will lose 63.2% of its steady-state value. (It will decay to 36.8% of the steady-state value.) The graph in Fig 4.51 shows the current-decay waveform to be identical to the voltage-discharge waveform of a capacitor. Be careful about applying the terms *charge* and *discharge* to an inductive circuit, however. These terms refer to energy storage in an electric field. An inductor stores energy in a magnetic field.

ALTERNATING CURRENT IN INDUCTORS

When an alternating voltage is applied to an ideal inductance (one with no resistance — all practical inductors have some resistance), the current is 90° out of phase with the applied voltage. In this case the current *lags* 90° behind the voltage, the opposite of the capacitor current-voltage relationship, as shown in Fig 4.52. (Here again, we can also say the voltage across an inductor *leads* the current by 90° .)

If you have difficulty remembering the phase relationships between voltage and current with inductors and capacitors, you may find it helpful to think of the phrase, “ELI the ICE man.” This will remind you that voltage across an inductor leads the current through it, because the E comes before the I, with an L between them, as you read from left to right. (The letter L represents inductance.) It will also help you remember the capacitor conditions because I comes before E with a C between them.

Interpreting Fig 4.52 begins with under-

standing that the primary cause for current lag in an inductor is the reverse voltage generated in the inductance. The amplitude of the reverse voltage is proportional to the rate at which the current changes. In time segment OA, when the applied voltage is at its positive maximum, the reverse or induced voltage is also maximum, allowing the least current to flow. The rate at which the current is changing is the highest, a 38% change in the time period OA. In the segment AB, the current changes by only 33%, yielding a reduced level of induced voltage, which is in step with the decrease in the applied voltage. The process continues in time segments BC and CD, the latter producing only an 8% rise in current as the applied and induced voltage approach zero.

In segment DE, the applied voltage changes direction. The induced voltage also changes direction, which returns current to the circuit from storage in the magnetic field. The direction of this current is now opposite to the applied voltage, which sustains the current in the positive direction. As the applied voltage continues to increase negatively, the current — although positive — decreases in value, reaching zero as the applied voltage reaches its negative maximum. The negative half-cycle continues just as did the positive half-cycle.

Compare Fig 4.52 with Fig 4.37. Whereas in a pure capacitive circuit, the current *leads* the voltage by 90° , in a pure inductive circuit, the current *lags* the voltage by 90° . These phenomena are especially important in circuits that combine

inductors and capacitors.

INDUCTIVE REACTANCE

The amplitude of alternating current in an inductor is inversely proportional to the applied frequency. Since the reverse voltage is directly proportional to inductance for a given rate of current change, the current is inversely proportional to inductance for a given applied voltage and frequency.

The combined effect of inductance and frequency is called inductive reactance, which — like capacitive reactance — is expressed in ohms. The formula for inductive reactance is:

$$X_L = 2\pi f L \quad (63)$$

where:

X_L = inductive reactance,

f = frequency in hertz,

L = inductance in henrys, and

$\pi = 3.1416$.

(If $\omega = 2\pi f$, then $X_L = \omega L$.)

Example: What is the reactance of a coil having an inductance of 8.00 H at a frequency of 120 Hz?

$$\begin{aligned} X_L &= 2\pi f L \\ &= 6.2832 \times 120 \text{ Hz} \times 8.00 \text{ H} \\ &= 6030 \Omega \end{aligned}$$

In RF circuits the inductance values are usually small and the frequencies are large. When the inductance is expressed in millihenrys and the frequency in kilohertz, the conversion factors for the two units cancel, and the formula for reactance may be used without first converting to fundamental units. Similarly, no conversion is necessary if the inductance is expressed in microhenrys and the frequency in megahertz.

Example: What is the reactance of a 15.0-microhenry coil at a frequency of 14.0 MHz?

$$\begin{aligned} X_L &= 2\pi f L \\ &= 6.2832 \times 14.0 \text{ MHz} \times 15.0 \mu\text{H} \\ &= 1320 \Omega \end{aligned}$$

The resistance of the wire used to wind the coil has no effect on the reactance, but simply acts as a separate resistor connected in series with the coil.

Example: What is the reactance of the same coil at a frequency of 7.0 MHz?

$$\begin{aligned} X_L &= 2\pi f L \\ &= 6.2832 \times 7.0 \text{ MHz} \times 15.0 \mu\text{H} \\ &= 660 \Omega \end{aligned}$$

Comparing the two examples suggests correctly that inductive reactance varies directly with frequency. The rate of

Fig 4.52 — Phase relationships between voltage and current when an alternating current is applied to an inductance.

change of the current varies directly with the frequency, and this rate of change also determines the amplitude of the induced or reverse voltage. Hence, the opposition to the flow of current increases proportionally to frequency. This opposition is called *inductive reactance*. The direct relationship between frequency and reactance in inductors, combined with the inverse relationship between reactance and frequency in the case of capacitors,

will be of fundamental importance in creating resonant circuits.

As a measure of the ability of an inductor to limit the flow of ac in a circuit, inductive reactance is similar to capacitive reactance in having a corresponding *susceptance*, or ability to pass ac current in a circuit. In an ideal inductor with no resistive losses — that is, no energy lost as heat — susceptance is simply the reciprocal of reactance.

$$B = \frac{1}{X_L} \quad (64)$$

where:

X_L = reactance, and
 B = susceptance.

The unit of susceptance for both inductors and capacitors is the *siemens*, abbreviated S.

Quality Factor, or Q of Components

Components that store energy, like capacitors and inductors, may be compared in terms of quality or Q. The Q of any such component is the ratio of its ability to store energy to the sum total of all energy losses within the component. In practical terms, this ratio reduces to the formula:

$$Q = \frac{X}{R} \quad (65)$$

where:

Q = figure of merit or quality (no units),
 $X = X_L$ (inductive reactance) for inductors and X_C (capacitive reactance) for capacitors (in ohms), and

R = the sum of all resistances associated with the energy losses in the component (in ohms).

The Q of capacitors is ordinarily high.

Good quality ceramic capacitors and mica capacitors may have Q values of 1200 or more. Small ceramic trimmer capacitors may have Q values too small to ignore in some applications. Microwave capacitors can have poor Q values; 10 or less at 10 GHz and higher frequencies.

Inductors are subject to many types of electrical energy losses, however, such as wire resistance, core losses and skin effect. All electrical conductors have some resistance through which electrical energy is lost as heat. Moreover, inductor wire must be sized to handle the anticipated current through the coil. Wire conductors suffer additional ac losses because alternating current tends to flow on the conductor surface. As the frequency increases, the current is confined to a thinner layer of the

conductor surface. This property is called *skin effect*. If the inductor's core is a conductive material, such as iron, ferrite, or brass, the core will introduce additional losses of energy. The specific details of these losses are discussed in connection with each type of core material.

The sum of all core losses may be depicted by showing a resistor in series with the inductor (as in Figs 4.50 and 4.51), although there is no separate component represented by the resistor symbol. As a result of inherent energy losses, inductor Q rarely, if ever, approaches capacitor Q in a circuit where both components work together. Although many circuits call for the highest Q inductor obtainable, other circuits may call for a specific Q, even a very low one.

AC Component Summary

Component	Resistor	Capacitor	Inductor
Basic Unit	ohm (Ω)	farad (F)	henry (H)
Units Commonly Used		microfarads (μF) picofarads (pF)	millihenrys (mH) microhenrys (μH)
Quantity Stored (Does not want to change in circuit)	(None)	Voltage	Current
Combining components in series	$R_1 + R_2$	$C_1 \times C_2 / C_1 + C_2$	$L_1 + L_2$
Combining components in parallel	$R_1 \times R_2 / R_1 + R_2$	$C_1 + C_2$	$L_1 \times L_2 / L_1 + L_2$
Time constant	(None)	RC	L/R
Voltage-Current Phase	In phase	Current leads voltage Voltage lags current	Voltage leads current Current lags voltage
Resistance or Reactance	Resistance	$X_C = 1 / 2\pi fC$	$X_L = 2\pi fL$
Change with increasing frequency	No	Reactance decreases	Reactance increases
Q of circuit	Not defined	X_C / R	X_L / R

Calculating Practical Inductors

Although builders and experimenters rarely construct their own capacitors, inductor fabrication is common. In fact, it is often necessary, since commercially available units may be unavailable or expensive. Even if available, they may consist of coil stock to be trimmed to the

required value. Core materials and wire for winding both solenoid and toroidal inductors are readily available. The following information includes fundamental formulas and design examples for calculating practical inductors, along with additional data on the theoretical limits in

the use of some materials.

AIR-CORE INDUCTORS

Many circuits require air-core inductors using just one layer of wire. The approximate inductance of a single-layer air-core coil may be calculated from the

simplified formula:

$$L (\mu\text{H}) = \frac{d^2 n^2}{18d + 40\ell} \quad (66)$$

where:

- L = inductance in microhenrys,
- d = coil diameter in inches (from wire center to wire center),
- ℓ = coil length in inches, and
- n = number of turns.

The notation is explained in **Fig 4.53**. This formula is a close approximation for coils having a length equal to or greater

Fig 4.53 — Coil dimensions used in the inductance formula for air-core inductors.

than 0.4 d. (Note: Inductance varies as the square of the turns. If the number of turns is doubled, the inductance is quadrupled. This relationship is inherent in the equation, but is often overlooked. For example, if you want to double the inductance, put on additional turns equal to 1.4 times the original number of turns, or 40% more turns.)

Example: What is the inductance of a coil if the coil has 48 turns wound at 32 turns per inch and a diameter of $\frac{3}{4}$ inch? In this case, $d = 0.75$, $\ell = \frac{48}{32} = 1.5$ and $n = 48$.

$$L = \frac{0.75^2 \times 48^2}{(18 \times 0.75) + (40 \times 1.5)}$$

$$= \frac{1300}{74} = 18 \mu\text{H}$$

To calculate the number of turns of a single-layer coil for a required value of inductance, the formula becomes:

$$n = \frac{\sqrt{L(18d + 40\ell)}}{d} \quad (67)$$

Example: Suppose an inductance of 10.0 μH is required. The form on which the coil is to be wound has a diameter of

one inch and is long enough to accommodate a coil of $1\frac{1}{4}$ inches. Then $d = 1.00$ inch, $\ell = 1.25$ inches and $L = 10.0$. Substituting:

$$n = \frac{\sqrt{10.0[(18 \times 1.00) + (40 \times 1.25)]}}{1}$$

$$= \sqrt{680} = 26.1 \text{ turns}$$

A 26-turn coil would be close enough in practical work. Since the coil will be 1.25 inches long, the number of turns per inch will be $26.1 / 1.25 = 20.9$. Consulting the wire table in the **Component Data and References** chapter, we find that #17 enameled wire (or anything smaller) can be used. The proper inductance is obtained by winding the required number of turns on the form and then adjusting the spacing between the turns to make a uniformly spaced coil 1.25 inches long.

Most inductance formulas lose accuracy when applied to small coils (such as are used in VHF work and in low-pass filters built for reducing harmonic interference to televisions) because the conductor thickness is no longer negligible in comparison with the size of the coil. **Fig 4.54** shows the measured inductance of VHF coils and may be used as a basis for circuit design. Two curves are given; curve A is for coils wound to an inside diameter of $\frac{1}{2}$ inch; curve B is for coils of $\frac{3}{4}$ -inch inside diameter. In both curves, the wire size is #12, and the winding pitch is eight turns to the inch ($\frac{1}{8}$ -inch center-to-center turn spacing). The inductance values given include leads $\frac{1}{2}$ -inch long.

Machine-wound coils with the preset diameters and turns per inch are available in many radio stores, under the trade names of B&W Miniductor, Airdux and Polycoid. The **Component Data and References** chapter provides information on using such coil stock to simplify the process of designing high-quality inductors for most HF applications. Forming a wire into a solenoid increases its inductance, and also introduces distributed capacitance. Since each turn is at a slightly different ac potential, each pair of turns effectively forms a parasitic capacitor. See the **Real-World Component Characteristics** chapter for information on the effects of these complications to the "ideal" inductors under discussion in this chapter. Moreover, the Q of air-core inductors is, in part, a function of the coil shape, specifically its ratio of length to diameter. Q tends to be highest when these dimensions are nearly equal. With wire properly sized to the current carried by the coil, and with high-caliber construction, air-core inductors can achieve Qs above 200. Air-core inductors with Qs as high as 400 are possible.

Fig 4.54 — Measured inductance of coils wound with #12 bare wire, eight turns to the inch. The values include half-inch leads.

STRAIGHT-WIRE INDUCTANCE

At low frequencies the inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left\{ \ln \left(\frac{2b}{a} \right) - 0.75 \right\} \quad (68)$$

where:

- L = inductance in μH ,
- a = wire radius in inches,
- b = wire length in inches, and
- ln = natural logarithm = $2.303 \times$ common logarithm (base 10).

If the dimensions are expressed in milli-

meters instead of inches, the equation may still be used, except replace the 0.00508 value with 0.0002.

Skin effect reduces the inductance at VHF and above. As the frequency approaches infinity, the 0.75 constant within the brackets approaches unity. As a practical matter, skin effect will not reduce the inductance by more than a few percent.

Example: What is the inductance of a wire that is 0.1575 inch in diameter and 3.9370 inches long? For the calculations, a = 0.0787 inch (radius) and b = 3.9370 inch.

$$\begin{aligned} L &= 0.00508 b \left\{ \ln \left(\frac{2b}{a} \right) - 0.75 \right\} \\ &= 0.00508 (3.9370) \times \\ &\quad \left\{ \ln \left(\frac{2 \times 3.9370}{0.0787} \right) - 0.75 \right\} \end{aligned}$$

$$\begin{aligned} L &= 0.0200 [1n (100) - 0.75] \\ &= 0.0200 (4.60 - 0.75) \\ &= 0.0200 \times 3.85 = 0.077 \mu\text{H} \end{aligned}$$

Fig 4.55 is a graph of the inductance for wires of various radii as a function of length.

A VHF or UHF tank circuit can be fabricated from a wire parallel to a ground plane, with one end grounded. A formula for the inductance of such an arrangement is given in **Fig 4.56**.

Example: What is the inductance of a wire 3.9370 inches long and 0.0787 inch in radius, suspended 1.5748 inch above a ground plane? (The inductance is measured between the free end and the ground plane, and the formula includes the inductance of the 1.5748-inch grounding link.) To demonstrate the use of the formula in Fig 4.56, begin by evaluating these quantities:

$$\begin{aligned} b + \sqrt{b^2 + a^2} &= 3.9370 + \sqrt{3.9370^2 + 0.0787^2} \\ &= 3.9370 + 3.94 = 7.88 \end{aligned}$$

$$\begin{aligned} b + \sqrt{b^2 + 4(h^2)} &= 3.9370 + \sqrt{3.9370^2 + 4(1.5748^2)} \\ &= 3.9370 + \sqrt{15.500 + 4(2.4800)} \\ &= 3.9370 + \sqrt{15.500 + 9.9200} \\ &= 3.9370 + 5.0418 = 8.9788 \end{aligned}$$

$$\frac{2h}{a} = \frac{2 \times 1.5748}{0.0787} = 40.0$$

$$\frac{b}{4} = \frac{3.9370}{4} = 0.98425$$

Fig 4.55 — Inductance of various conductor sizes as straight wires.

Fig 4.56 — Equation for determining the inductance of a wire parallel to a ground plane, with one end grounded. If the dimensions are in millimeters, the numerical coefficients become 0.0004605 for the first term and 0.0002 for the second term.

Fig 4.57 — Equation for determining the inductance of a flat strip inductor.

Substituting these values into the formula yields:

$$L = 0.0117 \times 3.9370 \left\{ \log_{10} \left[40.0 \times \left(\frac{7.88}{8.9788} \right) \right] \right\} + 0.00508 \times (5.0418 - 3.94 + 0.98425 - 3.1496 + 0.0787)$$

$$L = 0.0662 \mu\text{H}$$

Another conductor configuration that is frequently used is a flat strip over a ground plane. This arrangement has lower skin-effect loss at high frequencies than round wire because it has a higher surface-area to volume ratio. The inductance of such a strip can be found from the formula in **Fig 4.57**. For a large collection of formulas useful in constructing air-core inductors of many configurations, see the “Circuit Elements” section in Terman’s *Radio Engineers’ Handbook* or the “Transmission Media” chapter of *The ARRL UHF/Microwave Experimenter’s Manual*.

IRON-CORE INDUCTORS

If the permeability of an iron core in an inductor is 800, then the inductance of any given air-wound coil is increased 800 times by inserting the iron core. The inductance will be proportional to the magnetic flux through the coil, other things being equal. The inductance of an iron-core inductor is highly dependent on

Fig 4.58 — Typical construction of an iron-core inductor. The small air gap prevents magnetic saturation of the iron and thus maintains the inductance at high currents.

the current flowing in the coil, in contrast to an air-core coil, where the inductance is independent of current because air does not saturate.

Iron-core coils such as the one sketched in **Fig 4.58** are used chiefly in power-supply equipment. They usually have direct current flowing through the winding, and any variation in inductance with current is usually undesirable. Inductance variations may be overcome by keeping the flux density below the saturation point of the iron. Opening the core so there is a small air gap, indicated by the dashed lines in **Fig 4.58**, will achieve this goal. The reluctance or magnetic resistance introduced by such a gap is very large compared with that of the iron, even though the gap is only a small fraction of an inch. Therefore, the gap — rather than the iron — controls the flux density. Air gaps in iron cores reduce the inductance, but they hold the value practically constant regardless of the current magnitude.

When alternating current flows through a coil wound on an iron core, a voltage is induced. Since iron is a conductor, a current also flows in the core. Such currents are called *eddy currents*. Eddy currents represent lost power because they flow through the resistance of the iron and generate heat. Losses caused by eddy currents can be reduced by laminating the core (cutting the core into thin strips). These strips or laminations are then insulated from each other by painting them with some insulating material such as varnish or shellac. These losses add to hysteresis

losses, which are also significant in iron-core inductors.

Eddy-current and hysteresis losses in iron increase rapidly as the frequency of the alternating current increases. For this reason, ordinary iron cores can be used only at power-line and audio frequencies — up to approximately 15000 Hz. Even then, a very good grade of iron or steel is necessary for the core to perform well at the higher audio frequencies. Laminated iron cores become completely useless at radio frequencies.

SLUG-TUNED INDUCTORS

For RF work, the losses in iron cores can be reduced to a more useful level by grinding the iron into a powder and then mixing it with a “binder” of insulating material in such a way that the individual iron particles are insulated from each other. Using this approach, cores can be made that function satisfactorily even into the VHF range.

Because a large part of the magnetic path is through a nonmagnetic material (the “binder”), the permeability of the iron is low compared with the values obtained at power-line frequencies. The core is usually shaped in the form of a slug or cylinder for fit inside the insulating form on which the coil is wound. Despite the fact that the major portion of the magnetic path for the flux is in air, the slug is quite effective in increasing the coil inductance. By pushing (or screwing) the slug in and out of the coil, the inductance can be varied over a considerable range.

POWDERED-IRON TOROIDAL INDUCTORS

For fixed-value inductors intended for use at HF and VHF, the powdered-iron toroidal core has become almost the standard core and material in low power circuits. **Fig 4.59** shows the general outlines of a toroidal coil on a magnetic core. Manufacturers offer a wide variety of core materials, or mixes, to provide units that will perform over a desired frequency range with a reasonable permeability. Initial permeabilities for powdered-iron cores fall in the range of 3 to 35 for various mixes. In addition, core sizes are available in the range of 0.125-inch outside diameter (OD) up to 1.06-inch OD, with larger sizes to 5-inch OD available in certain mixes. The range of sizes permits the builder to construct single-layer inductors for almost any value using wire sized to meet the circuit current demands. While powdered-iron toroids are often painted various colors, you must know the manufacturer to identify the mix. There seems to be no set standard between manufac-

Fig 4.59 — A typical toroidal inductor wound on a powdered-iron or ferrite core. Some key physical dimensions are noted. Equally important are the core material, its permeability, its intended range of operating frequencies, and its A_L value. This is an 11-turn toroid.

turers. Iron-powder toroids usually have rounded edges.

The use of powdered iron in a binder reduces core losses usually associated with iron, while the permeability of the core permits a reduction in the wire length and associated resistance in forming a coil of a given inductance. Therefore, powdered-iron-core toroidal inductors can achieve Q_s well above 100, often approaching or exceeding 200 within the frequency range specified for a given core. Moreover, these coils are considered self-shielding since most of the flux lines are within the core, a fact that simplifies circuit design and construction.

Each powdered-iron core has a value of A_L determined and published by the core manufacturer. For powdered-iron cores, A_L represents the *inductance index*, that is, the inductance in μH per 100 turns of wire on the core, arranged in a single layer. The builder must select a core size capable of holding the calculated number of turns, of the required wire size, for the desired inductance. Otherwise, the coil calculation is straightforward. To calculate the inductance of a powdered-iron toroidal coil, when the number of turns and the core material are known, use the formula:

$$L = \frac{A_L \times N^2}{10000} \quad (69)$$

where:

L = the inductance in μH ,

A_L = the inductance index in μH per 100 turns, and

N = the number of turns.

Example: What is the inductance of a 60-turn coil on a core with an A_L of 55? This A_L value was selected from manufacturer's information about a 0.8-inch OD core with an initial permeability of 10. This particular core is intended for use in the range of 2 to 30 MHz. See the **Component Data and References** chapter for more detailed data on the range of available cores.

$$L = \frac{A_L \times N^2}{10000} = \frac{55 \times 60^2}{10000} \\ = \frac{198000}{10000} = 19.8 \mu\text{H}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 100 \sqrt{\frac{L}{A_L}} \quad (70)$$

Example: How many turns are needed for a 12.0- μH coil if the A_L for the selected core is 49?

$$N = 100 \sqrt{\frac{L}{A_L}} = 100 \sqrt{\frac{12.0}{49}} \\ = 100 \sqrt{0.245} = 100 \times 0.495 = 49.5 \text{ turns}$$

If the value is critical, experimenting with 49-turn and 50-turn coils is in order, especially since core characteristics may vary slightly from batch to batch. Count turns by each pass of the wire through the center of the core. (A straight wire through a toroidal core amounts to a one-turn coil.) Fine adjustment of the inductance may be possible by spreading or squeezing inductor turns.

The power-handling ability of toroidal cores depends on many variables, which include the cross-sectional area through the core, the core material, the numbers of turns in the coil, the applied voltage and the operating frequency. Although powdered-iron cores can withstand dc flux densities up to 5000 gauss without saturating, ac flux densities from sine waves above certain limits can overheat cores. Manufacturers provide guideline limits for ac flux densities to avoid overheating. The limits range from 150 gauss at 1 MHz

to 30 gauss at 28 MHz, although the curve is not linear. To calculate the maximum anticipated flux density for a particular coil, use the formula:

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \quad (71)$$

where:

B_{max} = the maximum flux density in gauss,

E_{RMS} = the voltage across the coil,

A_e = the cross-sectional area of the core in square centimeters,

N = the number of turns in the coil, and

f = the operating frequency in Hz.

Example: What is the maximum ac flux density for a coil of 15 turns if the frequency is 7.0 MHz, the RMS voltage is 25 V and the cross-sectional area of the core is 0.133 cm^2 ?

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \\ = \frac{25 \times 10^8}{4.44 \times 0.133 \times 15 \times 7.0 \times 10^6} \\ = \frac{25 \times 10^8}{62 \times 10^6} = 40 \text{ gauss}$$

Since the recommended limit for cores operated at 7 MHz is 57 gauss, this coil is well within guidelines.

FERRITE TOROIDAL INDUCTORS

Although nearly identical in general appearance to powdered-iron cores, ferrite cores differ in a number of important characteristics. They are often unpainted, unlike powdered-iron toroids. Ferrite toroids often have sharp edges, while powdered-iron toroids usually have rounded edges. Composed of nickel-zinc ferrites for lower permeability ranges and of manganese-zinc ferrites for higher permeabilities, these cores span the permeability range from 20 to above 10000. Nickel-zinc cores with permeabilities from 20 to 800 are useful in high-Q applications, but function more commonly in amateur applications as RF chokes. They are also useful in wide-band transformers (discussed later in this chapter).

Because of their higher permeabilities, the formulas for calculating inductance and turns require slight modification. Manufacturers list ferrite A_L values in mH per 1000 turns. Thus, to calculate inductance, the formula is

$$L = \frac{A_L \times N^2}{1000000} \quad (72)$$

where:

L = the inductance in mH,

A_L = the inductance index in mH per 1000 turns, and

N = the number of turns.

Example: What is the inductance of a 60-turn coil on a core with an A_L of 523? (See the **Component Data and References** chapter for more detailed data on the range of available cores.)

$$L = \frac{A_L \times N^2}{1000000} = \frac{523 \times 60^2}{1000000}$$

$$= \frac{1.88 \times 10^6}{1 \times 10^6} = 1.88 \text{ mH}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 1000 \sqrt{\frac{L}{A_L}} \quad (73)$$

Example: How many turns are needed for a 1.2-mH coil if the A_L for the selected core is 150?

$$N = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{1.2}{150}}$$

$$= 1000 \sqrt{0.008} = 1000 \times 0.089 = 89 \text{ turns}$$

For inductors carrying both dc and ac currents, the upper saturation limit for most ferrites is a flux density of 2000 gauss, with power calculations identical to those used for powdered-iron cores. For detailed information on available cores and their characteristics, see *Iron-Powder and Ferrite Coil Forms*, a combination catalog and information book from Amidon Associates, Inc.

Ohm's Law for Reactance

Only ac circuits containing capacitance or inductance (or both) have reactance. Despite the fact that the voltage in such circuits is 90° out of phase with the current, circuit reactance does limit current in a manner that corresponds to resistance. Therefore, the Ohm's Law equations relating voltage, current and resistance apply to purely reactive circuits:

$$E = IX \quad (74)$$

$$I = \frac{E}{X} \quad (75)$$

$$X = \frac{E}{I} \quad (76)$$

where:

E = ac voltage in RMS,

I = ac current in amperes, and

X = inductive or capacitive reactance.

Example: What is the voltage across a capacitor of 200 pF at 7.15 MHz, if the current through the capacitor is 50 mA?

Since the reactance of the capacitor is a function of both frequency and capacitance, first calculate the reactance:

$$X_C = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 7.15 \times 10^6 \text{ Hz} \times 200 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{8980} \quad 111 \Omega$$

Next, use Ohm's Law:

$$E = I \times X_C = 0.050 \text{ A} \times 111 \Omega = 5.6 \text{ V}$$

Example: What is the current through an 8.00-H inductor at 120 Hz, if 420 V is applied?

$$X_L = 2\pi f L = 2 \times 3.1416 \times 120 \text{ Hz} \times 8.00 \text{ H} = 6030 \Omega$$

Fig 4.60 charts the reactances of capacitors from 1 pF to 100 μF , and the reactances of inductors from 0.1 μH to 10 H, for frequencies between 100 Hz and 100 MHz. Approximate values of reactance can be read or interpolated from the chart. The formulas will produce more exact values, however.

Although both inductive and capacitive reactance limit current, the two types of reactance differ. With capacitive reactance, the current *leads* the voltage by 90° , whereas with inductive reactance, the current *lags* the voltage by 90° . The convention for charting the two types of reactance appears in **Fig 4.61**. On this graph, inductive reactance is plotted along the $+90^\circ$ vertical line, while capacitive reactance is plotted along the -90° vertical line. This convention of assigning a positive value to inductive reactance and a negative value to capacitive reactance results from the mathematics involved in impedance calculations.

REACTANCES IN SERIES AND PARALLEL

If a circuit contains two reactances of the same type, whether in series or in parallel, the resultant reactance can be deter-

mined by applying the same rules as for resistances in series and in parallel. Series reactance is given by the formula

$$X_{\text{total}} = X_1 + X_2 + X_3 + \dots + X_n \quad (77)$$

Example: Two noninteracting inductances are in series. Each has a value of 4.0 μH , and the operating frequency is 3.8 MHz. What is the resulting reactance?

The reactance of each inductor is:

$$X_L = 2\pi f L = 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 4 \times 10^{-6} \text{ H} = 96 \Omega$$

$$X_{\text{total}} = X_1 + X_2 = 96 \Omega + 96 \Omega = 192 \Omega$$

We might also calculate the total reactance by first adding the inductances:

$$L_{\text{total}} = L_1 + L_2 = 4.0 \mu\text{H} + 4.0 \mu\text{H} = 8.0 \mu\text{H}$$

$$X_{\text{total}} = 2\pi f L = 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 8.0 \times 10^{-6} \text{ H}$$

$$X_{\text{total}} = 191 \Omega$$

(The fact that the last digit differs by one illustrates the uncertainty of the calculation caused by the uncertainty of the measured values in the problem, and differences caused by rounding off the calculated values. This also shows why it is important to follow the rules for significant figures.)

Example: Two noninteracting capacitors are in series. One has a value of 10.0 pF, the other of 20.0 pF. What is the resulting reactance in a circuit operating at 28.0 MHz?

Fig 4.60 — Inductive and capacitive reactance vs frequency. Heavy lines represent multiples of 10, intermediate lines multiples of 5. For example, the light line between 10 μH and 100 μH represents 50 μH ; the light line between 0.1 μF and 1 μF represents 0.5 μF , and so on. Other values can be extrapolated from the chart. For example, the reactance of 10 H at 60 Hz can be found by taking the reactance of 10 H at 600 Hz and dividing by 10 for the 10 times decrease in frequency.

$$X_{C1} = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 10.0 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{1760} = 568 \Omega$$

$$X_{C2} = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 20.0 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{3520} = 284 \Omega$$

$$X_{\text{total}} = X_{C1} + X_{C2} = 568 \Omega + 284 \Omega = 852 \Omega$$

Alternatively, for series capacitors, the total capacitance is $6.67 \times 10^{-12} \text{ F}$ or 6.67 pF. Then:

$$X_{\text{total}} = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 6.67 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{1170} = 855 \Omega$$

(Within the uncertainty of the measured values and the rounding of values in the calculations, this is the same result as we obtained with the first method.)

This example serves to remind us that *series capacitance* is not calculated in the manner used by other *series resistance* and *inductance*, but *series capacitive reactance* does follow the simple addition formula.

For reactances of the same type in parallel, the general formula is:

$$X_{\text{total}} = \frac{1}{\frac{1}{X_1} + \frac{1}{X_2} + \frac{1}{X_3} + \dots + \frac{1}{X_n}} \quad (78)$$

Fig 4.61 — The conventional method of plotting reactances on the vertical axis of a graph, using the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance. The horizontal axis will be used for resistance in later examples.

or, for exactly two reactances in parallel

$$X_{\text{total}} = \frac{X_1 \times X_2}{X_1 + X_2} \quad (79)$$

Example: Place the capacitors in the last example (10.0 pF and 20.0 pF) in parallel in the 28.0 MHz circuit. What is the resultant reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{X_1 \times X_2}{X_1 + X_2} \\ &= \frac{568 \Omega \times 284 \Omega}{568 \Omega + 284 \Omega} = 189 \Omega \end{aligned}$$

Alternatively, two capacitors in parallel add their capacitances.

$$C_{\text{total}} = C_1 + C_2 = 10.0 \text{ pF} + 20.0 \text{ pF} = 30 \text{ pF}$$

$$\begin{aligned} X_C &= \frac{1}{2\pi f C} \\ &= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 30 \times 10^{-12} \text{ F}} \\ &= \frac{10^6 \Omega}{5280} = 189 \Omega \end{aligned}$$

Example: Place the series inductors above (4.0 μH each) in parallel in a 3.8-MHz circuit. What is the resultant reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{X_{L1} \times X_{L2}}{X_{L1} + X_{L2}} \\ &= \frac{96 \Omega \times 96 \Omega}{96 \Omega + 96 \Omega} = 48 \Omega \end{aligned}$$

Of course, equal reactances (or resistances) in parallel yield a reactance that is the value of one of them divided by the number (n) of equal reactances, or:

$$X_{\text{total}} = \frac{X}{n} = \frac{96 \Omega}{2} = 48 \Omega$$

All of these calculations apply only to reactances of the same type; that is, all capacitive or all inductive. Mixing types of reactances requires a different approach.

UNLIKE REACTANCES IN SERIES

When combining unlike reactances — that is, combinations of inductive and capacitive reactance — in series, it is necessary to take into account that the voltage-to-current phase relationships differ for the different types of reactance. **Fig 4.62** shows a series circuit with both types of reactance. Since the reactances are in series, the current must be the same in both. The voltage across each circuit element differs in phase, however. The voltage E_L leads the current by 90°, and the voltage E_C lags the current by 90°. Therefore, E_L and E_C have opposite polarities and cancel each other in whole or in part. The dotted line in **Fig 4.62** approximates the resulting voltage E , which is the difference between E_L and E_C .

Since, for a constant current, the reactance is directly proportional to the voltage, the net reactance must be the difference between the inductive and the capacitive reactances, or:

$$X_{\text{total}} = X_L - X_C \quad (80)$$

For this and subsequent calculations in which there is a mixture of inductive and capacitive reactance, use the absolute value of each reactance. The convention of recording inductive reactances as positive and capacitive reactances as negative is built into the mathematical operators in the formulas.

Example: Using **Fig 4.62** as a visual aid, let $X_C = 20.0 \Omega$ and $X_L = 80.0 \Omega$. What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= X_L - X_C \\ &= 80.0 \Omega - 20.0 \Omega = +60.0 \Omega \end{aligned}$$

Since the result is a positive value, reactance is inductive. Had the result been a negative number, the reactance would have been capacitive.

When reactance types are mixed in a series circuit, the resulting reactance is always smaller than the larger of the two reactances. Likewise, the resulting voltage across the series combination of reactances is always smaller than the larger of the two voltages across individual reactances.

Every series circuit of mixed reactance types with more than two circuit elements can be reduced to the type of circuit covered here. If the circuit has more than one capacitor or more than one inductor in the overall series string, first use the formulas given earlier to determine the total series inductance alone and the total series capacitance alone (or their respective reactances). Then combine the resulting single capacitive reactance and single inductive reactance as shown in this section.

UNLIKE REACTANCES IN PARALLEL

The situation of parallel reactances of mixed type appears in **Fig 4.63**. Since the elements are in parallel, the voltage is common to both reactive components. The current through the capacitor, I_C , leads the voltage by 90°, and the current through the inductor, I_L , lags the voltage by 90°. The two currents are 180° out of phase and thus cancel each other in whole or in part. The total current is the difference between the individual currents, as indicated by the dotted line in **Fig 4.63**.

Since reactance is the ratio of voltage to current, the total reactance in the circuit is:

$$X_{\text{total}} = \frac{E}{I_L - I_C} \quad (81)$$

In the drawing, I_C is larger than I_L , and the resulting differential current retains the phase of I_C . Therefore, the overall reactance, X_{total} , is capacitive in this case. The total reactance of the circuit will be smaller than the larger of the individual reactances, because the total current is smaller than the larger of the two individual currents.

In parallel circuits of this type, reactance and current are inversely proportional to each other for a constant voltage. Therefore, to calculate the total reactance directly from the individual reactances, use the formula:

Fig 4.62 — A series circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

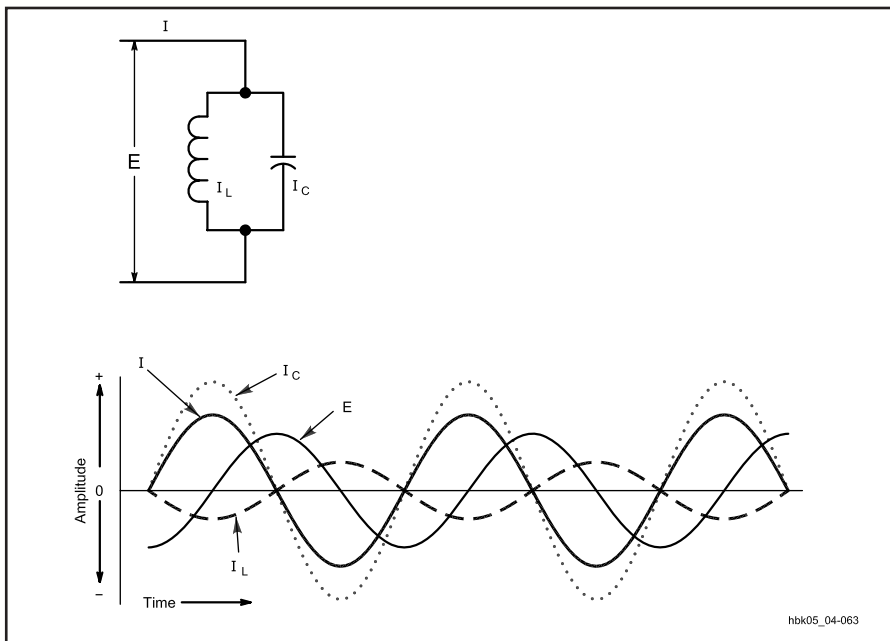

Fig 4.63 — A parallel circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

$$X_{\text{total}} = \frac{-X_L \times X_C}{X_L - X_C} \quad (82)$$

As with the series formula for mixed reactances, use the absolute values of the reactances, since the minus signs in the formula take into account the convention of treating capacitive reactances as nega-

tive numbers. If the solution yields a negative number, the resulting reactance is capacitive, and if the solution is positive, then the reactance is inductive.

Example: Using Fig 4.63 as a visual aid, place a capacitive reactance of 10.0Ω in parallel with an inductive reactance of 40.0Ω . What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{-X_L \times X_C}{X_L - X_C} \\ &= \frac{-40.0 \Omega \times 10.0 \Omega}{40.0 \Omega - 10.0 \Omega} \\ &= \frac{-400 \Omega}{30.0 \Omega} = -13.3 \Omega \end{aligned}$$

The reactance is capacitive, as indicated by the negative solution. Moreover, the resultant reactance is always smaller than the larger of the two individual reactances.

As with the case of series reactances, if each leg of a parallel circuit contains more than one reactance, first simplify each leg to a single reactance. If the reactances are of the same type in each leg, the series reactance formulas for reactances of the same type will apply. If the reactances are of different types, then use the formulas shown above for mixed series reactances to simplify the leg to a single value and type of reactance.

APPROACHING RESONANCE

When two unlike reactances have the same numerical value, any series or parallel circuit in which they occur is said to be *resonant*. For any given inductance or capacitance, it is theoretically possible to find a value of the opposite reactance type to produce a resonant circuit for any desired frequency.

When a series circuit like the one shown in Fig 4.62 is resonant, the voltages E_C and E_L are equal and cancel; their sum is zero. Since the reactance of the circuit is proportional to the sum of these voltages, the total reactance also goes to zero. Theoretically, the current, as shown in Fig 4.64, can rise without limit. In fact, it is limited only by power losses in the components and other resistances that would be in a real circuit of this type. As the frequency of operation moves slightly off resonance, the reactance climbs rapidly and then begins to level off. Similarly, the current drops rapidly off resonance and then levels.

In a parallel-resonant circuit of the type in Fig 4.63, the current I_L and I_C are equal and cancel to zero. Since the reactance is inversely proportional to the current, as the current approaches zero, the reactance rises without limit. As with series circuits, component power losses and other resistances in the circuit limit the current drop to some point above zero. Fig 4.65 shows the theoretical current curve near and at resonance for a purely reactive parallel-resonant circuit. Note that in both Fig 4.64 and Fig 4.65, the departure of current from the resonance value is close to, but not quite, symmetrical above and below the

resonant frequency.

Example: What is the reactance of a series L-C circuit consisting of a 56.04-pF capacitor and an 8.967- μ H inductor at 7.00, 7.10 and 7.20 MHz? Using the formulas from earlier in this chapter, we calculate a table of values:

Frequency (MHz)	X_L (Ω)	X_C (Ω)	X_{total} (Ω)
7.000	394.4	405.7	-11.3
7.100	400.0	400.0	0
7.200	405.7	394.4	11.3

The exercise shows the manner in which the reactance rises rapidly as the frequency moves above and below resonance. Note that in a series-resonant circuit, the reactance at frequencies below resonance is capacitive, and above resonance, it is inductive. Fig 4.66 displays this fact graphically. In a parallel-resonant circuit, where the reactance increases without limit at resonance, the opposite condition exists: above resonance, the reactance is capacitive and below resonance it is inductive, as shown in Fig 4.67. Of course, all graphs and calculations in this section are theoretical and presume a purely reactive circuit. Real circuits are never purely reactive; they contain some resistance that modifies their performance considerably. Real resonant circuits will be discussed later in this chapter.

REACTIVE POWER

Although purely reactive circuits, whether simple or complex, show a mea-

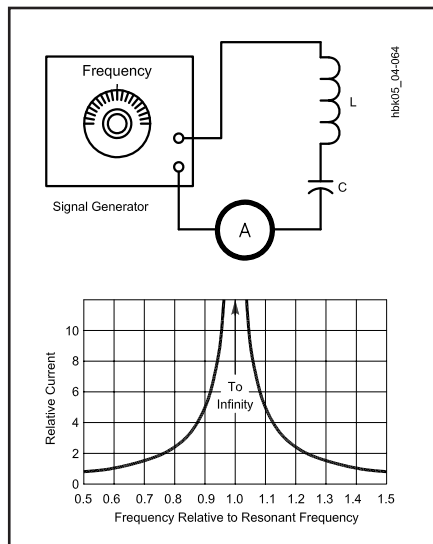

Fig 4.64 — The relative generator current with a fixed voltage in a series circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance.

Fig 4.65 — The relative generator current with a fixed voltage in a parallel circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance. (The circulating current through the parallel inductor and capacitor is a maximum at resonance.)

Fig 4.66 — The transition from capacitive to inductive reactance in a series-resonant circuit as the frequency passes resonance.

Fig 4.67 — The transition from inductive to capacitive reactance in a parallel-resonant circuit as the frequency passes resonance.

surable ac voltage and current, we cannot simply multiply the two together to arrive at power. Power is the rate at which energy is consumed by a circuit, and purely reactive circuits do not consume power. The charge placed on a capacitor during part of an ac cycle is returned to the circuit during the next part of a cycle. Likewise, the energy stored in the magnetic field of an inductor returns to the circuit as the field collapses later in the ac cycle. A reactive circuit simply cycles and recycles energy into and out of the reactive components. If a purely reactive circuit were possible in reality, it would consume no power at all.

In reactive circuits, circulation of energy accounts for seemingly odd phenomena. For example, in a series circuit with capacitance and inductance, the voltages across the components may exceed the supply voltage. That condition can exist because, while energy is being stored by the inductor, the capacitor is returning energy to the circuit from its previously charged state, and vice versa. In a parallel circuit with inductive and capacitive branches, the current circulating through the components may exceed the current drawn from the source. Again, the phenomenon occurs because the inductor's collapsing field supplies current to the capacitor, and the discharging capacitor provides current to the inductor.

To distinguish between the non-dissipated power in a purely reactive circuit and the dissipated power of a resistive circuit, the unit of reactive power is called the *volt-ampere reactive*, or VAR. The term watt is not used; sometimes reactive power is called wattless power. Formulas similar to those for resistive power are used to calculate VAR:

$$\text{VAR} = I \times E \quad (83)$$

$$\text{VAR} = I^2 \times X \quad (84)$$

$$\text{VAR} = \frac{E^2}{X} \quad (85)$$

These formulas have only limited use in radio work.

REACTANCE AND COMPLEX WAVEFORMS

All of the formulas and relationships shown in this section apply to alternating current in the form of regular sine waves. Complex wave shapes complicate the reactive situation considerably. A complex or nonsinusoidal wave can be resolved into a fundamental frequency and a series of harmonic frequencies whose amplitudes depend on the original wave shape. When such a complex wave — or

collection of sine waves — is applied to a reactive circuit, the current through the circuit will not have the same wave shape as the applied voltage. The difference results because the reactance of an inductor and capacitor depend in part on the applied frequency.

For the second-harmonic component of the complex wave, the reactance of the inductor is twice and the reactance of the capacitor is half their respective values at the fundamental frequency. A third-harmonic component produces inductive reactances that are triple and capacitive reactances that are one-third those at the fundamental frequency. Thus, the overall circuit reactance is different for each harmonic component.

The frequency sensitivity of a reactive circuit to various components of a com-

Fig 4.68 — A signal path with a series inductor and a shunt capacitor. The circuit presents different reactances to an ac signal and to its harmonics.

plex wave shape creates both difficulties and opportunities. On the one hand, calculating the circuit reactance in the presence of highly variable as well as complex waveforms, such as speech, is difficult at

best. On the other hand, the frequency sensitivity of reactive components and circuits lays the foundation for filtering, that is, for separating signals of different frequencies and passing them into different circuits. For example, suppose a coil is in the series path of a signal and a capacitor is connected from the signal line to ground, as represented in Fig 4.68. The reactance of the coil to the second harmonic of the signal will be twice that at the fundamental frequency and oppose more effectively the flow of harmonic current. Likewise, the reactance of the capacitor to the harmonic will be half that to the fundamental, allowing the harmonic an easier current path away from the signal line toward ground. See the **RF and AF Filters** chapter for detailed information on filter theory and construction.

Impedance

When a circuit contains both resistance and reactance, the combined opposition to current is called *impedance*. Symbolized by the letter *Z*, impedance is a more general term than either resistance or reactance. Frequently, the term is used even for circuits containing only resistance or reactance. Qualifications such as “resistive impedance” are sometimes added to indicate that a circuit has only resistance, however.

The reactance and resistance comprising an impedance may be connected either in series or in parallel, as shown in Fig 4.69. In these circuits, the reactance is shown as a box to indicate that it may be either inductive or capacitive. In the series circuit at A, the current is the same in both elements, with (generally) different voltages appearing across the resistance and reactance. In the parallel circuit at B, the same voltage is applied to both elements, but different currents may flow in the two branches.

In a resistance, the current is in phase with the applied voltage, while in a reactance it is 90° out of phase with the voltage. Thus, the phase relationship between current and voltage in the circuit as a whole may be anything between zero and 90° , depending on the relative amounts of resistance and reactance.

As shown in Fig 4.61 in the preceding

section, reactance is graphed on the vertical (Y) axis to record the phase difference between the voltage and the current. Fig 4.70 adds resistance to the graph. Since the voltage is in phase with the current, resistance is recorded on the horizontal axis, using the positive or right side of the scale.

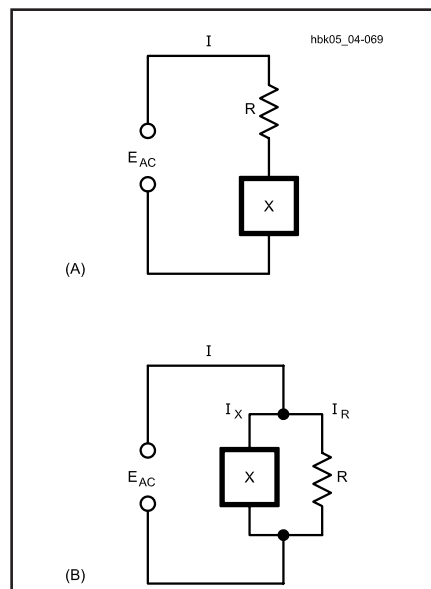

Fig 4.69 — Series and parallel circuits containing resistance and reactance.

CALCULATING Z FROM R AND X IN SERIES CIRCUITS

Impedance is the complex combination of resistance and reactance. Since there is a 90° phase difference between resistance and reactance (whether inductive or capacitive), simply adding the two values will not yield what actually happens in a

Fig 4.70 — The conventional method of charting impedances on a graph, using the vertical axis for reactance (the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance), and using the horizontal axis for resistance.

circuit. Therefore, expressions like “ $Z = R \pm X$ ” can be misleading, because they suggest simple addition. As a result, impedance is often expressed “ $Z = R \pm jX$.”

In pure mathematics, “ i ” indicates an imaginary number. Because i represents current in electronics, we use the letter “ j ” for the same mathematical operator, although there is nothing imaginary about what it represents in electronics. With respect to resistance and reactance, the letter j is normally assigned to those figures on the vertical scale, 90° out of phase with the horizontal scale. The actual function of j is to indicate that calculating impedance from resistance and reactance requires *vector addition*. In vector addition, the result of combining two values at a 90° phase difference results in a new quantity for the combination, and also in a new combined phase angle relative to the base line.

Consider Fig 4.71, a series circuit consisting of an inductive reactance and a resistance. As given, the inductive reactance is 100Ω and the resistance is 50Ω . Using *rectangular coordinates*, the impedance becomes

$$Z = R + jX \quad (86)$$

Fig 4.71 — A series circuit consisting of an inductive reactance of 100Ω and a resistance of 50Ω . At B, the graph plots the resistance, reactance, and impedance.

where:

Z = the impedance in ohms,

R = the resistance in ohms, and

X = the reactance in ohms.

In the present example,

$$Z = 50 + j100 \Omega$$

As the graph shows, the combined opposition to current (or impedance) is represented by a line triangulating the two given values. The graph will provide an estimate of the value. A more exact way to calculate the resultant impedance involves the formula for right triangles, where the square of the hypotenuse equals the sum of the squares of the two sides. Since impedance is the hypotenuse:

$$Z = \sqrt{R^2 + X^2} \quad (87)$$

In this example:

$$\begin{aligned} Z &= \sqrt{(50 \Omega)^2 + (100 \Omega)^2} \\ &= \sqrt{2500 \Omega^2 + 10000 \Omega^2} \\ &= \sqrt{12500 \Omega^2} = 112 \Omega \end{aligned}$$

The impedance that results from combining 50Ω of resistance with 100Ω of inductive reactance is 112Ω . The phase angle of the resultant is neither 0° nor $+90^\circ$. Instead, it lies somewhere between the two. Let θ be the angle between the horizontal axis and the line representing the impedance. From trigonometry, the tangent of the angle is the side opposite the angle divided by the side adjacent to the angle, or

$$\tan \theta = \frac{X}{R} \quad (88)$$

where:

X = the reactance, and

R = the resistance.

Find the angle by taking the inverse tangent, or arctan:

$$\theta = \arctan \frac{X}{R} \quad (89)$$

In the example shown in Fig 6.57,

$$\theta = \arctan \frac{100 \Omega}{50 \Omega} = \arctan 2.0 = 63.4^\circ$$

Combining the resultant impedance with the angle provides the impedance in *polar coordinate* form:

$$Z \angle \theta \quad (90)$$

Using the information just calculated, the impedance is:

$$Z = 112 \Omega \angle 63.4^\circ$$

The expressions $R \pm jX$ and $Z \angle \theta$ both provide the same information, but in two different forms. The procedure just given permits conversion from rectangular coordinates into polar coordinates. The reverse procedure is also important. Fig 4.72 shows an impedance composed of a capacitive reactance and a resistance. Since capacitive reactance appears as a negative value, the impedance will be at a negative phase angle, in this case, 12.0Ω at a phase angle of -42.0° or $Z = 12.0 \Omega \angle -42.0^\circ$.

Think of the impedance as forming a triangle with the values of X and R from the rectangular coordinates. The reactance axis forms the side opposite the angle θ .

$$\sin \theta = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{X}{Z} \quad (91)$$

Fig 4.72 — A series circuit consisting of a capacitive reactance and a resistance: the impedance is given as 12.0Ω at a phase angle θ of -42 degrees. At B, the graph plots the resistance, reactance, and impedance.

Solving this equation for reactance, we have:

$$X = Z \times \sin \theta \text{ (ohms)} \quad (92)$$

Likewise, the resistance forms the side adjacent to the angle.

$$\cos \theta = \frac{\text{side adjacent}}{\text{hypotenuse}} = \frac{R}{Z}$$

Solving for resistance, we have:

$$R = Z \times \cos \theta \text{ (ohms)} \quad (93)$$

Then from our example:

$$\begin{aligned} X &= 12.0 \Omega \times \sin(-42^\circ) \\ &= 12.0 \Omega \times -0.669 = -8.03 \Omega \\ R &= 12.0 \Omega \times \cos(-42.0^\circ) \\ &= 12.0 \Omega \times 0.743 = 8.92 \Omega \end{aligned}$$

Since X is a negative value, it plots on the lower vertical axis, as shown in Fig 4.72, indicating capacitive reactance. In rectangular form, $Z = 8.92 \Omega - j8.03 \Omega$.

In performing impedance and related calculations with complex circuits, rectangular coordinates are most useful when formulas require the addition or subtraction of values. Polar notation is most useful for multiplying and dividing complex numbers.

All of the examples shown so far in this section have presumed values of reactance that contribute to the circuit impedance. Reactance is a function of frequency, however, and many impedance calculations may begin with a value of capacitance or inductance and an operating frequency. In terms of these values, the series impedance formula (Eq 87) becomes two formulas:

$$Z = \sqrt{R^2 + (2\pi f L)^2} \quad (94)$$

$$Z = \sqrt{R^2 + \left(\frac{1}{2\pi f C}\right)^2} \quad (95)$$

Example: What is the impedance of a circuit like Fig 4.71 with a resistance of 100Ω and a $7.00\text{-}\mu\text{H}$ inductor operating at a frequency of 7.00 MHz ? Using equation 94,

$$\begin{aligned} Z &= \sqrt{R^2 + (2\pi f L)^2} \\ &= \sqrt{(100\Omega)^2 + (2\pi \times 7.00 \times 10^{-6} \text{ H} \times 7.00 \times 10^6 \text{ Hz})^2} \\ Z &= \sqrt{10,000 \Omega^2 + (308 \Omega)^2} \end{aligned}$$

$$= \sqrt{10,000 \Omega^2 + 94,900 \Omega^2}$$

$$= \sqrt{104900 \Omega^2} = 323.9 \Omega$$

Since 308Ω is the value of inductive reactance of the $7.00\text{-}\mu\text{H}$ coil at 7.00 MHz , the phase angle calculation proceeds as given in the earlier example (equation 89):

$$\begin{aligned} \theta &= \arctan \frac{X}{R} = \arctan \left(\frac{308.0 \Omega}{100.0 \Omega} \right) \\ &= \arctan(3.08) = 72.0^\circ \end{aligned}$$

Since the reactance is inductive, the phase angle is positive.

CALCULATING Z FROM R AND X IN PARALLEL CIRCUITS

In a parallel circuit containing reactance and resistance, such as shown in Fig 4.73, calculation of the resultant impedance from the values of R and X does not proceed by direct triangulation. The general formula for such parallel circuits is:

$$Z = \frac{RX}{\sqrt{R^2 + X^2}} \quad (96)$$

where the formula uses the absolute (unsigned) reactance value. The phase angle for the parallel circuit is given by:

$$\theta = \arctan \left(\frac{R}{X} \right) \quad (97)$$

If the parallel reactance is capacitive, then θ is a negative angle, and if the parallel reactance is inductive, then θ is a positive angle.

Example: An inductor with a reactance of 30.0Ω is in parallel with a resistor of 40.0Ω . What is the resulting impedance and phase angle?

Fig 4.73 — A parallel circuit containing an inductive reactance of 30.0Ω and a resistor of 40.0Ω . No graph is given, since parallel impedances do not triangulate in the simple way of series impedances.

$$\begin{aligned} Z &= \frac{RX}{\sqrt{R^2 + X^2}} = \frac{30.0 \Omega \times 40.0 \Omega}{\sqrt{(30.0 \Omega)^2 + (40.0 \Omega)^2}} \\ &= \frac{1200 \Omega^2}{\sqrt{900 \Omega^2 + 1600 \Omega^2}} = \frac{1200 \Omega^2}{\sqrt{2500 \Omega^2}} \end{aligned}$$

$$Z = \frac{1200 \Omega^2}{50.0 \Omega} = 24.0 \Omega$$

$$\theta = \arctan \left(\frac{R}{X} \right) = \arctan \left(\frac{40.0 \Omega}{30.0 \Omega} \right)$$

$$\theta = \arctan(1.33) = 53.1^\circ$$

Since the parallel reactance is inductive, the resultant angle is positive.

Example: A capacitor with a reactance of 16.0Ω is in parallel with a resistor of 12.0Ω . What is the resulting impedance and phase angle?

$$\begin{aligned} Z &= \frac{RX}{\sqrt{R^2 + X^2}} = \frac{16.0 \Omega \times 12.0 \Omega}{\sqrt{(16.0 \Omega)^2 + (12.0 \Omega)^2}} \\ &= \frac{192 \Omega^2}{\sqrt{256 \Omega^2 + 144 \Omega^2}} = \frac{192 \Omega^2}{\sqrt{400 \Omega^2}} \end{aligned}$$

$$Z = \frac{192 \Omega^2}{20.0 \Omega} = 9.60 \Omega$$

$$\theta = \arctan \left(\frac{R}{X} \right) = \arctan \left(\frac{12.0 \Omega}{16.0 \Omega} \right)$$

$$\theta = \arctan(0.750) = -36.9^\circ$$

Because the parallel reactance is capacitive, the resultant phase angle is negative.

ADMITTANCE

Just as the inverse of resistance is conductance (G) and the inverse of reactance is susceptance (B), so too impedance has an inverse: admittance (Y), measured in siemens (S). Thus,

$$Y = \frac{1}{Z} \quad (98)$$

Since resistance, reactance and impedance are inversely proportional to the current ($Z = E / I$), conductance, susceptance and admittance are directly proportional to current. That is,

$$Y = \frac{1}{Z} \quad (99)$$

One handy use for admittance is in simplifying parallel circuit impedance calculations. A parallel combination of reactance and resistance reduces to a vector addition of susceptance and con-

ductance, if admittance is the desired outcome. In other words, for parallel circuits:

$$Y = \sqrt{G^2 + B^2} \quad (100)$$

where:

- Y = admittance,
- G = conductance or 1 / R, and
- B = susceptance or 1 / X.

Example: An inductor with a reactance of 30.0 Ω is in parallel with a resistor of 40.0 Ω. What is the resulting impedance and phase angle? The susceptance is 1 / 30.0 Ω = 0.0333 S and the conductance is 1 / 40.0 Ω = 0.0250 S.

$$\begin{aligned} Y &= \sqrt{(0.0333 \text{ S})^2 + (0.0250 \text{ S})^2} \\ &= \sqrt{0.00173 \text{ S}^2} = 0.0417 \text{ S} \\ Z &= \frac{1}{Y} = \frac{1}{0.0417 \text{ S}} = 24.0 \Omega \end{aligned}$$

The phase angle in terms of conductance and susceptance is:

$$\theta = \arctan\left(\frac{B}{G}\right) \quad (101)$$

In this example,

$$\theta = \arctan\left(\frac{0.0333 \text{ S}}{0.0250 \text{ S}}\right) = \arctan(1.33) = 53.1^\circ$$

Again, since the reactive component is inductive, the phase angle is positive. For a capacitively reactive parallel circuit, the phase angle would have been negative. Compare these results with the direct calculation earlier in the section.

Conversion from resistance, reactance and impedance to conductance, susceptance and admittance is perhaps most useful in complex-parallel-circuit calculations. Many advanced facets of active-circuit analysis will demand familiarity both with the concepts and with the calculation strategies introduced here, however.

More than Two Elements in Series or Parallel

When a circuit contains several resistances or several reactances in series, simplify the circuit before attempting to calculate the impedance. Resistances in series add, just as in a purely resistive circuit. Series reactances of the same kind — that is, all capacitive or all inductive — also add, just as in a purely reactive circuit. The goal is to produce a single value of resistance and a single value of reactance for the impedance calculation.

Fig 4.74 illustrates a more difficult case in which a circuit contains two different reactive elements in series, along with a

further series resistance. The series combination of X_C and X_L reduce to a single value using the same rules of combination discussed in the section on purely reactive components. As Fig 4.74B demonstrates, the resultant reactance is the difference between the two series reactances.

For parallel circuits with multiple resistances or multiple reactances of the same type, use the rules of parallel combination to reduce the resistive and reactive components to single elements. Where two or more reactive components of different types appear in the same circuit, they can be combined using formulas shown earlier for pure reactances. As Fig 4.75 suggests, however, they can also be combined as susceptances. Parallel susceptances of different types add, with attention to their differing signs. The resulting single susceptance can then be combined with the conductance to arrive at the overall circuit admittance. The inverse of the admittance is the final circuit impedance.

Equivalent Series and Parallel Circuits

The two circuits shown in Fig 4.69 are equivalent if the same current flows when a given voltage of the same frequency is applied, and if the phase angle between voltage and current is the same in both cases. It is possible, in fact, to transform any given series circuit into an equivalent parallel circuit, and vice versa.

A series RX circuit can be converted into its parallel equivalent by means of the formulas:

$$R_P = \frac{R_S^2 + X_S^2}{R_S} \quad (102)$$

$$X_P = \frac{R_S^2 + X_S^2}{X_S} \quad (103)$$

Fig 4.74 — A series impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance by combining the reactances algebraically.

where the subscripts P and S represent the parallel- and series-equivalent values, respectively. If the parallel values are known, the equivalent series circuit can be found from:

$$R_S = \frac{R_P X_P^2}{R_P^2 + X_P^2} \quad (104)$$

and

$$X_S = \frac{R_P^2 X_P}{R_P^2 + X_P^2} \quad (105)$$

Example: Let the series circuit in Fig 4.69 have a series reactance of -50.0Ω (indicating a capacitive reactance) and a resistance of 50.0Ω . What are the values of the equivalent parallel circuit?

$$\begin{aligned} R_P &= \frac{R_S^2 + X_S^2}{R_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{50.0 \Omega} \\ &= \frac{2500 \Omega^2 + 2500 \Omega^2}{50.0 \Omega} = \frac{5000 \Omega^2}{50.0 \Omega} = 100 \Omega \end{aligned}$$

$$\begin{aligned} X_P &= \frac{R_S^2 + X_S^2}{X_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{-50.0 \Omega} \\ &= \frac{2500 \Omega^2 + 2500 \Omega^2}{-50.0 \Omega} = \frac{5000 \Omega^2}{-50.0 \Omega} \\ &= -100 \Omega \end{aligned}$$

Fig 4.75 — A parallel impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance using formulas shown earlier in the chapter. By converting reactances to susceptances, as shown in A, you can combine the susceptances algebraically into a single susceptance, as shown in B.

The parallel circuit in Fig 4.69 calls for a capacitive reactance of $100\ \Omega$ and a resistance of $100\ \Omega$ to be equivalent to the series circuit.

OHM'S LAW FOR IMPEDANCE

Ohm's Law applies to circuits containing impedance just as readily as to circuits having resistance or reactance only. The formulas are:

$$E = IZ \quad (106)$$

$$I = \frac{E}{Z} \quad (107)$$

$$Z = \frac{E}{I} \quad (108)$$

where:

- E = voltage in volts,
- I = current in amperes, and
- Z = impedance in ohms.

Fig 4.76 shows a simple circuit consisting of a resistance of $75.0\ \Omega$ and a reactance of $100\ \Omega$ in series. From the series-impedance formula previously given, the impedance is

$$\begin{aligned} Z &= \sqrt{R^2 + X_L^2} = \sqrt{(75.0\ \Omega)^2 + (100\ \Omega)^2} \\ &= \sqrt{5630\ \Omega^2 + 10000\ \Omega^2} = \sqrt{15600\ \Omega^2} \\ &= 125\ \Omega \end{aligned}$$

If the applied voltage is 250 V, then

$$I = \frac{E}{Z} = \frac{250\ \text{V}}{125\ \Omega} = 2.00\ \text{A}$$

This current flows through both the resistance and reactance, so the voltage drops are:

$$E_R = IR = 2.00\ \text{A} \times 75.0\ \Omega = 150\ \text{V}$$

$$E_{X_L} = IX_L = 2.00\ \text{A} \times 100\ \Omega = 200\ \text{V}$$

The simple arithmetical sum of these

two drops, 350 V, is greater than the applied voltage because the two voltages are 90° out of phase. Their actual resultant, when phase is taken into account, is:

$$\begin{aligned} E &= \sqrt{(150\ \text{V})^2 + (200\ \text{V})^2} \\ &= \sqrt{22500\ \text{V}^2 + 40000\ \text{V}^2} = \sqrt{62500\ \text{V}^2} \\ &= 250\ \text{V} \end{aligned}$$

POWER FACTOR

In the circuit of Fig 4.76, an applied voltage of 250 V results in a current of 2.00 A, giving an apparent power of $250\ \text{V} \times 2.00\ \text{A} = 500\ \text{W}$. Only the resistance actually consumes power, however. The power in the resistance is:

$$P = I^2 R = (2.00\ \text{A})^2 \times 75.0\ \Omega = 300\ \text{W}$$

The ratio of the consumed power to the apparent power is called the power factor of the circuit.

$$\text{PF} = \frac{P_{\text{consumed}}}{P_{\text{apparent}}} = \frac{R}{Z} \quad (109)$$

Fig 4.76 — A series circuit consisting of an inductive reactance of $100\ \Omega$ and a resistance of $75.0\ \Omega$. Also shown is the applied voltage, voltage drops across the circuit elements, and the current.

In this example the power factor would be $300\ \text{W} / 500\ \text{W} = 0.600$. Power factor is frequently expressed as a percentage; in this case, 60%. An equivalent definition of power factor is:

$$\text{PF} = \cos \theta$$

where θ is the phase angle. Since the phase angle equals:

$$\theta = \arctan \left(\frac{X}{R} \right) = \arctan \left(\frac{100\ \Omega}{75.0\ \Omega} \right)$$

$$= \arctan(1.33) = 53.1^\circ$$

Then the power factor is:

$$\text{PF} = \cos 53.1^\circ = 0.600$$

as the earlier calculation confirms.

Real, or dissipated, power is measured in watts. Apparent power, to distinguish it from real power, is measured in volt-amperes (VA). It is simply the product of the voltage across and the current through an overall impedance. It has no direct relationship to the power actually dissipated unless the power factor of the circuit is known. The power factor of a purely resistive circuit is 100% or 1, while the power factor of a pure reactance is zero. In this illustration, the reactive power is:

$$\text{VAR} = I^2 X_L = (2.00\ \text{A})^2 \times 100\ \Omega = 400\ \text{VA}$$

Since power factor is always rendered as a positive number, the value must be followed by the words "leading" or "lagging" to identify the phase of the voltage with respect to the current. Specifying the numerical power factor is not always sufficient. For example, many dc-to-ac power inverters can safely operate loads having a large net reactance of one sign but only a small reactance of the opposite sign. Hence, the final calculation of the power factor in this example yields the value 0.600, leading.

Resonant Circuits

A circuit containing both an inductor and a capacitor — and therefore, both inductive and capacitive reactance — is often called a *tuned circuit*. There is a particular frequency at which the inductive and capacitive reactances are the same, that is, $X_L = X_C$. For most purposes, this is the *resonant frequency* of the circuit. (Special considerations apply to parallel circuits; they will emerge in the section devoted to such circuits.) At the resonant frequency — or at resonance, for short:

$$X_L = 2\pi f L = X_C = \frac{1}{2\pi f C}$$

By solving for f , we can find the resonant frequency of any combination of inductor and capacitor from the formula:

$$f = \frac{1}{2\pi\sqrt{LC}} \quad (110)$$

where:

- f = frequency in hertz (Hz),
- L = inductance in henrys (H),
- C = capacitance in farads (F), and
- $\pi = 3.1416$.

For most high-frequency (HF) radio work, smaller units of inductance and capacitance and larger units of frequency are more convenient. The basic formula becomes:

$$f = \frac{10^3}{2\pi\sqrt{LC}} \quad (111)$$

where:

- f = frequency in megahertz (MHz),
- L = inductance in microhenrys (μH),
- C = capacitance in picofarads (pF), and
- $\pi = 3.1416$.

Example: What is the resonant frequency of a circuit containing an inductor of $5.0 \mu\text{H}$ and a capacitor of 35 pF ?

$$f = \frac{10^3}{2\pi\sqrt{LC}} = \frac{10^3}{6.2832 \times \sqrt{5.0 \times 35}}$$

$$= \frac{10^3}{83} = 12 \text{ MHz}$$

To find the matching component (inductor or capacitor) when the frequency and one component is known (capacitor or inductor) for general HF work, use the formula:

$$f^2 = \frac{1}{4\pi^2 LC} \quad (112)$$

where F , L and C are in basic units. For HF

work in terms of MHz, μH and pF, the basic relationship rearranges to these handy formulas:

$$L = \frac{25330}{f^2 C} \quad (113)$$

$$C = \frac{25330}{f^2 L} \quad (114)$$

where:

- f = frequency in MHz,
- L = inductance in μH , and
- C = capacitance in pF.

Example: What value of capacitance is needed to create a resonant circuit at 21.1 MHz , if the inductor is $2.00 \mu\text{H}$?

$$C = \frac{25330}{f^2 L} = \frac{25330}{(21.1^2 \times 2.00)}$$

$$= \frac{25330}{890} = 28.5 \text{ pF}$$

For most radio work, these formulas will permit calculations of frequency and component values well within the limits of component tolerances. Resonant circuits have other properties of importance, in addition to the resonant frequency, however. These include impedance, voltage drop across components in series-resonant circuits, circulating current in parallel-resonant circuits, and bandwidth. These properties determine such factors as the selectivity of a tuned circuit and the component ratings for circuits handling considerable power. Although the basic determination of the tuned-circuit resonant frequency ignored any resistance in the circuit, that resistance will play a vital role in the circuit's other characteristics.

SERIES-RESONANT CIRCUITS

Fig 4.77 presents a basic schematic diagram of a *series-resonant circuit*. Although most schematic diagrams of radio circuits would show only the inductor and the capacitor, resistance is always present in such circuits. The most notable resistance is associated with losses in the inductor at HF; resistive losses in the capacitor are low enough at those frequencies to be ignored. The current meter shown in the circuit is a reminder that in series circuits, the same current flows through all elements.

At resonance, the reactance of the capacitor cancels the reactance of the inductor. The voltage and current are in phase with each other, and the impedance

of the circuit is determined solely by the resistance. The actual current through the circuit at resonance, and for frequencies near resonance, is determined by the formula:

$$I = \frac{E}{Z} = \frac{E}{\sqrt{R^2 + \left[2\pi f L - \frac{1}{2\pi f C}\right]^2}} \quad (115)$$

where all values are in basic units.

At resonance, the reactive factor in the formula is zero. As the frequency is shifted above or below the resonant frequency without altering component values, however, the reactive factor becomes significant, and the value of the current becomes smaller than at resonance. At frequencies far from resonance, the reactive components become dominant, and the resistance no longer significantly affects the current amplitude.

The exact curve created by recording the current as the frequency changes depends on the ratio of reactance to resistance. When the reactance of either the coil or capacitor is of the same order of magnitude as the resistance, the current decreases rather slowly as the frequency is moved in either direction away from resonance. Such a curve is said to be *broad*. Conversely, when the reactance is considerably larger than the resistance, the current decreases rapidly as the frequency moves away from resonance, and the circuit is said to be *sharp*. A sharp circuit will respond a great deal more readily to the resonant frequency than to frequencies quite close to resonance; a broad circuit will respond almost equally well to a

Fig 4.77 — A series circuit containing L , C , and R is resonant at the applied frequency when the reactance of C is equal to the reactance of L . The I in the circle is the schematic symbol for an ammeter.

group or band of frequencies centered around the resonant frequency.

Both types of resonance curves are useful. A sharp circuit gives good selectivity — the ability to respond strongly (in terms of current amplitude) at one desired frequency and to discriminate against others. A broad circuit is used when the apparatus must give about the same response over a band of frequencies, rather than at a single frequency alone.

Fig 4.78 presents a family of curves, showing the decrease in current as the frequency deviates from resonance. In each case, the reactance is assumed to be 1000 Ω. The maximum current, shown as a relative value on the graph, occurs with the lowest resistance, while the lowest peak current occurs with the highest resistance. Equally important, the rate at which the current decreases from its maximum value also changes with the ratio of reactance to resistance. It decreases most rapidly when the ratio is high and most slowly when the ratio is low.

Q

As noted in earlier sections of this chapter, the ratio of reactance or stored energy to resistance or consumed energy is Q. Since both terms of the ratio are measured in ohms, Q has no units and is variously known as the *quality factor*, the *figure of merit* or the *multiplying factor*. Since the resistive losses of the coil dominate the energy consumption in HF series-resonant

Fig 4.78 — Current in series-resonant circuits with various values of series resistance and Q. The current values are relative to an arbitrary maximum of 1.0. The reactance for all curves is 1000 Ω. Note that the current is hardly affected by the resistance in the circuit at frequencies more than 10% away from the resonant frequency.

circuits, the inductor Q largely determines the resonant-circuit Q. Since this value of Q is independent of any external load to which the circuit might transfer power, it is called the *unloaded Q* or Q_U of the circuit.

Example: What is the unloaded Q of a series-resonant circuit with a loss resistance of 5 Ω and inductive and capacitive components having a reactance of 500 Ω each? With a reactance of 50 Ω each?

$$Q_{U1} = \frac{X1}{R} = \frac{500 \Omega}{5 \Omega} = 100$$

$$Q_{U2} = \frac{X2}{R} = \frac{50 \Omega}{5 \Omega} = 10$$

Bandwidth

Fig 4.79 is an alternative way of drawing the family of curves that relate current to frequency for a series-resonant circuit. By assuming that the peak current of each curve is the same, the rate of change of current for various values of Q_U and the associated ratios of reactance to resistance are more easily compared. From the curves, it is evident that the lower Q_U circuits pass frequencies over a greater *bandwidth* of frequencies than the circuits with a higher Q_U . For the purpose of comparing tuned circuits, bandwidth is often defined as the frequency spread between the two frequencies at which the current amplitude decreases to 0.707 (or $1/\sqrt{2}$) times the

Fig 4.79 — Current in series-resonant circuits having different values of Q_U . The current at resonance is set at the same level for all curves in order to show the rate of change of decrease in current for each value of Q_U . The half-power points are shown to indicate relative bandwidth of the response for each curve. The bandwidth is indicated for a circuit with a Q_U of 10.

maximum value. Since the power consumed by the resistance, R, is proportional to the square of the current, the power at these points is half the maximum power at resonance, assuming that R is constant for the calculations. The half-power, or -3 dB, points are marked on Fig 4.79.

For Q values of 10 or greater, the curves shown in Fig 4.79 are approximately symmetrical. On this assumption, bandwidth (BW) can be easily calculated:

$$BW = \frac{f}{Q_U} \quad (116)$$

where BW and f are in the same units, that is, in Hz, kHz or MHz.

Example: What is the bandwidth of a series-resonant circuit operating at 14 MHz with a Q_U of 100?

$$BW = \frac{f}{Q_U} = \frac{14 \text{ MHz}}{100} = 0.14 \text{ MHz} = 140 \text{ kHz}$$

The relationship between Q_U , f and BW provides a means of determining the value of circuit Q when inductor losses may be difficult to measure. By constructing the series-resonant circuit and measuring the current as the frequency varies above and below resonance, the half-power points can be determined. Then:

$$Q_U = \frac{f}{BW} \quad (117)$$

Example: What is the Q_U of a series-resonant circuit operating at 3.75 MHz, if the bandwidth is 375 kHz?

$$Q_U = \frac{f}{BW} = \frac{3.75 \text{ MHz}}{0.375 \text{ MHz}} = 10.0$$

Table 4.7 provides some simple formulas for estimating the maximum current and phase angle for various bandwidths, if both f and Q_U are known.

Voltage Drop Across Components

The voltage drop across the coil and across the capacitor in a series-resonant circuit are each proportional to the reactance of the component for a given current (since $E = I X$). These voltages may be many times the source voltage for a high-Q circuit. In fact, at resonance, the voltage drop is:

$$E_X = Q_U E \quad (118)$$

where:

E_X = the voltage across the reactive component,

Q_U = the circuit unloaded Q, and
E = the source voltage.

Table 4.7

The Selectivity of Resonant Circuits

Approximate percentage of current at resonance ¹ or of impedance at resonance ²	Bandwidth (between half-power or -3 dB points on response curve)	Series circuit current phase angle (degrees)
95	f / 3Q	18.5
90	f / 2Q	26.5
70.7	f / Q	45
44.7	2f / Q	63.5
24.2	4f / Q	76
12.4	8f / Q	83

¹For a series resonant circuit
²For a parallel resonant circuit

(Note that the voltage drop across the inductor is the vector sum of the voltages across the resistance and the reactance; however, for Qs greater than 10, the error created by using equation 96 is not ordinarily significant.) Since the calculated value of E_x is the RMS voltage, the peak voltage will be higher by a factor of 1.414. Antenna couplers and other high-Q circuits handling significant power may experience arcing from high values of E_x , even though the source voltage to the circuit is well within component ratings.

Capacitor Losses

Although capacitor energy losses tend to be insignificant compared to inductor losses up to about 30 MHz, the losses may affect circuit Q in the VHF range. Leakage resistance, principally in the solid dielectric that forms the insulating support for the capacitor plates, is not exactly like the wire resistance losses in a coil. Instead of forming a series resistance, capacitor leakage usually forms a parallel resistance with the capacitive reactance. If the leakage resistance of a capacitor is significant enough to affect the Q of a series-resonant circuit, the parallel resistance must be converted to an equivalent series resistance before adding it to the inductor's resistance.

$$R_s = \frac{X_C^2}{R_p} = \frac{1}{R_p \times (2\pi f C)^2} \quad (119)$$

Example: A 10.0 pF capacitor has a leakage resistance of 10000 Ω at 50.0 MHz. What is the equivalent series resistance?

$$R_s = \frac{1}{R_p \times (2\pi f C)^2}$$

$$= \frac{1}{1.00 \times 10^4 \times (6.283 \times 50.0 \times 10^6 \times 10.0 \times 10^{-12})^2}$$

Fig 4.80 — A typical parallel-resonant circuit, with the resistance shown in series with the inductive leg of the circuit. Below a Q_U of 10, resonance definitions may lead to three separate frequencies which converge at higher Q_U levels. See text.

$$R_s = \frac{1}{1.00 \times 10^4 \times 9.87 \times 10^{-6}}$$

$$= \frac{1}{0.0987} = 10.1 \Omega$$

In calculating the impedance, current and bandwidth for a series-resonant circuit in which this capacitor might be used, the series-equivalent resistance of the unit is added to the loss resistance of the coil. Since inductor losses tend to increase with frequency because of skin effect, the combined losses in the capacitor and the

inductor can seriously reduce circuit Q, without special component- and circuit-construction techniques.

PARALLEL-RESONANT CIRCUITS

Although series-resonant circuits are common, the vast majority of resonant circuits used in radio work are *parallel-resonant circuits*. Fig 4.80 represents a typical

Fig 4.81 — Resonant conditions for a low- Q_U parallel circuit. Resonance may be defined as (a) $X_L = X_C$, (b) minimum current flow and maximum impedance or (c) voltage and current in phase with each other. With the circuit of Fig 4.80 and a Q_U of less than 10, these three definitions may represent three distinct frequencies.

HF parallel-resonant circuit. As is the case for series-resonant circuits, the inductor is the chief source of resistive losses, and these losses appear in series with the coil. Because current through parallel-resonant circuits is lowest at resonance, and impedance is highest, they are sometimes called *antiresonant* circuits. Likewise, the names *acceptor* and *rejector* are occasionally applied to series- and parallel-resonant circuits, respectively.

Because the conditions in the two legs of the parallel circuit in Fig 4.80 are not the same — the resistance is in only one of the legs — all of the conditions by which series resonance is determined do not occur simultaneously in a parallel-resonant circuit. Fig 4.81 graphically illustrates the situation by showing the currents through the two components. When the inductive and capacitive reactances are identical, the condition defined for series resonance is met as shown in line (A). The impedance of the inductive leg is composed of both X_L and R , which yields an impedance that is greater than X_C and that is not 180° out of phase with X_C . The resultant current is greater than its minimum possible value and not in phase with the voltage.

By altering the value of the inductor slightly (and holding the Q constant), a new frequency can be obtained at which the current reaches its minimum. When parallel circuits are tuned using a current meter as an indicator, this point (B) is ordinarily used as an indication of resonance. The current “dip” indicates a condition of maximum impedance and is sometimes called the *antiresonant* point or *maximum impedance resonance* to distinguish it from the condition where $X_C = X_L$. Maximum impedance is achieved by vector addition of X_C , X_L and R , however, and the result is a current somewhat out of phase with the voltage.

Point (C) on the curve represents the *unity-power-factor* resonant point. Adjusting the inductor value and hence its reactance (while holding Q constant) produces a new resonant frequency at which the resultant current is in phase with the voltage. The inductor’s new value of reactance is the value required for a parallel-equivalent inductor and its parallel-equivalent resistor (calculated according to the formulas in the last section) to just cancel the capacitive reactance. The value of the parallel-equivalent inductor is always smaller than the actual inductor in series with the resistor and has a proportionally smaller reactance. (The parallel-equivalent resistor, conversely, will always be larger than the coil-loss resistor shown in series with the inductor.) The result is a resonant frequency slightly dif-

ferent from the one for minimum current and the one for $X_L = X_C$.

The points shown in the graph in Fig 4.81 represent only one of many possible situations, and the relative positions of the three resonant points do not hold for all possible cases. Moreover, specific circuit designs can draw some of the resonant points together, for example, compensating for the resistance of the coil by retuning the capacitor. The differences among these resonances are significant for circuit Q s below 10, where the inductor’s series resistance is a significant percentage of the reactance. Above a Q of 10, the three points converge to within a percent of the frequency and can be ignored for practical calculations. Tuning for minimum current will not introduce a sufficiently large phase angle between voltage and current to create circuit difficulties.

Parallel Circuits of Moderate to High Q

The resonant frequencies defined above converge in parallel-resonant circuits with Q s higher than about 10. Therefore, a single set of formulas will sufficiently approximate circuit performance for accurate predictions. Indeed, above a Q of 10, the performance of a parallel circuit appears in many ways to be simply the inverse of the performance of a series-resonant circuit using the same components.

Accurate analysis of a parallel-resonant circuit requires the substitution of a parallel-equivalent resistor for the actual inductor-loss series resistor, as shown in Fig 4.82. Sometimes called the *dynamic resistance* of the parallel-resonant circuit, the parallel-equivalent resistor value will increase with circuit Q , that is, as the series resistance value decreases. To calculate

the approximate parallel-equivalent resistance, use the formula:

$$R_P = \frac{X_L^2}{R_S} = \frac{(2\pi f L)^2}{R_S} = Q_U X_L \quad (120)$$

Example: What is the parallel-equivalent resistance for a coil with an inductive reactance of 350Ω and a series resistance of 5.0Ω at resonance?

$$\begin{aligned} R_P &= \frac{X_L^2}{R_S} = \frac{(350 \Omega)^2}{5.0 \Omega} \\ &= \frac{122,500 \Omega^2}{5.0 \Omega} = 24,500 \Omega \end{aligned}$$

Since the coil Q_U remains the inductor’s reactance divided by its series resistance, the coil Q_U is 70. Multiplying Q_U by the reactance also provides the approximate parallel-equivalent resistance of the coil series resistance.

At resonance, where $X_L = X_C$, R_P defines the impedance of the parallel-resonant circuit. The reactances just equal each other, leaving the voltage and current in phase with each other. In other words, the circuit shows only the parallel resistance. Therefore, equation 120 can be rewritten as:

$$Z = \frac{X_L^2}{R_S} = \frac{(2\pi f L)^2}{R_S} = Q_U X_L \quad (121)$$

In this example, the circuit impedance at resonance is $24,500 \Omega$.

At frequencies below resonance the current through the inductor is larger than that through the capacitor, because the reactance of the coil is smaller and that of the capacitor is larger than at resonance. There is only partial cancellation of the two reactive currents, and the line current therefore is larger than the current taken by the resistance alone. At frequencies above resonance the situation is reversed and more current flows through the capacitor than through the inductor, so the line current again increases. The current at resonance, being determined wholly by R_P , will be small if R_P is large, and large if R_P is small. Fig 4.83 illustrates the relative current flows through a parallel-tuned circuit as the frequency is moved from below resonance to above resonance. The base line represents the minimum current level for the particular circuit. The actual current at any frequency off resonance is simply the vector sum of the currents through the parallel equivalent resistance and through the reactive components.

To obtain the impedance of a parallel-tuned circuit either at or off the resonant

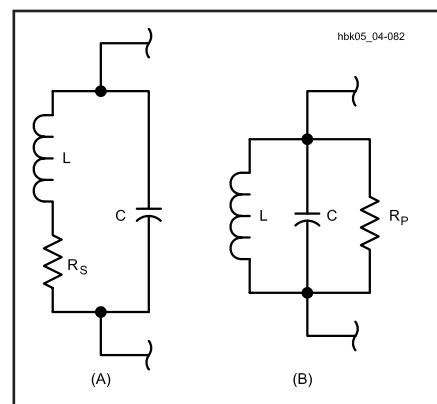

Fig 4.82 — Series and parallel equivalents when both circuits are resonant. The series resistance, R_S in A, is replaced by the parallel resistance, R_P in B, and vice versa. $R_P = X_L^2 / R_S$.

frequency, apply the general formula:

$$Z = \frac{Z_C Z_L}{Z_S} \quad (122)$$

where:

- Z = overall circuit impedance
- Z_C = impedance of the capacitive leg (usually, the reactance of the capacitor),
- Z_L = impedance of the inductive leg (the vector sum of the coil's reactance and resistance), and
- Z_S = series impedance of the capacitor-inductor combination as derived from the denominator of equation 115.

After using vector calculations to obtain Z_L and Z_S , converting all the values to polar form — as described earlier in this chapter — will ease the final calculation. Of course, each impedance may be derived from the resistance and the application of the basic reactance formulas on the values of the inductor and capacitor at the frequency of interest.

Since the current rises off resonance, the parallel-resonant-circuit impedance must fall. It also becomes complex, resulting in an ever greater phase difference between the voltage and the current. The rate at

which the impedance falls is a function of Q_U . **Fig 4.84** presents a family of curves showing the impedance drop from resonance for circuit Q s ranging from 10 to 100. The curve family for parallel-circuit impedance is essentially the same as the curve family for series-circuit current.

As with series tuned circuits, the higher the Q of a parallel-tuned circuit, the sharper the response peak. Likewise, the lower the Q , the wider the band of frequencies to which the circuit responds. Using the half-power (-3 dB) points as a comparative measure of circuit performance, equations 116 and 117 apply equally to parallel-tuned circuits. That is, $BW = f / Q_U$ and $Q_U = f / BW$, where the resonant frequency and the bandwidth are in the same units. As a handy reminder, **Table 4.8** summarizes the performance of parallel-resonant circuits at high and low Q s and above and below resonant frequency.

It is possible to use either series or parallel-resonant circuits do the same work in many circuits, thus giving the designer considerable flexibility. **Fig 4.85** illustrates this general principle by showing a series-resonant circuit in the signal path and a parallel-resonant circuit shunted from the

signal path to ground. Assume both circuits are resonant at the same frequency, f , and have the same Q . The series tuned circuit at A has its lowest impedance at f , permitting the maximum possible current to flow along the signal path. At all other frequencies, the impedance is greater and the current at those frequencies is less. The circuit passes the desired signal and tends to impede signals at undesired frequencies. The parallel circuit at B provides the highest impedance at resonance, f , making the signal path the lowest impedance

Fig 4.83 — The currents in a parallel-resonant circuit as the frequency moves through resonance. Below resonance, the current lags the voltage; above resonance the current leads the voltage. The base line represents the current level at resonance, which depends on the impedance of the circuit at that frequency.

Fig 4.84 — Relative impedance of parallel-resonant circuits with different values of Q_U . The curves are similar to the series-resonant circuit current level curves of Fig 4.78. The effect of Q_U on impedance is most pronounced within 10% of the resonance frequency.

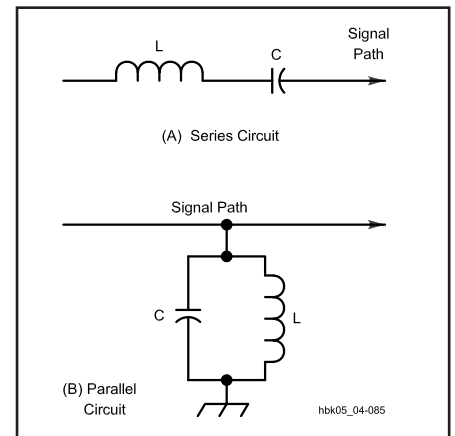

Fig 4.85 — Series- and parallel-resonant circuits configured to perform the same theoretical task: passing signals in a narrow band of frequencies along the signal path. A real design example would consider many other factors.

Table 4.8

The Performance of Parallel-Resonant Circuits

A. High and Low Q Circuits (in relative terms)

Characteristic	High Q Circuit	Low Q Circuit
Selectivity	high	low
Bandwidth	narrow	wide
Impedance	high	low
Line current	low	high
Circulating current	high	low

B. Off-Resonance Performance for Constant Values of Inductance and Capacitance

Characteristic	Above Resonance	Below Resonance
Inductive reactance	increases	decreases
Capacitive reactance	decreases	increases
Circuit resistance	unchanged*	unchanged*
Circuit impedance	decreases	decreases
Line current	increases	increases
Circulating current	decreases	decreases
Circuit behavior	capacitive	inductive

*This is true for frequencies near resonance. At distant frequencies, skin effect may alter the resistive losses of the inductor.

Fig 4.87 — A loaded parallel-resonant circuit, showing both the inductor-loss resistance and the load, R_L . If smaller than the inductor resistance, R_L will control the loaded Q of the circuit (Q_L).

resistance of the circuit itself. At frequencies below 30 MHz, most of this resistance is in the coil. Within limits, increasing the number of turns in the coil increases the reactance faster than it raises the resistance, so coils for circuits in which the Q must be high are made with relatively large inductances for the frequency.

When the circuit delivers energy to a load (as in the case of the resonant circuits used in transmitters), the energy consumed in the circuit itself is usually negligible compared with that consumed by the load. The equivalent of such a circuit is shown in **Fig 4.87**, where the parallel resistor, R_L , represents the load to which power is delivered. If the power dissipated in the load is at least 10 times as great as the power lost in the inductor and capacitor, the parallel impedance of the resonant circuit itself will be so high compared with the resistance of the load that for all practical purposes the impedance of the combined circuit is equal to the load impedance. Under these conditions, the load resistance replaces the circuit impedance in calculating Q. The Q of a parallel-resonant circuit loaded by a resistive impedance is:

$$Q_L = \frac{R_L}{X} \tag{124}$$

where:

Q_L = circuit loaded Q,

R_L = parallel load resistance in ohms, and

X = reactance in ohms of either the inductor or the capacitor.

Example: A resistive load of 3000 Ω is connected across a resonant circuit in which the inductive and capacitive reactances are each 250 Ω . What is the circuit Q?

$$Q_L = \frac{R_L}{X} = \frac{3000 \Omega}{250 \Omega} = 12$$

The effective Q of a circuit loaded by a parallel resistance increases when the re-

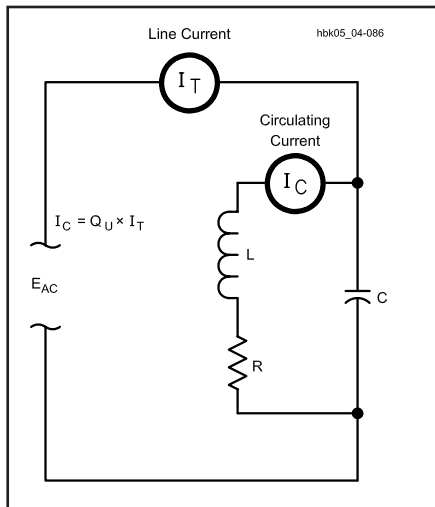

Fig 4.86 — A parallel-resonant circuit redrawn to illustrate both the line current and the circulating current.

path for the signal. At frequencies off resonance, the parallel-resonant circuit presents a lower impedance, thus presenting signals with a path to ground and away from the signal path. In theory, the effects will be the same relative to a signal current on the signal path. In actual circuit design exercises, of course, many other variables will enter the design picture to make one circuit preferable to the other.

Circulating Current

In a parallel-resonant circuit, the source voltage is the same for all the circuit elements. The current in each element,

however, is a function of the element's reactance. **Fig 4.86** redraws the parallel-tuned circuit to indicate the line current and the current circulating between the coil and the capacitor. The current drawn from the source may be low, because the overall circuit impedance is high. The current through the individual elements may be high, however, because there is little resistive loss as the current circulates through the inductor and capacitor. For parallel-resonant circuits with an unloaded Q of 10 or greater, this *circulating current* is approximately:

$$I_C = Q_U I_T \tag{123}$$

where:

I_C = circulating current in A, mA or μ A,

Q_U = unloaded circuit Q, and

I_T = line current in the same units as I_C .

Example: A parallel-resonant circuit permits an ac or RF line current of 30 mA and has a Q of 100. What is the circulating current through the elements?

$$I_X = Q_U I = 100 \times 30 \text{ mA} = 3000 \text{ mA} = 3 \text{ A}$$

Circulating currents in high-Q parallel-tuned circuits can reach a level that causes component heating and power loss. Therefore, components should be rated for the anticipated circulating currents, and not just the line current.

The Q of Loaded Circuits

In many resonant-circuit applications, the only power lost is that dissipated in the

actances are decreased. A circuit loaded with a relatively low resistance (a few thousand ohms) must have low-reactance elements (large capacitance and small inductance) to have reasonably high Q . Many power-handling circuits, such as the output networks of transmitters, are designed by first choosing a loaded Q for the circuit and then determining component values. See the **RF Power Amplifiers** chapter for more details.

Parallel load resistors are sometimes added to parallel-resonant circuits to lower the circuit Q and increase the circuit bandwidth. By using a high- Q circuit and adding a parallel resistor, designers can tailor the circuit response to their needs. Since the parallel resistor consumes power, such techniques ordinarily apply to receiver and similar low-power circuits, however.

Example: Specifications call for a parallel-resonant circuit with a bandwidth of 400 kHz at 14.0 MHz. The circuit at hand has a Q_U of 70.0 and its components have reactances of 350 Ω each. What is the parallel load resistor that will increase the bandwidth to the specified value? The bandwidth of the existing circuit is:

$$\begin{aligned} BW &= \frac{f}{Q_U} = \frac{14.0 \text{ MHz}}{70.0} = 0.200 \text{ MHz} \\ &= 200 \text{ kHz} \end{aligned}$$

The desired bandwidth, 400 kHz, requires a circuit with a Q of:

$$Q = \frac{f}{BW} = \frac{14.0 \text{ MHz}}{0.400 \text{ MHz}} = 35.0$$

Since the desired Q is half the original value, halving the resonant impedance or parallel-resistance value of the circuit is in order. The present impedance of the circuit is:

$$Z = Q_U X_L = 70.0 \times 350 \Omega = 24500 \Omega$$

The desired impedance is:

$$\begin{aligned} Z &= Q_U X_L = 35.0 \times 350 \Omega \\ &= 12250 \Omega = 12.25 \text{ k}\Omega \end{aligned}$$

or half the present impedance.

A parallel resistor of 24500 Ω , or the nearest lower value (to guarantee sufficient bandwidth), will produce the required reduction in Q and bandwidth increase. Although this example simplifies the situation encountered in real design cases by ignoring such factors as the shape of the band-pass curve, it illustrates the interaction of the ingredients that determine the performance of parallel-resonant circuits.

Impedance Transformation

An important application of the parallel-resonant circuit is as an impedance matching device in the output circuit of an RF power amplifier. There is an optimum value of load resistance for each type of tube or transistor and each set of required operating conditions. The resistance of the load to which the active device delivers power may be considerably lower than the value required for proper device operation, or the load impedance may be considerably higher than the amplifier output impedance.

To transform the actual load resistance to the desired value, the load may be tapped across part of the coil, as shown in

Fig 4.88 — A parallel-resonant circuit with a tapped coil to effect an impedance match. Although the impedance presented by the entire circuit is very high, the impedance “seen” by the load, R_L , is lower.

Fig 4.88. This is equivalent to connecting a higher value of load resistance across the whole circuit, and is similar in principle to impedance transformation with an iron-core transformer (described in the next section of this chapter). In high-frequency resonant circuits, the impedance ratio does not vary exactly as the square of the turns ratio, because all the magnetic flux lines do not cut every turn of the coil. A desired impedance ratio usually must be obtained by experimental adjustment.

When the load resistance has a very low value (say below 100 Ω) it may be connected in series in the resonant circuit (R_S in Fig 4.82A, for example), in which case it is transformed to an equivalent parallel impedance as previously described. If the Q is at least 10, the equivalent parallel impedance is:

$$Z_R = \frac{X^2}{R_L} \quad (125)$$

where:

Z_R = resistive parallel impedance at resonance,

X = reactance (in ohms) of either the coil or the capacitor, and

R_L = load resistance inserted in series.

If the Q is lower than 10, the reactance will have to be adjusted somewhat — for the reasons given in the discussion of low- Q circuits — to obtain a resistive impedance of the desired value.

Networks like the one in Fig 4.88 have some serious disadvantages for some applications. For instance, the common connection between the input and the output provides no dc isolation. Also, the common ground is sometimes troublesome with regard to ground-loop currents. Consequently, a network with only mutual magnetic coupling is often preferable. With the advent of ferrites, constructing impedance transformers that are both broadband and permit operation well up into the VHF portion of the spectrum has become relatively easy. The basic principles of broadband impedance transformers appear in the following section.

Transformers

When the ac source current flows through every turn of an inductor, the generation of a counter-voltage and the storage of energy during each half cycle is said to be by virtue of *self-inductance*. If another inductor — not connected to the source of the original current — is positioned so the expanding and contracting magnetic field of the first inductor cuts across its turns, a current will be induced into the second coil. A load such as a resistor may be connected across the second coil to consume the energy transferred magnetically from the first inductor. This phenomenon is called *mutual inductance*.

Two inductors positioned so that the magnetic field of one (the *primary* inductor) induces a current in the other (the *secondary* inductor) are *coupled*. **Fig 4.89** illustrates a pair of coupled inductors, showing an ac energy source connected to one and a load connected to the other. If the coils are wound tightly on an iron core so that nearly all the lines of force or magnetic flux from the first coil link with the turns of the second coil, the pair is said to be *tightly coupled*. Coils with air cores separated by a distance would be *loosely coupled*. The signal source for the primary inductor may be household ac power lines, audio or other waveforms at lower frequencies, or RF currents. The load may be a device needing power, a speaker converting electrical energy into sonic energy, an antenna using RF energy for communications or a particular circuit set up to process a signal from a preceding circuit. The uses of magnetically coupled energy in electronics are innumerable.

Mutual inductance (M) between coils is measured in henrys. Two coils have a mutual inductance of 1 H under the following conditions: as the primary inductor current changes at a rate of 1 A/s, the voltage across the secondary inductor is 1 V. The level of mutual inductance varies with many factors: the size and shape of the inductors, their relative positions and distance from each other, and the perme-

ability of the inductor core material and of the space between them.

If the self-inductance values of two coils are known, it is possible to derive the mutual inductance by way of a simple experiment schematically represented in **Fig 4.90**. Without altering the physical setting or position of two coils, measure the inductance of the series-connected coils with their windings complementing each other and again with their windings opposing each other. Since, for the two coils, $L_C = L_1 + L_2 + 2M$, in the complementary case, and $L_O = L_1 + L_2 - 2M$ for the opposing case,

$$M = \frac{L_C - L_O}{4} \quad (126)$$

The ratio of magnetic flux set up by the secondary coil to the flux set up by the primary coil is a measure of the extent to which two coils are coupled, compared to the maximum possible coupling between

them. This ratio is the *coefficient of coupling* (k) and is always less than 1. If k were to equal 1, the two coils would have the maximum possible mutual coupling. Thus:

$$M = k\sqrt{L_1 L_2} \quad (127)$$

where:

- M = mutual inductance in henrys,
- L_1 and L_2 = individual coupled inductors, each in henrys, and
- k = the coefficient of coupling.

Using the experiment above, it is possible to solve equation 127 for k with reasonable accuracy.

Any two coils having mutual inductance comprise a *transformer* having a *primary winding* or inductor and a *secondary winding* or inductor. **Fig 4.91** provides a pictorial representation of a typical iron-core transformer, along with the schematic symbols for both iron-core and air-core

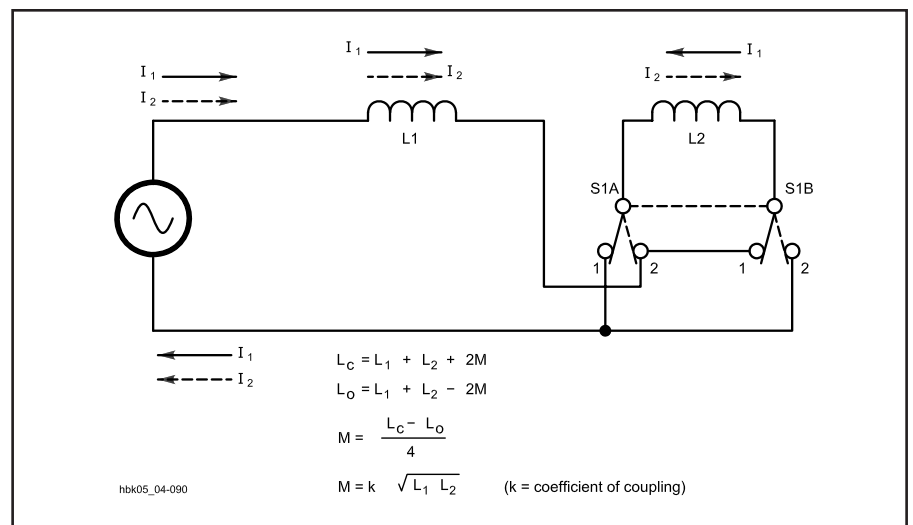

Fig 4.90 — An experimental setup for determining mutual inductance. Measure the inductance with the switch in each position and use the formula in the text to determine the mutual inductance.

Fig 4.89 — A basic transformer: two inductors — one connected to an ac energy source, the other to a load — with coupled magnetic fields.

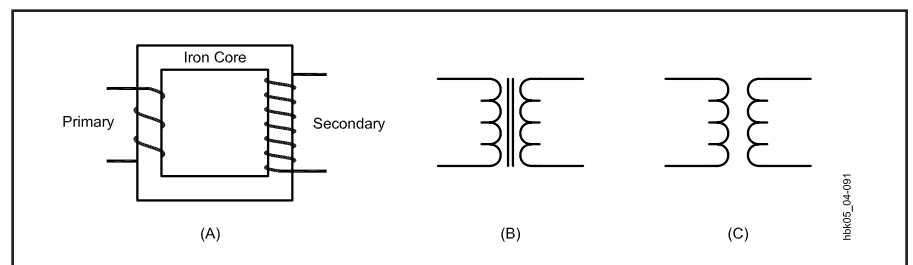

Fig 4.91 — A transformer. A is a pictorial diagram. Power is transferred from the primary coil to the secondary by means of the magnetic field. B is a schematic diagram of an iron-core transformer, and C is an air-core transformer.

transformers. Conventionally, the term *transformer* is most commonly applied to coupled inductors having a magnetic core material, while coupled air-wound inductors are not called by that name. They are still transformers, however.

We normally think of transformers as ac devices, since mutual inductance only occurs when magnetic fields are expanding or contracting. A transformer connected to a dc source will exhibit mutual inductance only at the instants of closing and opening the primary circuit, or on the rising and falling edges of dc pulses, because only then does the primary winding have a changing field. The principle uses of transformers are three: to physically isolate the primary circuit from the secondary circuit, to transform voltages and currents from one level to another, and to transform circuit impedances from one level to another. These functions are not mutually exclusive and have many variations.

IRON-CORE TRANSFORMERS

The primary and secondary coils of a transformer may be wound on a core of magnetic material. The permeability of the magnetic material increases the inductance of the coils so a relatively small number of turns may be used to induce a given voltage value with a small current. A closed core having a continuous magnetic path, such as that shown in Fig 4.91, also tends to ensure that practically all of the field set up by the current in the primary coil will cut the turns of the secondary coil. For power transformers and impedance-matching transformers used in audio work, cores of iron strips are most common and generally very efficient.

The following principles presume a coefficient of coupling (k) of 1, that is, a perfect transformer. The value $k = 1$ indicates that all the turns of both coils link with all the magnetic flux lines, so that the voltage induced per turn is the same with both coils. This condition makes the induced voltage independent of the inductance of the primary and secondary inductors. Iron-core transformers for low frequencies most closely approach this ideal condition. Fig 4.92 illustrates the conditions for transformer action.

Voltage Ratio

For a given varying magnetic field, the voltage induced in a coil within the field is proportional to the number of turns in the coil. When the two coils of a transformer are in the same field (which is the case when both are wound on the same closed core), it follows that the induced voltages will be proportional to the num-

Fig 4.92 — The conditions for transformer action: two coils that exhibit mutual inductance, an ac power source, and a load. The magnetic field set up by the energy in the primary circuit transfers energy to the secondary for use by the load, resulting in a secondary voltage and current.

ber of turns in each coil. In the primary, the induced voltage practically equals, and opposes, the applied voltage, as described earlier. Hence:

$$E_S = E_P \left(\frac{N_S}{N_P} \right) \quad (128)$$

where:

- E_S = secondary voltage,
- E_P = primary applied voltage,
- N_S = number of turns on secondary,
- and
- N_P = number of turns on primary.

Example: A transformer has a primary of 400 turns and a secondary of 2800 turns, and a voltage of 120 V is applied to the primary. What voltage appears across the secondary winding?

$$E_S = 120 \text{ V} \left(\frac{2800}{400} \right) = 120 \text{ V} \times 7 = 840 \text{ V}$$

(Notice that the number of turns is taken as a known value rather than a measured quantity, so they do not limit the significant figures in the calculation.) Also, if 840 V is applied to the 2800-turn winding (which then becomes the primary), the output voltage from the 400-turn winding will be 120 V.

Either winding of a transformer can be used as the primary, provided the winding has enough turns (enough inductance) to induce a voltage equal to the applied voltage without requiring an excessive current. The windings must also have insulation with a voltage rating sufficient for the voltage present.

Current or Ampere-Turns Ratio

The current in the primary when no current is taken from the secondary is called the *magnetizing current* of the transformer. An ideal transformer, with no internal losses, would consume no power, since the current through the primary in-

ductor would be 90° out of phase with the voltage. In any properly designed transformer, the power consumed by the transformer when the secondary is open (not delivering power) is only the amount necessary to overcome the losses in the iron core and in the resistance of the wire with which the primary is wound.

When power is taken from the secondary winding by a load, the secondary current sets up a magnetic field that opposes the field set up by the primary current. For the induced voltage in the primary to equal the applied voltage, the original field must be maintained. The primary must draw enough additional current to set up a field exactly equal and opposite to the field set up by the secondary current.

In practical transformer calculations it may be assumed that the entire primary current is caused by the secondary load. This is justifiable because the magnetizing current should be very small in comparison with the primary load current at rated power output.

If the magnetic fields set up by the primary and secondary currents are to be equal, the primary current multiplied by the primary turns must equal the secondary current multiplied by the secondary turns.

$$I_P = I_S \left(\frac{N_S}{N_P} \right) \quad (129)$$

where:

- I_P = primary current,
- I_S = secondary current,
- N_P = number of turns on primary, and
- N_S = number of turns on secondary.

Example: Suppose the secondary of the transformer in the previous example is delivering a current of 0.20 A to a load. What will be the primary current?

$$I_P = 0.20 \text{ A} \times \left(\frac{2800}{400} \right) = 0.20 \text{ A} \times 7 = 1.4 \text{ A}$$

Although the secondary voltage is higher than the primary voltage, the secondary current is lower than the primary current, and by the same ratio. The secondary current in an ideal transformer is 180° out of phase with the primary current, since the field in the secondary just offsets the field in the primary. The phase relationship between the currents in the windings holds true no matter what the phase difference between the current and the voltage of the secondary. In fact, the phase difference, if any, between voltage and current in the secondary winding will be reflected back to the primary as an identical phase difference.

Power Ratio

A transformer cannot create power; it can only transfer it and change the voltage level. Hence, the power taken from the secondary cannot exceed that taken by the primary from the applied voltage source. There is always some power loss in the resistance of the coils and in the iron core, so in all practical cases the power taken from the source will exceed that taken from the secondary.

$$P_O = n P_I \quad (130)$$

where:

P_O = power output from secondary,
 P_I = power input to primary, and
 n = efficiency factor.

The efficiency, n , is always less than 1. It is usually expressed as a percentage: if n is 0.65, for instance, the efficiency is 65%.

Example: A transformer has an efficiency of 85.0% at its full-load output of 150 W. What is the power input to the primary at full secondary load?

$$P_I = \frac{P_O}{n} = \frac{150 \text{ W}}{0.850} = 176 \text{ W}$$

A transformer is usually designed to have the highest efficiency at the power output for which it is rated. The efficiency decreases with either lower or higher outputs. On the other hand, the losses in the transformer are relatively small at low output but increase as more power is taken. The amount of power that the transformer can handle is determined by its own losses, because these losses heat the wire and core. There is a limit to the temperature rise that can be tolerated, because too high a temperature can either melt the wire or cause the insulation to break down. A transformer can be operated at reduced output, even though the efficiency is low, because the actual loss will be low under such conditions. The full-load efficiency of small power transformers such as are used in radio receivers and transmitters usually lies between about 60 and 90%, depending on the size and design.

IMPEDANCE RATIO

In an ideal transformer — one without losses or leakage reactance — the following relationship is true:

$$Z_P = Z_S \left(\frac{N_P}{N_S} \right)^2 \quad (131)$$

where:

Z_P = impedance looking into the primary terminals from the power source,

Z_S = impedance of load connected to secondary, and
 N_P, N_S = turns ratio, primary to secondary.

A load of any given impedance connected to the transformer secondary will be transformed to a different value looking into the primary from the power source. The impedance transformation is proportional to the square of the primary-to-secondary turns ratio.

Example: A transformer has a primary-to-secondary turns ratio of 0.6 (the primary has six-tenths as many turns as the secondary) and a load of 3000 Ω is connected to the secondary. What is the impedance at the primary of the transformer?

$$Z_P = 3000 \Omega \times (0.6)^2 = 3000 \Omega \times 0.36$$

$$Z_P = 1080 \Omega$$

By choosing the proper turns ratio, the impedance of a fixed load can be transformed to any desired value, within practical limits. If transformer losses can be neglected, the transformed (reflected) impedance has the same phase angle as the actual load impedance. Thus, if the load is a pure resistance, the load presented by the primary to the power source will also be a pure resistance. If the load impedance is complex, that is, if the load current and voltage are out of phase with each other, then the primary voltage and current will show the same phase angle.

Many devices or circuits require a specific value of load resistance (or impedance) for optimum operation. The impedance of the actual load that is to dissipate the power may differ widely from the impedance of the source device or circuit, so a transformer is used to change the actual load into an impedance of the desired value. This is called impedance matching.

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} \quad (132)$$

where:

N_P / N_S = required turns ratio, primary to secondary,
 Z_P = primary impedance required, and
 Z_S = impedance of load connected to secondary.

Example: A transistor audio amplifier requires a load of 150 Ω for optimum performance, and is to be connected to a loudspeaker having an impedance of 4.0 Ω . What is the turns ratio, primary to secondary, required in the coupling transformer?

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} = \frac{N_P}{N_S} \sqrt{\frac{150 \Omega}{4.0 \Omega}} = \sqrt{38} = 6.2$$

The primary therefore must have 6.2 times as many turns as the secondary.

These relationships may be used in practical work even though they are based on an ideal transformer. Aside from the normal design requirements of reasonably low internal losses and low leakage reactance, the only other requirement is that the primary have enough inductance to operate with low magnetizing current at the voltage applied to the primary.

The primary terminal impedance of an iron-core transformer is determined wholly by the load connected to the secondary and by the turns ratio. If the characteristics of the transformer have an appreciable effect on the impedance presented to the power source, the transformer is either poorly designed or is not suited to the voltage and frequency at which it is being used. Most transformers will operate quite well at voltages from slightly above to well below the design figure.

Transformer Losses

In practice, none of the formulas given so far provides truly exact results, although they afford reasonable approximations. Transformers in reality are not simply two coupled inductors, but a network of resistances and reactances, most of which appear in **Fig 4.93**. Since only the terminals numbered 1 through 4 are accessible to the user, transformer ratings and specifications take into account the additional losses created by these complexities.

In a practical transformer not all of the magnetic flux is common to both windings, although in well designed transformers the amount of flux that cuts one coil and not the other is only a small percentage of the total flux. This *leakage flux* causes a voltage of self-induction. Consequently, there are small amounts of leakage inductance associated with both windings of the transformer. Leakage inductance acts in exactly the same way as an equivalent amount of ordinary inductance inserted in series with the circuit. It has, therefore, a certain reactance, depending on the amount of leakage inductance and the frequency. This reactance is called *leakage reactance*, shown as X_{L1} and X_{L2} in **Fig 4.93**.

Current flowing through the leakage reactance causes a voltage drop. This voltage drop increases with increasing current; hence, it increases as more power is taken from the secondary. Thus, the greater the secondary current, the smaller the secondary terminal voltage becomes.

Fig 4.93 — A transformer as a network of resistances, inductances and capacitances. Only L1 and L2 contribute to the transfer of energy.

The resistances of the transformer windings, R_1 and R_2 , also cause voltage drops when there is current. Although these voltage drops are not in phase with those caused by leakage reactance, together they result in a lower secondary voltage under load than is indicated by the transformer turns ratio.

Thus, the voltage regulation in a real transformer is not perfect. At ac line frequencies (50 or 60 Hz), the voltage at the secondary, with a reasonably well-designed transformer, should not drop more than about 10% from open-circuit conditions to full load. The voltage drop may be considerably more than this in a transformer operating at voice and music frequencies, because the leakage reactance increases directly with the frequency.

In addition to wire strays and leakage reactances, certain stray capacitances occur in transformers. An electric field exists between any two points having a different voltage. When current flows through a coil, each turn has a slightly different voltage than its adjacent turns, creating a capacitance between turns. This *distributed capacitance* appears in Fig 4.93 as C_1 and C_2 . Another capacitance, C_M , appears between the two windings for the same reason. Moreover, transformer windings can exhibit capacitance relative to nearby metal, for example, the chassis, the shield and even the core.

Although these stray capacitances are of little concern with power and audio transformers, they become important as the frequency increases. In transformers for RF use, the stray capacitance can resonate with either the leakage reactance or, at lower frequencies, with the winding reactances, L_1 or L_2 , especially under very light or zero loads. In the frequency region around resonance, transformers no longer exhibit the properties formulated above or the impedance properties to be described below.

Iron-core transformers also experience losses within the core itself. *Hysteresis*

losses include the energy required to overcome the retentivity of the core's magnetic material. Circulating currents through the core's resistance are *eddy currents*, which form part of the total core losses. These losses, which add to the required magnetizing current, are equivalent to adding a resistance in parallel with L_1 in Fig 4.93.

Core Construction

Audio and power transformers usually employ one or another grade of silicon steel as the core material. With permeabilities of 5000 or greater, these cores saturate at flux densities approaching 10^5 lines per square inch of cross section. The cores consist of thin insulated laminations to break up potential eddy current paths.

Each core layer consists of an E and an I piece butted together, as represented in Fig 4.94. The butt point leaves a small gap. Since the pieces in adjacent layers have a continuous magnetic path, however, the flux density per unit of applied magnetic force is increased and flux leakage reduced.

Two core shapes are in common use, as shown in Fig 4.95. In the shell type, both windings are placed on the inner leg, while in the core type the primary and secondary windings may be placed on separate legs, if desired. This is sometimes done when it is necessary to minimize capacitive effects between the primary and secondary, or when one of the windings must operate at very high voltage.

The number of turns required in the primary for a given applied voltage is determined by the size, shape and type of core material used, as well as the frequency. The number of turns required is inversely proportional to the cross-sectional area of the core. As a rough indication, windings of small power transformers frequently have about six to eight turns per volt on a core of 1-square-inch cross section and have a magnetic path 10 or 12 inches in length. A longer path or smaller cross sec-

Fig 4.94 — A typical transformer iron core. The E and I pieces alternate direction in successive layers to improve the magnetic path while attenuating eddy currents in the core.

Fig 4.95 — Two common transformer constructions: shell and core.

Fig 4.96 — A shielded transformer: the core plus an outer shield of magnetic material contain nearly all of the magnetic field.

tion requires more turns per volt, and vice versa.

In most transformers the coils are wound in layers, with a thin sheet of treated-paper insulation between each layer. Thicker insulation is used between adjacent coils and between the first coil and the core.

Shielding

Because magnetic lines of force are continuous and closed upon themselves, shielding requires a path for the lines of force of the leakage flux. The high-permeability of iron cores tends to concentrate the field, but additional shielding is often needed. As depicted in Fig 4.96, enclosing the transformer in a good magnetic material can restrict virtually all of the magnetic field in the outer case. The

nonmagnetic material between the case and the core creates a region of high reluctance, attenuating the field before it reaches the case.

AUTOTRANSFORMERS

The transformer principle can be used with only one winding instead of two, as shown in Fig 4.97A. The principles that relate voltage, current and impedance to the turns ratio also apply equally well. A one-winding transformer is called an *autotransformer*. The current in the common section (A) of the winding is the difference between the line (primary) and the load (secondary) currents, since these currents are out of phase. Hence, if the line and load currents are nearly equal, the common section of the winding may be wound with comparatively small wire. The line and load currents will be equal only when the primary (line) and secondary (load) voltages are not very different.

Autotransformers are used chiefly for boosting or reducing the power-line voltage by relatively small amounts. Fig 4.97B illustrates the principle schematically with a switched, stepped autotransformer. Continuously variable autotransformers are commercially available under a variety of trade names; Variac and Powerstat are typical examples.

Technically, tapped air-core inductors, such as the one in the network in Fig 4.88 at the close of the discussion of resonant circuits, are also autotransformers. The voltage from the tap to the bottom of the coil is less than the voltage across the entire coil. Likewise, the impedance of the tapped part of the winding is less than the impedance of the entire winding. Because leakage reactances are great and the co-efficient of coupling is quite low, the relationships true of a perfect transformer grow quite unreliable in predicting the exact values. For this reason, tapped inductors are rarely referred to as transformers. The stepped-down situation in Fig 4.88 is better approximated — at or close to resonance — by the formula

$$R_p = \frac{R_L X_{COM}^2}{X_L} \quad (133)$$

where:

R_p = tuned-circuit parallel-resonant impedance,

R_L = load resistance tapped across part of the coil,

X_{COM} = reactance of the portion of the coil common to both the resonant circuit and the load tap, and

X_L = reactance of the entire coil.

The result is approximate and applies only

to circuits with a Q of 10 or greater.

AIR-CORE RF TRANSFORMERS

Air-core transformers often function as mutually coupled inductors for RF applications. They consist of a primary winding and a secondary winding in close proximity. Leakage reactances are ordinarily high, however, and the coefficient of coupling between the primary and secondary windings is low. Consequently, unlike transformers having a magnetic core, the turns ratio does not have as much significance. Instead, the voltage induced in the secondary depends on the mutual inductance.

Nonresonant RF Transformers

In a very basic transformer circuit operating at radio frequencies, such as in Fig 4.98A, the source voltage is applied to L1. R_S is the series resistance inherent in the source. By virtue of the mutual inductance, M, a voltage is induced in L2. A current flows in the secondary circuit through the reactance of L2 and the load resistance of R_L . Let X_{L2} be the reactance of L2 independent of L1, that is, independent of the effects of mutual inductance. The impedance of the secondary circuit is then:

$$Z_S = \sqrt{R_L^2 + X_{L2}^2} \quad (134)$$

where:

Z_S = the impedance of the secondary circuit in ohms,

R_L = the load resistance in ohms, and

X_{L2} = the reactance of the secondary inductance in ohms.

The effect of Z_S upon the primary circuit is the same as a coupled impedance in series with L1. Fig 4.98B displays the coupled impedance (Z_p) in a dashed enclosure to indicate that it is not a new physical component. It has the same absolute value of phase angle as in the secondary impedance, but the sign of the reactance is reversed; it appears as a capacitive reactance. The value of Z_p is:

$$Z_p = \frac{(2\pi f M)^2}{Z_S} \quad (135)$$

where:

Z_p = the impedance introduced into the primary,

Z_S = the impedance of the secondary circuit in ohms, and

$2\pi f M$ = the mutual reactance between the reactances of the primary and secondary coils (also designated as X_M).

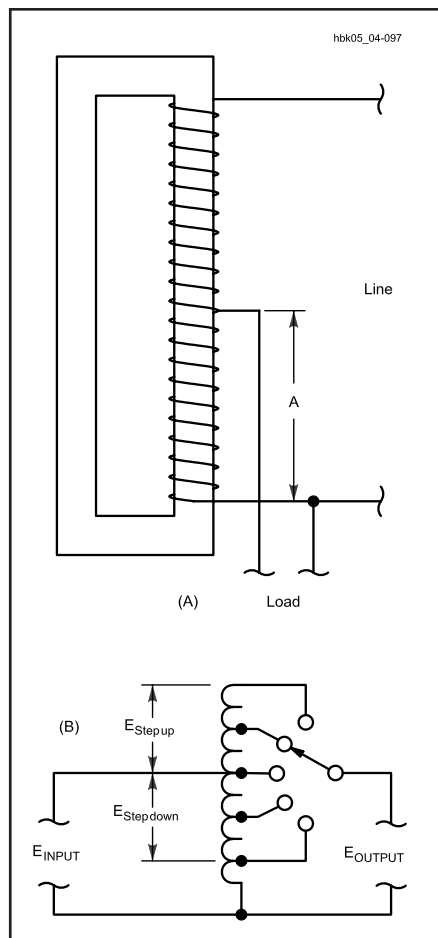

Fig 4.97 — The autotransformer is based on the transformer, but uses only one winding. The pictorial diagram at A shows the typical construction of an autotransformer. The schematic diagram at B demonstrates the use of an autotransformer to step up or step down ac voltage, usually to compensate for excessive or deficient line voltage.

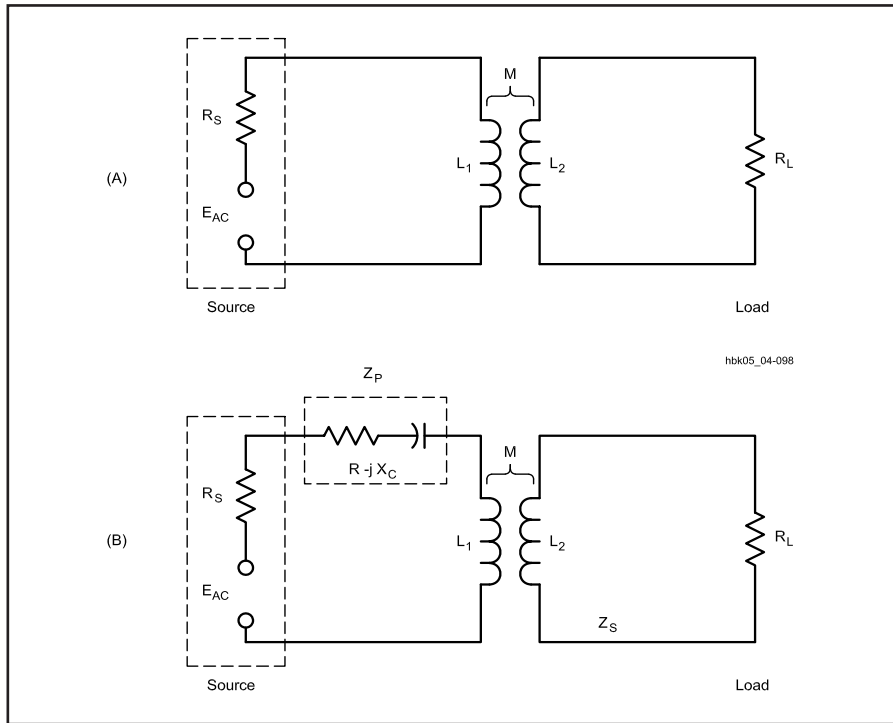

Fig 4.98 — The coupling of a complex impedance back into the primary circuit of a transformer composed of nonresonant air-core inductors.

Resonant RF Transformers

The use of at least one resonant circuit in place of a pair of simple reactances eliminates the reactance from the transformed impedance in the primary. For loaded or operating Q s of at least 10, the resistances of individual components is negligible. **Fig 4.99** represents just one of many configurations in which at least one of the inductors is in a resonant circuit. The reactance coupled into the primary circuit is cancelled if the circuit is tuned to resonance while the load is connected. If the reactance of the load capacitance, C_L is at least 10 times any stray capacitance in the circuit, as is the case for low imped-

ance loads, the value of resistance coupled to the primary is

$$R_1 = \frac{X_M^2 R_L}{X_2^2 + R_L^2} \quad (136)$$

where:

R_1 = series resistance coupled into the primary circuit,

X_M = mutual reactance,

R_L = load resistance, and

X_2 = reactance of the secondary inductance.

The parallel impedance of the resonant circuit is just R_1 transformed from a

Fig 4.99 — An air-core transformer circuit consisting of a resonant primary circuit and an untuned secondary. R_S and C_S are functions of the source, while R_L and C_L are functions of the load circuit.

series to a parallel value by the usual formula, $R_p = X^2 / R_1$.

The higher the loaded or operating Q of the circuit, the smaller the mutual inductance required for the same power transfer. If both the primary and secondary circuits consist of resonant circuits, they can be more loosely coupled than with a single tuned circuit for the same power transfer. At the usual loaded Q of 10 or greater, these circuits are quite selective, and consequently narrowband.

Although coupling networks have to a large measure replaced RF transformer coupling that uses air-core transformers, these circuits are still useful in antenna tuning units and other circuits. For RF work, powdered-iron toroidal cores have generally replaced air-core inductors for almost all applications except where the circuit handles very high power or the coil must be very temperature stable. Slugg-tuned solenoid coils for low-power circuits offer the ability to tune the circuit precisely to resonance. For either type of core, reasonably accurate calculation of impedance transformation is possible. It is often easier to experiment to find the correct values for maximum power transfer, however. For further information on coupled circuits, see the section on Tuned (Resonant) Networks in the **Receivers and Transmitters**, chapter.

BROADBAND FERRITE RF TRANSFORMERS

The design concepts and general theory of ideal transformers presented earlier in this chapter apply also to transformers wound on ferromagnetic-core materials (ferrite and powdered iron). As is the case with stacked cores made of laminations in the classic I and E shapes, the core material has a specific permeability factor that determines the inductance of the windings versus the number of wire turns used.

Toroidal cores are useful from a few hundred hertz well into the UHF spectrum. The principal advantage of this type of core is the self-shielding characteristic. Another feature is the compactness of a transformer or inductor. Therefore, toroidal-core transformers are excellent for use not only in dc-to-dc converters, where tape-wound steel cores are employed, but at frequencies up to at least 1000 MHz with the selection of the proper core material for the range of operating frequencies. Toroidal cores are available from micro-miniature sizes up to several inches in diameter. The latter can be used, as one example, to build a 20-kW balun for use in antenna systems.

One of the most common ferromagnetic transformers used in Amateur Radio work

is the *conventional broadband transformer*. Broadband transformers with losses of less than 1 dB are employed in circuits that must have a uniform response over a substantial frequency range, such as a 2- to 30-MHz broadband amplifier. In applications of this sort, the reactance of the windings should be at least four times the impedance that the winding is designed to look into at the lowest design frequency.

Example: What should be the winding reactances of a transformer that has a 300-Ω primary and a 50-Ω secondary load? Relative to the 50-Ω secondary load:

$$X_S = 4 Z_S = 4 \times 50 \Omega = 200 \Omega$$

The primary winding reactance (XP) is:

$$X_P = 4 Z_P = 4 \times 300 \Omega = 1200 \Omega$$

The core-material permeability plays a vital role in designing a good broadband transformer. The effective permeability of the core must be high enough to provide ample winding reactance at the low end of the operating range. As the operating frequency is increased, the effects of the core tend to disappear until there are scarcely any core effects at the upper limit of the operating range. The limiting factors for high frequency response are distributed capacity and leakage inductance due to uncoupled flux. A high-permeability core minimizes the number of turns needed for a given reactance and therefore also minimizes the distributed capacitance at high frequencies.

Ferrite cores with a permeability of 850 are common choices for transformers used between 2 and 30 MHz. Lower frequency ranges, for example, 1 kHz to 1 MHz, may require cores with permeabilities up to 2000. Permeabilities from 40 to 125 are useful for VHF transformers. Conventional broadband transformers require resistive loads. Loads with reactive components should use appropriate networks to cancel the reactance.

Conventional transformers are wound in the same manner as a power transformer. Each winding is made from a separate length of wire, with one winding placed over the previous one with suitable insulation between. Unlike some transmission-line transformer designs, conventional broadband transformers provide dc isolation between the primary and secondary circuits. The high voltages encountered in high-impedance-ratio step-up transformers may require that the core be wrapped with glass electrical tape before adding the windings (as an additional protection from arcing and voltage break-

down), especially with ferrite cores that tend to have rougher edges. In addition, high voltage applications should also use wire with high-voltage insulation and a high temperature rating.

Fig 4.100 illustrates one method of transformer construction using a single toroid as the core. The primary of a step-down impedance transformer is wound to occupy the entire core, with the secondary wound over the primary. The first step in planning the winding is to select a core of the desired permeability. Convert the required reactances determined earlier into inductance values for the lowest frequency of use. To find the number of turns for each winding, use the A_L value for the selected core and equation 73 from the section on ferrite toroidal inductors earlier in this chapter. Be certain the core can handle the power by calculating the maximum flux using equation 71, given earlier in the chapter, and comparing the result with the manufacturer's guidelines.

Example: Design a small broadband transformer having an impedance ratio of 16:1 for a frequency range of 2.0 to 20.0 MHz to match the output of a small-signal stage (impedance $\approx 500 \Omega$) to the input (impedance $\approx 32 \Omega$) of an amplifier.

1. Since the impedance of the smaller winding should be at least 4 times the lower impedance to be matched at the lowest frequency,

$$X_S = 4 \times 32 \Omega = 128 \Omega$$

2. The inductance of the secondary winding should be

$$L_S = X_S / 2 \pi f = 128 / (6.2832 \times 2.0 \times 10^6 \text{ Hz}) = 0.0101 \text{ mH}$$

3. Select a suitable core. For this low-power application, a $3/8$ -inch ferrite core with permeability of 850 is suitable. The core has an value of 420. Calculate the number of turns for the secondary.

$$N_S = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{0.010}{420}}$$

4. A 5-turn secondary winding should suffice. The primary winding derives from the impedance ratio:

$$NP = N_S \sqrt{\frac{Z_P}{Z_S}} = 5 \sqrt{\frac{16}{1}} = 5 \times 4 = 20 \text{ turns}$$

This low power application will not approach the maximum flux density limits for the core, and #28 enamel wire should both fit the core and handle the currents involved.

A second style of broadband transformer

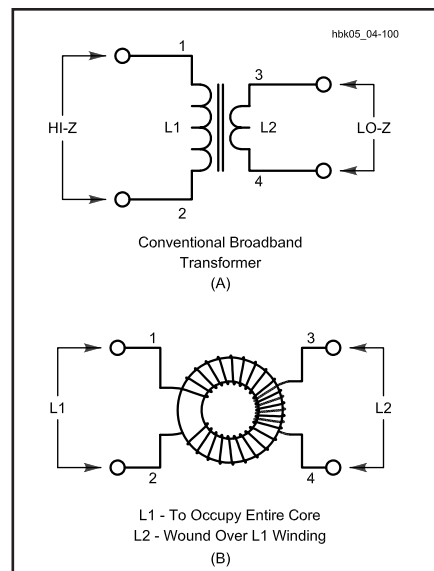

Fig 4.100 — Schematic and pictorial representation of a conventional broadband transformer wound on a ferrite toroidal core. The secondary winding (L2) is wound over the primary winding (L1).

Fig 4.101 — Schematic and pictorial representation of a "binocular" style of conventional broadband transformer. This style is used frequently at the input and output ports of transistor RF amplifiers. It consists of two rows of high-permeability toroidal cores, with the winding passed through the center holes of the resulting stacks.

construction appears in **Fig 4.101**. The key elements in this transformer are the stacks of ferrite cores aligned with tubes soldered to pc-board end plates. This style of transformer is suited to high power applications, for example, at the input and output ports of transistor RF power amplifiers. Low-power versions of this transformer can be wound on “binocular” cores having pairs of parallel holes through them.

For further information on conventional transformer matching using ferromagnetic materials, see the Matching Networks section in the **RF Power Amplifiers** chapter. Refer to the **Component Data and References** chapter for more detailed information on available ferrite cores. A standard reference on conventional broadband transformers using ferro-magnetic materials is *Ferromagnetic Core Design and Applications Handbook* by Doug DeMaw, W1FB, published by Prentice Hall.

TRANSMISSION-LINE TRANSFORMERS

Conventional transformers use flux linkages to deliver energy to the output circuit. *Transmission line transformers* use transmission line modes of energy transfer between the input and the output terminals of the devices. Although toroidal versions of these transformers physically resemble toroidal conventional broadband transformers, the principles of operation differ significantly. Stray inductances and intertwining capacitances form part of the characteristic impedance of the transmission line, largely eliminating resonances that limit high frequency response. The limiting factors for transmission line transformers include line length, deviations in the constructed line from the design value of characteristic impedance, and parasitic capacitances and inductances that are independent of the characteristic impedance of the line.

The losses in conventional transformers depend on current and include wire, eddy-current and hysteresis losses. In contrast, transmission line transformers exhibit voltage-dependent losses, which make higher impedances and higher VSWR values limiting factors in design. Within design limits, the cancellation of flux in the cores of transmission line transformers permits very high efficiencies across their passbands. Losses may be lower than 0.1 dB with the proper core choice.

Transmission-line transformers can be configured for several modes of operation, but the chief amateur use is in *baluns* (*balanced-to-unbalanced transformers*) and in *ununs* (*unbalanced-to-unbalanced transformers*). The basic principle behind a balun appears in **Fig 4.102**, a representation of the classic Guanella 1:1 balun. The input and output impedances are the same, but the output is balanced about a real or virtual center point (terminal 5). If the characteristic impedance of the transmission line forming the inductors with numbered terminals equals the load impedance, then E_2 will equal E_1 . With respect to terminal 5, the voltage at terminal 4 is $E_1 / 2$, while the voltage at terminal 2 is $-E_1 / 2$, resulting in a balanced output.

The small losses in properly designed baluns of this order stem from the potential gradient that exists along the length of transmission line forming the transformer. The value of this potential is $-E_1 / 2$, and it forms a dielectric loss that can't be eliminated. Although the loss is very small in well-constructed 1:1 baluns at low impedances, the losses climb as impedances climb (as in 4:1 baluns) and as the VSWR climbs. Both conditions yield higher voltage gradients.

The inductors in the transmission-line transformer are equivalent to — and may be — coiled transmission line with a char-

acteristic impedance equal to the load. They form a choke isolating the input from the output and attenuating undesirable currents, such as antenna current, from the remainder of the transmission line to the energy source. The result is a *current* or *choke* balun. Such baluns may take many forms: coiled transmission line, ferrite beads placed over a length of transmission line, windings on linear ferrite cores or windings on ferrite toroids.

Reconfiguring the windings of Fig 4.102 can alter the transformer operation. For example, if terminal 2 is connected to terminal 3, a positive potential gradient appears across the lengths of line, resulting in a terminal 4 potential of $2 E_1$ with respect to ground. If the load is disconnected from terminal 2 and reconnected to ground, $2 E_1$ appears across the load — instead of $\pm E_1 / 2$. The product of this experiment is a 4:1 impedance ratio, forming an unun. The bootstrapping effect of the new connection is applicable to many other design configurations involving multiple windings to achieve custom impedance ratios from 1:1 up to 9:1.

Balun and unun construction for the impedances of most concern to amateurs requires careful selection of the feed line used to wind the balun. Building transmission line transformers on ferrite toroids may require careful attention to wire size and spacing to approximate a 50- Ω line. Wrapping wire with polyimide tape (one or two coatings, depending upon the wire size) and then glass taping the wires together periodically produces a reasonable 50- Ω transmission line. Ferrite cores in the permeability range of 125 to 250 are generally optimal for transformer windings, with 1.25-inch cores suitable to 300- Ω power levels and 2.4-inch cores usable to the 5 kW level. Special designs may alter the power-handling capabilities of the core sizes. For the 1:1 balun shown in Fig 4.102, 10 bifilar turns (#16 wire for the smaller core and #12 wire for the larger, both Thermaleze wire) yields a transformer operable from 160 to 10 m.

Transmission-line transformers have their most obvious application to antennas, since they isolate the antenna currents from the feed line, especially where a coaxial feed line is not exactly perpendicular to the antenna. The balun prevents antenna currents from flowing on the outer surface of the coax shielding, back to the transmitting equipment. Such currents would distort the antenna radiation pattern. Appropriately designed baluns can also transform impedance values at the same time. For example, one might use a 4:1 balun to match a 12.5- Ω Yagi antenna impedance to a 50- Ω feed line. A 4:1 balun

Fig 4.102 — Schematic representation of the basic Guanella “choke” balun or 1:1 transmission line transformer. The inductors are a length of two-wire transmission line. R_S is the source impedance and R_L is the load impedance.

might also be used to match a $75\text{-}\Omega$ TV antenna to $300\text{-}\Omega$ feed line.

Interstage coupling within solid-state transmitters represents another potential for transmission-line transformers. Broadband coupling between low-impedance, but mismatched stages can benefit from

the low losses of transmission-line transformers. Depending upon the losses that can be tolerated and the bandwidth needed, it is often a matter of designer choice between a transmission-line transformer and a conventional broadband transformer as the coupling device.

For further information on transmission-line transformers and their applications, see the **RF Power Amplifiers** chapter. Another reference on the subject is *Transmission Line Transformers*, by Jerry Sevick, W2FMI, published by Noble Publishing.

Chapter 5

Electrical Signals and Components

Analog Glossary

- Active Region** — The region in the characteristic curve of an analog device in which the signal is amplified linearly.
- Amplification** — The process of increasing the size of a signal. Also called gain.
- Analog signal** — A signal, usually electrical, that can have any amplitude (voltage or current) value and exists at any point in time.
- Anode** — The element of an analog device that accepts electrons.
- Base** — The middle layer of a bipolar transistor, often the input.
- Biasing** — The addition of a dc voltage or current to a signal at the input of an analog device, which changes the signal's position on the characteristic curve.
- Bipolar Transistor** — An analog device made by sandwiching a layer of doped semiconductor between two layers of the opposite type: PNP or NPN.
- Buffer** — An analog stage that prevents loading of one analog stage by another.
- Cascade** — Placing one analog stage after another to combine their effects on the signal.
- Cathode** — The element of an analog device that emits electrons.
- Characteristic Curve** — A plot of the relative responses of two or three analog-device parameters, usually output with respect to input.
- Clamping** — A nonlinearity in amplification where the signal can be made no larger.
- Collector** — One of the outer layers of a bipolar transistor, often the output.
- Compensation** — The process of counteracting the effects of signals that are inadvertently fed back from the output to the input of an analog system. The process increases stability and prevents oscillation.
- Cutoff Region** — The region in the characteristic curve of an analog device in which there is no current through the device. Also called the OFF region.
- Diode** — A two-element vacuum tube or semiconductor with only a cathode and an anode (or plate).
- Drain** — The connection at one end of a field-effect-transistor channel, often the output.
- Electron** — A subatomic particle that has a negative charge and is the basis of electrical current.
- Emitter** — One of the outer layers of a bipolar transistor, often the reference.
- Field-Effect Transistor (FET)** — An analog device with a semiconductor channel whose width can be modified by an electric field. Also called a unipolar transistor.
- Gain** — see *Amplification*.
- Gain-Bandwidth Product** — The interrelationship between amplification and frequency that defines the limits of the ability of a device to act as a linear amplifier. In many amplifiers, gain times bandwidth is approximately constant.
- Gate** — The connection at the control point of a field-effect transistor, often the input.
- Grid** — The vacuum-tube element that controls the electron flow from cathode to plate. Additional grids in some tubes perform other control functions to improve performance.
- Hole** — A positively charged "particle" that results when an electron is removed from an atom in a semiconductor crystal structure.
- Integrated Circuit (IC)** — A semiconductor device in which many components, such as diodes, bipolar transistors, field-effect transistors, resistors and capacitors are fabricated to make an entire circuit.
- Junction FET (JFET)** — A field-effect transistor that forms its electric field across a PN junction.
- Linearity** — The property found in nature and most analog electrical circuits that governs the processing and combination of signals by treating all signal levels the same way.
- Load Line** — A line drawn through a family of characteristic curves that shows the operating points of an analog device for a given output load impedance.
- Loading** — The condition that occurs when a cascaded analog stage modifies the operation of the previous stage.
- Metal-Oxide Semiconductor (MOSFET)** — A field-effect transistor that forms its electric field through an insulating oxide layer.
- N-Type Impurity** — A doping atom with an excess of electrons that is added to semiconductor material to give it a net negative charge.
- Noise** — Any unwanted signal.
- Noise Figure (NF)** — A measure of the noise added to a signal by an analog processing stage.
- Operational Amplifier (op amp)** — An integrated circuit that contains a symmetrical circuit of transistors and resistors with highly improved characteristics over other forms of analog amplifiers.
- Oscillator** — An unstable analog system, which causes the output signal to vary spontaneously.
- P-Type Impurity** — A doping atom with an excess of holes that is added to semiconductor material to give it a net positive charge.
- Peak Inverse Voltage (PIV)** — The highest voltage that can be tolerated by a reverse-biased PN junction before current is conducted.
- Pentode** — A five-element vacuum tube with a cathode, a control grid, a screen grid, a suppressor grid, and a plate.
- Plate** — See anode, usually used with vacuum tubes.
- PN Junction** — The region that occurs when P-type semiconductor material is placed in contact with N-type semiconductor material.
- Saturation Region** — The region in the characteristic curve of an analog device in which the output signal can be made no larger. See *Clamping*.
- Semiconductor** — An elemental material whose current conductance can be controlled.
- Signal-To-Noise Ratio (SNR)** — The ratio of the strength of the desired signal to that of the unwanted signal (noise).
- Slew Rate** — The maximum rate at which a signal may change levels and still be accurately amplified in a particular device.
- Source** — The connection at one end of the channel of a field-effect transistor, often the reference.
- Superposition** — The natural process of adding two or more signals together and having each signal retain its unique identity.
- Tetrode** — A four-element vacuum tube with a cathode, a control grid, a screen grid, and a plate.
- Triode** — A three-element vacuum tube with a cathode, a grid, and a plate.
- Unipolar Transistor** — see *Field-Effect Transistor (FET)*.
- Zener Diode** — A PN-junction diode with a controlled peak inverse voltage so that it will start conducting current at a preset reverse voltage.

Introduction

This section, written by Greg Lapin, N9GL, treats analog signal processing in two major parts. Analog signals behave in certain well-defined ways regardless of the specific hardware used to implement the processing. Signal processing involves various electronic stages to perform functions such as amplifying, filtering, modulation and demodulation. A piece of electronic equipment, such as a radio, cascades a number of these circuits. How these stages interact with each other and how they affect the signal individually and in tandem is the subject of

the first part of this chapter.

Implementing analog signal processing functions involves several types of active components. An active electronic component is one that requires a power source to function, and is distinguished in this way from passive components (such as resistors, capacitors and inductors) that are described in the **Real-World Component Characteristics** chapter. The second part of this chapter describes the various technologies that implement active devices. Vacuum tubes, bipolar semiconductors, field-effect

semiconductors and integrated semiconductor circuitry comprise a wide spectrum of active devices used in analog signal processing. Several different devices can perform the same function. The second part of the chapter describes the physical basis of each device. Understanding the specific characteristics of each device allows you to make educated decisions about which device would be best for a particular purpose when designing analog circuitry, or understanding why an existing circuit was designed in a particular way.

Analog Signal Processing

LINEARITY

The term, *analog signal*, refers to the continuously variable voltage of which all radio and audio signals are made. Some signals are man-made and others occur naturally. In nature, analog signals behave according to laws that make radio communication possible. These same laws can be put to use in electronic instruments to allow us to manipulate signals in a variety of ways.

The premier properties of signals in nature are *superposition* and *scaling*. Superposition is the property by which signals combine. If two signals are placed together, whether in a circuit, in a piece of wire, or even in air, they become one combined signal that is the sum of the individual signals. This is to say that at any one point in time, the voltage of the combined signal is the sum of the voltages of the two original signals at the same time. In a linear system any number of signals will add in this way to give a single combined signal.

One of the more important features of superposition, for the purposes of signal processing, is that signals that have been combined can be separated into their original components. This is what allows signals that have been contaminated with noise to be separated from the noise, for example.

Amplification and attenuation scale signals to be larger and smaller, respectively. The operation of scaling is the same as multiplying the signal at each point in time by a constant value; if the constant is greater than one then the signal is amplified, if less than one then the signal is attenuated.

Fig 5.1 — Generic amplifier. (A) Symbol. For the linear amplifier, gain is the constant value, G , and the output voltage is equal to the input voltage times G ; (B) Transfer function, input voltage along the x-axis is converted to the output voltage along the y-axis. The linear portion of the response is where the plot is diagonal; its slope is equal to the gain, G . Above and below this range are the clipping limits, where the response is not linear and the output signal is clipped.

Linear Operations

Any operation that modifies a signal and obeys the rules of superposition and scaling is a *linear operation*. The most basic linear operation occurs in an amplifier, a circuit that increases the amplitude of a signal. Schematically, a generic amplifier is signified by a triangular symbol, its input along the left face and its output

at the point on the right (see Fig 5.1). The linear amplifier multiplies every value of a signal by a constant value. Amplifier gain is often expressed as a multiplication factor (x 5, for example).

$$\text{Gain} = \frac{V_o}{V_i} \quad (1)$$

where V_o is the output voltage from an amplifier when an input voltage, V_i , is applied.

Ideal linear amplifiers have the same gain for all parts of a signal. Thus, a gain of 10 changes 10 V to 100 V, 1 V to 10 V and -1 V to -10 V. Amplifiers are limited by their dynamic range and frequency response, however. An amplifier can only produce output levels that are within the range of its power supply. The power-supply voltages are also called the *rails* of an amplifier. As the amplified output approaches one of the rails, the output will not go beyond a given voltage that is near the rail. The output is limited at the *clipping level* of an amplifier. When an amplifier tries to amplify a signal to be larger than this value, the output remains at this level; this is called output *clipping*. Clipping is a nonlinear effect; an amplifier is considered linear only between its clipping levels. See Fig 5.1.

Another limitation of an amplifier is its frequency response. Signals within a range of frequencies are amplified consistently but outside that range the amplification changes. At higher frequencies an amplifier acts as a low-pass filter, decreasing amplification with increasing frequency. For lower frequencies, amplifiers are of two kinds: dc and ac coupled.

A dc-coupled amplifier equally amplifies signals with frequencies down to dc. An ac-coupled amplifier acts as a high-pass filter, decreasing amplification as the frequency decreases toward dc.

The combination of gain and frequency limitations is often expressed as a *gain-bandwidth product*. At high gains many amplifiers work properly only over a small range of frequencies. In many amplifiers, gain times bandwidth is approximately constant. As gain increases, bandwidth decreases, and vice versa. Another similar descriptor is called *slew rate*. This term describes the maximum rate at which a signal can change levels and still be accurately amplified in a particular device. There is a direct correlation between the signal-level rate of change and the frequency content of that signal.

Feedback and Oscillation

The stability of an amplifier refers to its ability to provide gain to a signal without tending to oscillate. For example, an amplifier just on the verge of oscillating is not generally considered to be “stable.” If the output of an amplifier is fed back to the input, the feedback can affect the amplifier stability. If the amplified output is added to the input, the output of the sum will be larger. This larger output, in turn, is also fed back. As this process continues, the amplifier output will continue to rise until the amplifier cannot go any higher (clamps). Such *positive feedback* increases the amplifier gain, and is called *regeneration*.

Most practical amplifiers have intrinsic feedback that is unavoidable. To improve the stability of an amplifier, *negative*

feedback can be added to counteract any unwanted positive feedback. Negative feedback is often combined with a phase-shift *compensation* network to improve the amplifier stability.

Although negative feedback reduces amplifier or stage gain, the advantages of *stable* gain, freedom from unwanted oscillations, and the reduction of distortion are often key design objectives and advantages of using negative feedback.

The design of feedback networks depends on the desired result. For amplifiers, which should not oscillate, the feedback network is customized to give the desired frequency response without loss of stability. For oscillators, the feedback network is designed to create a steady oscillation at the desired frequency.

Filtering

A filter is a common linear stage in radio equipment. Filters are characterized

Fig 5.2 — Summing amplifier. The output voltage is equal to the sum of the input voltages times the amplifier gain, *G*. As long as the resistance values, *R*, are equal and the amplifier input impedance is much higher, the actual value of *R* does not affect the output signal.

by their ability to selectively attenuate certain frequencies (stop band) while passing or amplifying others (pass band). Passive filters are described in the **RF and AF Filters** chapter. Filters can also be designed using active devices. All practical amplifiers are low-pass filters or band-pass filters, because the gain decreases as the frequency increases beyond their gain-bandwidth products.

Summing Amplifiers

In a linear system, nature does most of the work for us when it comes to adding signals; placing two signals together naturally causes them to add. When processing signals, we would like to control the summing operation so the signals do not distort. If two signals come from separate stages and they are connected, the stages may interact, causing both stages to distort their signals. Summing amplifiers generally use a resistor in series with each stage, so the resistors connect to the common input of the following stage. **Fig 5.2** illustrates the resistors connecting to a summing amplifier. Ideally, any time we wanted to combine signals (for example, combining an audio signal with a PL tone in a 2-m FM transmitter prior to modulating the RF signal) we could use a summing amplifier.

Buffering

It is often necessary to isolate the stages of an analog circuit. This isolation reduces the loading, coupling and feedback between stages. An intervening stage, called a *buffer*, is often used for this purpose. A buffer is a linear circuit that is a type of amplifier. It is often necessary to change the characteristic impedance of a circuit

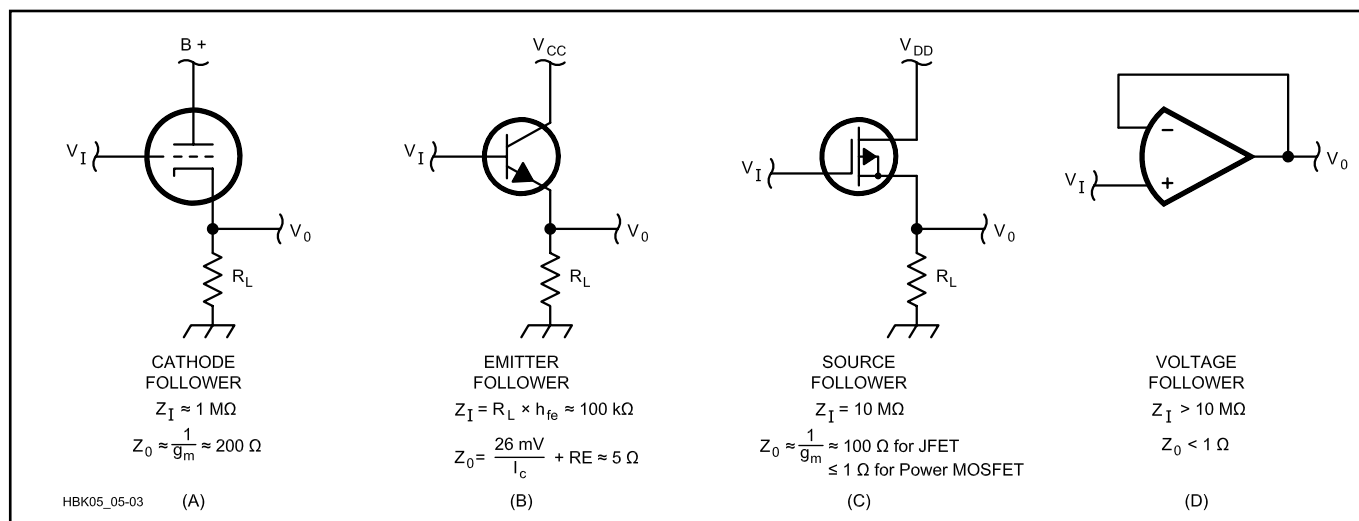

Fig 5.3 — Common buffer stages and some typical input (Z_I) and output (Z_O) impedances. (A) Cathode follower, made with triode tube; (B) Emitter follower, made with NPN bipolar transistor; (C) Source follower, made with FET; and (D) Voltage follower, made with operational amplifier. All of these buffers are terminated with a load resistance, R_L , and have an output voltage that is approximately equal to the input voltage (gain ≈ 1).

between stages. Buffers can have high values of amplification but this is unusual. A buffer performs impedance transformations most efficiently when it has a low or unity gain. **Fig 5.3** shows common forms of buffers with low-impedance outputs: the cathode follower using a triode tube, the emitter follower using a bipolar transistor, the source follower using a field-effect transistor and the voltage follower, using an operational amplifier.

In some circuits, notably power amplifiers, the desired goal is to deliver a maximum amount of power to the output device (such as a speaker or an antenna). Matching the amplifier output impedance to the output-device impedance provides maximum power transfer. A buffer amplifier may be just the circuit for this type of application. Such amplifier circuits must be carefully designed to avoid distortion.

Amplitude Modulation/ Demodulation

Voice signals are transmitted over the air by amplitude modulating them on higher frequency carrier signals (see the **Mixers, Modulators and Demodulators** chapter). The process of amplitude modulation can be mathematically described as the multiplication (product) of the voice signal and the carrier signal. Multiplication is a linear process since amplitude modulating the sum of two audio signals produces a signal that is identical to the sum of amplitude modulating each audio signal individually. When two equal-strength SSB signals are transmitted on the same frequency, the observer hears both of the voices simultaneously. Another aspect of the linear behavior of amplitude modulation is that amplitude-modulated signals can be demodulated to be exactly in their original form. Amplitude demodulation is the converse of amplitude modulation, and is represented as a division operation.

In the linear model of amplitude modulation, the signal to be modulated (such as the audio signal in an AM transmitter) is shifted in frequency by multiplying it with the carrier. The modulated waveform is considered to be a linear function of the signal. The carrier is considered to be part of a time-varying linear system and not a second signal.

A curious trait of amplitude modulation is that it can be performed nonlinearly. Each nonlinear form of amplitude modulation generates the desired linear product term in addition to other unwanted terms that must be removed. Accurate analog multipliers and dividers are difficult and expensive to fabricate. Two common nonlinear amplitude-modulating schemes are much simpler to implement but have dis-

advantages as well.

Power-law modulators generate many frequencies in addition to the desired ones. These unwanted frequencies, often called *intermodulation products*, steal energy from the desired *first order product*. The unwanted signals must be filtered out. The inefficiency of this process makes this type of modulator good only for low-level modulation, with additional amplification required for the modulated signal. A *square-law modulator* can be implemented with a single FET, biased in its saturation region, as the only active component.

Switching modulators are more efficient and provide high-level modulation. A single active device acts as a switch to turn the signal on and off at the carrier frequency. Both the signal and the carrier must be amplified to relatively high levels prior to this form of modulation. The modulated carrier must be filtered by a tank circuit to remove unwanted frequency components generated by the switching artifacts.

Nonlinear demodulation of an amplitude-modulated signal can be realized with a single diode. The diode rectifies the signal (a nonlinear process) and then the nonlinear products are filtered out before the desired signal is recovered.

NONLINEAR OPERATORS

All signal processing doesn't have to be linear. Any time that we treat various signal levels differently, the operation is called *nonlinear*. This is not to say that all signals must be treated the same for a circuit to be linear. High-frequency signals are attenuated in a low-pass filter while low-frequency signals are not, yet the filter can be linear. The distinction is that all voltages of the high-frequency signal are attenuated by the same amount, thus satisfying one of the linearity conditions. What if we do not want to treat all voltage levels the same way? This is commonly desired in analog signal processing for clipping, rectification, compression, modulation and switching.

Clipping and Rectification

Clipping is the process of limiting the range of signal voltages passing through a circuit (in other words, *clipping* those voltages outside the desired range from the signals). There are a number of reasons why we would like to do this. Clipping generally refers to the process of limiting the positive and negative peaks of a signal. We might use this technique to avoid overdriving an amplifier, for example. Another kind of clipping results in rectification. The rectifier clips off all voltages of one polarity (positive or nega-

tive) and allows only the other polarity through, thus changing ac to pulsating dc (see the **Power Supplies** chapter). Another use of clipping is when only one signal polarity is allowed to drive an amplifier input; a clipping stage precedes the amplifier to ensure this.

Logarithmic Amplification

It is sometimes desirable to amplify a signal logarithmically, which means amplifying low levels more than high levels. This type of amplification is often called *signal compression*. Speech compression is sometimes used in audio amplifiers that feed modulators. The voice signal is compressed into a small range of amplitudes, allowing more voice energy to be transmitted without overmodulation (see the **Modes and Modulation Sources** chapter).

ANALOG BUILDING BLOCKS

Many kinds of electronic equipment are developed by combining basic analog signal processing circuits called "building blocks." This section describes several of these building blocks and how they are combined to perform complex functions. Although not all basic electronic functions are discussed here, the characteristics of combining them can be applied generally.

An analog building block can contain any number of discrete components. Since our main concern is the effect that circuitry has on a signal, we often describe the building block by its actions rather than its specific components. For this reason, an analog building block is often referred to as a *two-port network* or a *black box*. Two basic properties of analog networks are of principal concern: the effect that the network has on an analog signal and the interaction that the network has with the circuitry surrounding it. The two network ports are the input and output connections. The signal is fed into the input port, is modified inside the network and then exits from the output port.

An analog network modifies a signal in a specific way that can be described mathematically. The output is related to the input by a *transfer function*. The mathematical operation that combines a signal with a transfer function is pictured symbolically in **Fig 5.4**. The output signal, $w(t)$, has a

Fig 5.4 — Linear function block. The output signal, $w(t)$ is produced by the action of the transfer function, $h(t)$ on the input signal $s(t)$.

value that changes with time. The output signal is created by the action of an analog transfer function, $h(t)$, on the input signal, $g(t)$.

While it is not necessary to understand transfer functions mathematically to work with analog circuits, it is useful to realize that they describe how a signal interacts with other signals in an electronic system. In general, the output signal of an analog system depends not only on the input signal at the same time, but also on past values of the input signal. This is a very important concept and is the basis of such essential functions as analog filtering.

Cascading Stages

If an analog circuit can be described with a transfer function, a combination of analog circuits can also be described similarly. This description of the combined circuits depends upon the relationship between the transfer functions of the parts and that of the combined circuits. In many cases this relationship allows us to predict the behavior of large and complex circuits from what we know about the parts of which they are made. This aids in the design and analysis of analog circuits.

When two analog circuits are cascaded (the output signal of one stage becomes the input signal to the next stage) their transfer functions are combined. The mechanism of the combination depends on the interaction between the stages. The ideal case is when there is no interaction between stages. In other words, the action of the first stage is unchanged, regardless of whether or not the second stage follows it. Just as the signal entering the first stage is modified by the action of the first transfer function, the ideal cascading of analog circuits results in changes produced only by the individual transfer functions. For any number of stages that are cascaded, the combination of their transfer functions results in a new transfer function. The signal that enters the circuit is changed by the composite transfer function, to produce the signal that exits the cascaded circuits.

While each stage in a series may use feedback within itself, feedback around more than one stage may create a function — and resultant performance — different from any of the included stages (oscillation or negative feedback).

Cascaded Buffers

Buffer stages that are made with single active devices can be more effective if cascaded. Two types of such buffers are in common use. The *Darlington pair* is a cascade of two common-collector transistors as shown in **Fig 5.5**. (The various

amplifier configurations will be described later in this chapter.) The input impedance of the Darlington pair is equal to the load impedance times the current gain, h_{FE} . The current gain of the Darlington pair is the product of the current gains for the two transistors.

$$Z_I = Z_{LOAD} \times h_{FE1} \times h_{FE2} \quad (2)$$

For example, if a typical bipolar transistor has $h_{FE} = 100$ and a circuit has a $Z_{LOAD} = 15 \text{ k}\Omega$, a pair of these transistors in the Darlington-pair configuration would have:

$$Z_I = 15 \text{ k}\Omega \times 100 \times 100 = 150 \text{ M}\Omega$$

The shunt capacitance at the input of real transistors can lower the actual impedance as the frequency increases.

A common-emitter amplifier followed by a common-base amplifier is called a *cascode buffer* (see **Fig 5.6**). Cascodes are also made with FETs by following a common-source amplifier by a common-gate configuration. The input impedance and current gain of the cascode are approximately the same as those of the first stage. The output impedance is much higher than that of a single stage. Cascode amplifiers have excellent input/output isolation (very low unwanted feedback) and this can provide high gain with good stability. An example of a cascode buffer made with bipolar transistors has moderate input impedance, $Z_I = 1 \text{ k}\Omega$, high current gain, $h_{FE} = 50$ and high output impedance, $Z_O = 1 \text{ M}\Omega$. There is very little reverse internal feedback in the cascode design, making it very stable, and the amplifier design has little effect on external tuning components. Cascode circuits are often used in tuned amplifier designs for these reasons.

Interstage Loading and Impedance Matching

If the transfer function of a stage changes when it is cascaded with another stage, we say that the second stage has *loaded* the first stage. This often occurs when an appreciable amount of current passes from one stage to the next.

Every two-port network can be further defined by its input and output impedance. The input impedance is the opposition to current, as a function of frequency, seen when looking into the input port of the network. Likewise, the output impedance is similarly defined when looking back into a network through its output port. Interstage loading is related to the relative output impedance of a stage and the input impedance of the stage that is cascaded after it.

In some applications the goal is to transfer a maximum amount of power. In an RF

Fig 5.5 — Darlington pair made with two emitter followers. Input impedance, Z_I , is far higher than for a single transistor and output impedance, Z_O , is nearly the same as for a single transistor. DC biasing has been omitted for simplicity.

Fig 5.6 — Cascode pair made with two NPN bipolar transistors has a medium input impedance and high output impedance. DC biasing has been omitted for simplicity.

amplifier, the impedance at the input of the transmission line feeding an antenna is transformed by means of a matching network to produce the resistance the amplifier needs in order to efficiently produce RF power.

In contrast, it is the goal of most analog signal processing circuitry to modify a signal rather than to deliver large amounts of energy. Thus, an impedance-matched condition may not be what is desired. Instead, current between stages can be minimized by using mismatched impedances. Ideally, if the output impedance of a network approaches zero ohms and the input impedance of the following stage is very high, very little current will pass between the stages, and interstage loading will be negligible.

Noise

Generally we are only interested in specific man-made signals. Nature allows many signals to combine, however, so the desired signal becomes combined with many other unwanted signals, both man-made and naturally occurring. The broadest definition of noise is any signal that is not the one in which we are interested. One of the goals of signal processing is to separate desired signals from noise.

One form of noise that occurs naturally and must be dealt with in low-level processing circuits is called *thermal noise*, or *Johnson noise*. Thermal noise is produced by random motion of free electrons in conductors and semiconductors. This motion increases as temperature increases, hence the name. This kind of noise is present at all frequencies and is proportional to temperature. Naturally occurring noise can be reduced either by decreasing the bandwidth or by reducing the temperature in the system. Thermal noise voltage and current vary with the circuit impedance, according to Ohm's Law. Low-noise-amplifier-design techniques are based on these relationships.

Analog signal processing stages are characterized in part by the noise they add

to a signal. A distinction is made between enhancing existing noise (such as amplifying it) and adding new noise. The noise added by analog signal processing is commonly quantified by the *noise factor*, f . Noise factor is the ratio of the total output noise power (thermal noise plus noise added by the stage) to the input noise power when the termination is at the standard temperature of 290 K (17°C). When the noise factor is expressed in dB, we often call it *noise figure*, NF . NF is calculated as:

$$NF = 10 \log \frac{P_{NO}}{A P_{NTH}} \quad (3)$$

where:

P_{NO} = total noise output power,

A = amplification gain, and

P_{NTH} = input thermal noise power.

The noise factor can also be calculated as the difference between the input and output signal-to-noise ratios (SNR), with SNR expressed in dB.

In a system of many cascaded signal processing stages, each stage affects the noise of the system. The noise factor of the first stage dominates the noise factor of the entire system. Designers try to optimize system noise factor by using a first stage with a minimum possible noise factor and maximum possible gain. A circuit that overloads is often as useless as one that generates too much noise. See the **Receivers and Transmitters** chapter for more information about circuit noise.

Analog Devices

There are several different kinds of components that can be used to build circuits for analog signal processing. The same processing can be performed with vacuum tubes, bipolar semiconductors, field-effect semiconductors or integrated circuitry, each with its own advantages and disadvantages.

TERMINOLOGY

A similar terminology is used for most active electronic devices. The letter V stands for voltages and I for currents. Voltages generally have two subscripts indicating the terminals between which the voltage is measured (V_{BE} is the voltage between the base and the emitter of a bipolar transistor). Currents have a single subscript indicating the terminal into which the current flows (I_p is the current into the plate of a vacuum tube). If the current flows out of the device, it is generally indicated with a negative sign. Power supply voltages have two subscripts that are the same, indicating the terminal to which the voltage is applied (V_{DD} is the power supply voltage applied to the drain of a field-effect transistor). A transfer characteristic is a ratio of an output parameter to an input parameter, such as output current divided by input current. Transfer characteristics are represented with letters, such as h , s , y or z . Resistance is designated with the letter r , and impedance with the letter Z . For example, r_{DS} is resistance between drain and source of an FET and Z_i is input impedance. In some designators, values differ for dc and ac signals. This is indicated by using capital letters in the subscripts for dc and lowercase subscripts for ac. For example, the

common-emitter dc current gain for a bipolar transistor is designated as h_{FE} , and h_{fe} is the ac current gain. Qualifiers are sometimes added to the subscripts to indicate certain operating modes of the device. SS for saturation, BR for breakdown, ON and OFF are all commonly used.

The abbreviations for tubes existed before these standards were adopted so some tube-performance descriptors are different. For example, $B+$ is usually used for the plate bias voltage. Since integrated circuits are collections of semiconductor components, the abbreviations for the type of semiconductor used also apply to the integrated circuit. V_{CC} is a power supply voltage for an integrated circuit made with bipolar transistor technology.

Amplifier Types

Amplifier configurations are described by the *common* part of the device. The word "common" is used to describe the connection of a lead directly to a reference. The most common reference is ground, but positive and negative power sources are also valid references. The type of reference used depends on the type of device (vacuum tube, transistor [NPN or PNP], FET [P-channel or N-channel]), which lead is common and the range of signal levels. Once a common lead is chosen, the other two leads are used for signal input and output. Based on the biasing conditions, there is only one way to select these leads. Thus, there are three possible amplifier configurations for each type of three-lead device.

The operation of an amplifier is specified by its gain. A gain in this sense is defined as the change (Δ) in the output

parameter divided by the corresponding change in the input parameter. If a particular device measures its input and output as currents, the gain is called a current gain. If the input and output are voltages, the amplifier is defined by its voltage gain. If the input is a voltage and the output is a current, the ratio is called the *transconductance*.

Characteristic Curves

Analog devices are described most completely with their *characteristic curves*. Almost all devices of concern are nonlinear over a wide range of operating parameters. We are often interested in using a device only in the region that approximates a linear response. The characteristic curve is a plot of the interrelationships between two or three variables. The vertical (y) axis parameter is the output, or result of the device being operated with an input parameter on the horizontal (x) axis. Often the output is the result of two input values. The first input parameter is represented along the x axis and the second input parameter by several curves, each for a different value. For example, a vacuum tube characteristic curve may have the plate current along the y axis, the grid voltage along the x axis and several curves, each representing a different value of the plate bias voltage (see **Fig 5.7**).

The parameters plotted in the characteristic curve depend on how the device will be used. The common amplifier configuration defines the input and output leads, and their relationship is diagrammed by the curves. Device parameters are usually derived from the characteristic curve. To calculate a gain,

Fig 5.7 — Tube characteristic curve. Input signal is the grid voltage, V_g , along the x-axis, and the output signal is the plate current, I_p , along the y-axis. Different curves are plotted for various values of plate bias voltage, V_p (also called B+).

the operating region of the curve is specified, usually a straight portion of the curve if linear operation is desired. Two points along that portion of the curve are selected, each defined by its location along the x and y axes. If the two points are defined by (x_1, y_1) and (x_2, y_2) , the slope, m , of the curve, which can be a gain, a resistance or a conductance, is calculated as:

$$m = \frac{\Delta y}{\Delta x} = \frac{y_1 - y_2}{x_1 - x_2} \quad (4)$$

A characteristic curve that plots device output voltage and current along the x and y axes permits the inclusion of an additional curve. The *load line* is a straight line with a slope that is equal to the load impedance. The intersections between the load line and the characteristic curves indicate the operating points for that circuit. Load lines are only applicable to output characteristic plots; they cannot be used with input or transfer (input versus output) characteristic curves.

BIASING

The operation of an analog signal-processing device is greatly affected by which portion of the characteristic curve is used to do the processing. As an example, consider the vacuum tube characteristic curves in **Fig 5.8** and **Fig 5.9**.

The relationship between the input and the output of a tube amplifier is illustrated in **Fig 5.8**. The input signal (a sine wave in this example) is plotted in the vertical direction and below the graph. For a grid bias level of -5 V, the sine wave causes the grid voltage, V_g , to deviate between -3 and -7 V. These values correspond to a range of plate currents, I_p , between 1.4 and 2.6 mA. With a plate bias of 200 V and

a load resistance, R_p , of 50 k Ω , the corresponding change in plate voltage, V_p , is between 70 and 130 V. Thus, this triode amplifier configuration changes a range of 4 V at the input to 60 V at the output. Also there is a change of output-signal voltage polarity; this amplifier both amplifies the signal magnitude 15 times and shifts the phase of the signal by 180 $^\circ$.

In the previous example the signal was biased so that it fell on a linear (straight) portion of the characteristic curve. If a different bias voltage is selected so that the signal does not fall on a linear portion of the curve, the output signal will be a distorted version of the input signal. This is illustrated in **Fig 5.9**. The input signal is amplified within a curved region of the characteristic curve. The positive part of the signal is amplified more than the negative part of the signal. Proper biasing is crucial to ensure amplifier linearity.

Input biasing serves to modify the relative level (dc offset) of the input signal so that it falls on the desired portion of the characteristic curve. Devices that perform signal processing (vacuum tubes, diodes, bipolar transistors, field-effect transistors and operational amplifiers) usually require appropriate input signal biasing.

Manufacturers' Data Sheets

Manufacturer's data sheets list device characteristics, along with the specifics of the part type (polarity, semiconductor type), identification of the pins, and the typical use (such as small signal, RF, switching or power amplifier). The pin identification is important because, although common package pinouts are normally used, there are exceptions. Manufacturers may differ slightly in the values reported, but certain basic parameters are listed. Different batches of the same devices are rarely identical, so manufacturers specify the guaranteed limits for the parameters of their device. There are usually three columns of values listed in the data sheet. For each parameter, the columns may list the guaranteed minimum value, the guaranteed maximum value and/or the typical value.

Another section of the data sheet lists ABSOLUTE MAXIMUM RATINGS, beyond which device damage may result. For example, the parameters listed in the ABSOLUTE MAXIMUM RATINGS section for a solid-state device are typically voltages, continuous currents, total device power dissipation (P_D) and operating- and storage-temperature ranges.

Rather than plotting the characteristic curves for each device, the manufacturer often selects key operating parameters that describe the device operation for the

Fig 5.8 — Determination of output signal (to the right of the plot) for a given input signal (below the plot, turned on its side) with a tube characteristic curve plotted for a given plate bias. Note that the grid bias voltage, -5 V, causes the entire range of the input signal to be mapped onto the linear (diagonal straight line) portion of the characteristic curve. The output signal has the same shape as the input signal except that it is larger in amplitude.

Fig 5.9 — Same characteristic curve and input signal as in **Fig 5.8 except the grid bias voltage is now about -8.75 V. The input signal falls on the curved (non-linear) portion of the plot and causes distortion in the output signal. Note how the upper portion of the output sine wave was amplified more than the lower portion.**

configurations and parameter ranges that are most commonly used. For example, a bipolar transistor data sheet might include an OPERATING PARAMETERS section. Parameters are listed in an OFF CHARACTERISTICS subsection and an ON CHARACTERISTICS subsection that describe the conduction properties of the device for dc voltages. The SMALL-SIGNAL CHARACTERISTICS section

often contains the guaranteed minimum Gain-Bandwidth Product (f_T), the guaranteed maximum output capacitance, the guaranteed maximum input capacitance and the guaranteed range of the transfer parameters applicable to a given device. Finally, the SWITCHING CHARACTERISTICS section lists absolute maximum ratings for Delay Time (t_d), Rise Time (t_r), Storage Time (t_s) and Fall Time (t_f). Other types of devices list characteristics important to operation of that specific device.

When selecting equivalent parts for replacement of specified devices, the data sheet provides the necessary information to tell if a given part will perform the functions of another. Lists of equivalencies generally only specify devices that have nearly identical parameters. There are usually a large number of additional devices that can be chosen as replacements. Knowledge of the circuit requirements adds even more to the list of possible replacements. The device parameters should be compared individually to make sure that the replacement part meets or exceeds the parameter values of the original part required by the circuit. Be aware that in some applications a far superior part may fail as a replacement, however. A transistor with too much gain could easily oscillate if there were insufficient negative feedback to ensure stability.

VACUUM TUBES

Current is generally described as the flow of electrons through a conductor, such as metal. The vacuum tube controls the flow of electrons in a vacuum, which is analogous to a faucet that adjusts the flow of a fluid. The British commonly refer to vacuum tubes as *valves*. Although the physics of the operation of vacuum tubes varies greatly from that of semiconductors, there are many similarities in the way that they behave in analog circuits.

Thermionic Theory

Metals are elements that are characterized by their large number of free electrons. Individual atoms do not hold onto all of their electrons very tightly, and it is relatively easy to dislodge them. This property makes metals good conductors of electricity. Under electrical pressure (voltage), electrons collide with metal atoms, dislodging an equal number of free electrons from the metal. These collide with adjoining metal atoms to continue the process, resulting in a flow of electrons.

It is also possible to cause the free electrons to be emitted into space if enough energy is added to them. Heat is one way of adding energy to metal atoms, and the

resulting flow of electrons into space is called *thermionic emission*. It is important to remember that the metal atoms don't permanently lose electrons; the emitted electrons are replaced by others that come from an electrical connection to the heated metal. Thus, an electron that flows into the heated metal collides with and is captured by a metal atom, knocking loose a highly energized electron that is emitted into space.

In a vacuum, there are no other atoms with which the emitted electron can collide, so it follows a straight path until it collides with another atom. A *vacuum tube* has nearly all of the air evacuated from it, so the emitted electrons proceed unhindered to another piece of metal, where they continue to move as part of the electrical current.

Components of a Vacuum Tube

A basic vacuum tube contains at least two parts: a *cathode* and a *plate*. The electrons are emitted from the *cathode*. The cathode can either be heated directly by passing a large dc current through it, or it can be located adjacent to a heating element. Although ac currents can also be used to directly heat cathodes, if any of the ac voltage mixes with the signal, ac hum will be introduced into the output. If the ac heater supply voltage can be obtained from a center tapped transformer, and the center tap is connected to the signal ground, hum can be minimized. Cathodes are made of substances that have the highest emission of electrons for the lowest temperatures and voltages. Tungsten, thoriated-tungsten and oxide-coated metals are commonly used.

Every vacuum tube needs a receptor for the emitted electrons. After moving through the vacuum, the electrons are absorbed by the *plate*. Since the plate receives electrons, it is also called the *anode*. Each electron has a negative charge, so a positively biased plate will attract the emitted electrons to it, and a current will result. For every electron that is accepted by the plate, another electron flows into the cathode; the plate and cathode currents must be the same. As the plate voltage is increased, there is a larger electrical field attracting electrons, causing more of them to be emitted from the cathode. This increases the current through the tube. This relationship continues until a limit is reached where further increases to the electrical field do not cause any more electrons to be emitted. This is the *saturation point* of the vacuum tube.

A vacuum tube that contains only a cathode and a plate is called a *diode tube*

(di- for two components). See Fig 5.10. The diode tube is similar to a semiconductor diode since it allows current to pass in only one direction; it is used as a rectifier. When the plate voltage becomes

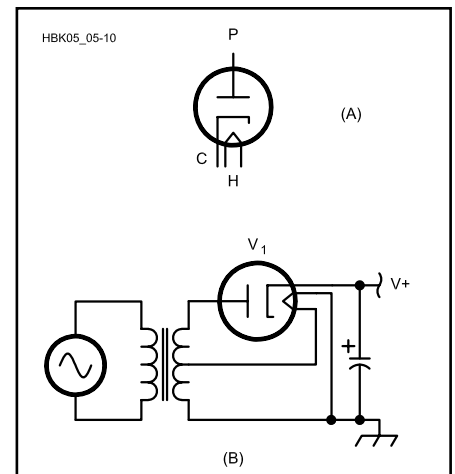

Fig 5.10 — Vacuum tube diode. (A) Schematic symbol detailing heater (H), cathode (C) and plate (P). (B) Power supply circuit using diode as a half wave rectifier.

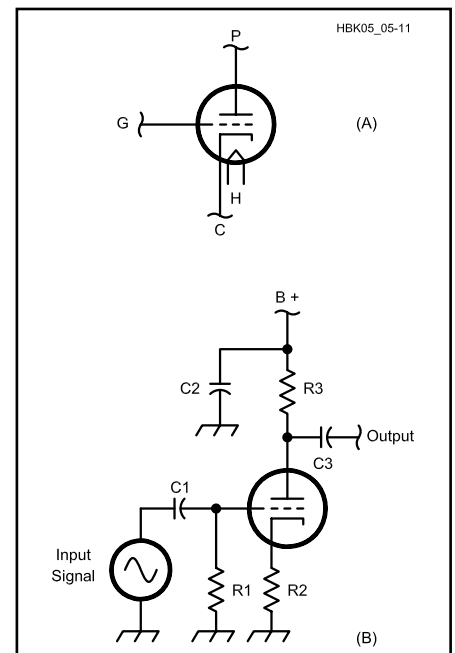

Fig 5.11 — Vacuum tube triode. (A) Schematic symbol detailing heater (H), cathode (C), grid (G) and plate (P). (B) Audio amplifier circuit using a triode. C1 and C3 are dc blocking capacitors for the input and output signals to isolate the grid and plate bias voltages. C2 is a bypass filter capacitor to decrease noise in the plate bias voltage, B+. R1 is the grid bias resistor, R2 is the cathode bias resistor and R3 is the plate bias resistor. Note that although the cathode and grid bias voltages are positive with respect to ground, they are still negative with respect to the plate.

negative, the electrical field that is set up repels electrons, preventing them from being emitted from the cathode.

To amplify signals, a vacuum tube must also contain a control *grid*. This name comes from its physical construction. The grid is a mesh of wires located between the cathode and the plate. Electrons from the cathode pass between the grid wires on their way to the plate. The electrical field that is set up by the voltage on these wires affects the electron flow from cathode to plate. A negative grid voltage sets up an electrical field that repels electrons, decreasing emission from the cathode because of the higher energy needed for the electrons to escape from their atoms into the vacuum. A positive grid voltage will have the opposite effect. Since the plate voltage is always positive, however, grid voltages are usually negative. The more negative the grid, the less effective the electrical field from the plate will be at attracting electrons from the cathode.

Vacuum tubes containing a cathode, a grid and a plate are called *triode* tubes (tri- for three components). See Fig 5.11. They are generally used as amplifiers, particularly at frequencies in the HF range and below. Characteristic curves for triodes normally relate grid bias voltage and plate bias voltage to plate current for the triode (Fig 5.7). There are three descriptors of a tube's performance that can be derived from the characteristic curves. The *plate resistance*, r_p , describes the resistance to the flow of electrons from cathode to plate. The r_p is calculated by selecting a vertical line in the characteristic curve and dividing the change in plate-to-cathode voltage (ΔV_p) of two of the lines by the corresponding change in plate current (ΔI_p).

$$r_p = \frac{\Delta V_p}{\Delta I_p} \quad (5)$$

The ratio of change in plate voltage (ΔV_p) to the change in grid-to-cathode voltage (ΔV_g) for a given plate current is the *amplification factor* (μ). Amplification factor is calculated by selecting a horizontal line in the characteristic curve and dividing the difference in plate voltage of two of the lines by the difference in grid voltages that corresponds to the same points.

$$\mu = \frac{\Delta V_p}{\Delta V_g} \quad (6)$$

Triode amplification factors range from 10 to about 100.

The plate current flows to the plate bias supply, so the output from a triode ampli-

Fig 5.12 — Vacuum tube dynamic characteristic curve. This corresponds to the $V_p = 300$ line in Fig 5.7 with different values of load resistance. This shows how the tube will behave when cascaded to circuits with different input impedances.

Fig 5.13 — Vacuum tube tetraode. Schematic symbol detailing heater (H), cathode (C), the two grids: control and screen, and the plate (P).

fier is often expressed as the voltage that is developed as this current passes through a load resistor. The value of the load resistance affects the tube amplification, as illustrated by the dynamic characteristic curves in Fig 5.12, so the tube μ does not fully describe its action as an amplifier. *Grid-plate transconductance* (g_m) takes into account the change of amplification due to load resistance. The slope of the lines in the characteristic curve represents g_m . (Since the various lines are nearly parallel in the linear operating region, they have about the same slope.)

$$g_m = \frac{\Delta I_p}{\Delta V_g} \quad (7)$$

This ratio represents a conductance, which is measured in siemens. Triodes have g_m values that range from about 1000 to several thousand microsiemens, the higher values indicating greater possible amplification.

The input impedance of a vacuum tube amplifier is directly related to the grid current. Grid current varies with grid volt-

age, increasing as the voltage becomes more positive. The normal operation uses a negative grid-bias voltage, and the input impedance can be in the megohm range for very negative grid bias values. This is, however, limited by the desired operating point on the characteristic curve as illustrated in Figs 5.8 and 5.9. The output impedance of the amplifier is a function of the plate resistance, r_p , in parallel with the output capacitance. Typical output impedance is on the order of hundreds of ohms.

The physical configuration of the components within the vacuum tube appears as conductors that are separated by an insulator (in this case, the vacuum). This description is very similar to that of a capacitor. The capacitance between the cathode and grid, between the grid and plate, and between the cathode and plate can be large enough to affect the operation of the amplifier at high frequencies. These capacitances, which are usually on the order of a few picofarads, can limit the frequency response of a vacuum tube amplifier and can also provide signal feedback paths that may lead to unwanted oscillation. Neutralizing circuits are sometimes used to counteract the effects of internal capacitances and to prevent oscillations.

The grid-to-plate capacitance is the chief source of unwanted signal feedback. A special form of vacuum tube has been developed to deal with the grid-to-plate capacitance. A second grid, called a *screen grid*, is inserted between the original grid (now called a *control grid*) and the plate. The additional tube component leads to the name for this new tube — *tetrode* (tetra- for four components). See Fig 5.13. The screen grid reduces the capacitance between the control grid and the plate, but it also reduces the electrical field from the plate that attracts electrons from the cathode. Like the control grid, the screen grid is made of a wire mesh and electrons pass through the spaces between the wires to get to the plate. The bias of the screen grid is positive with respect to the cathode, in order to enhance the attraction of electrons from the cathode. The electrons accelerate toward the screen grid and most of them pass through the spaces and continue to accelerate until they reach the plate. The presence of the screen grid adversely affects the overall efficiency of the tube, since some of the electrons strike the grid wires. A bypass capacitor with a low reactance at the frequency being amplified by the vacuum tube is generally connected between the screen grid and the cathode.

A special form of tetrode concentrates the electrons flowing between the cathode and the plate into a tight beam. The decreased electron-beam area increases the

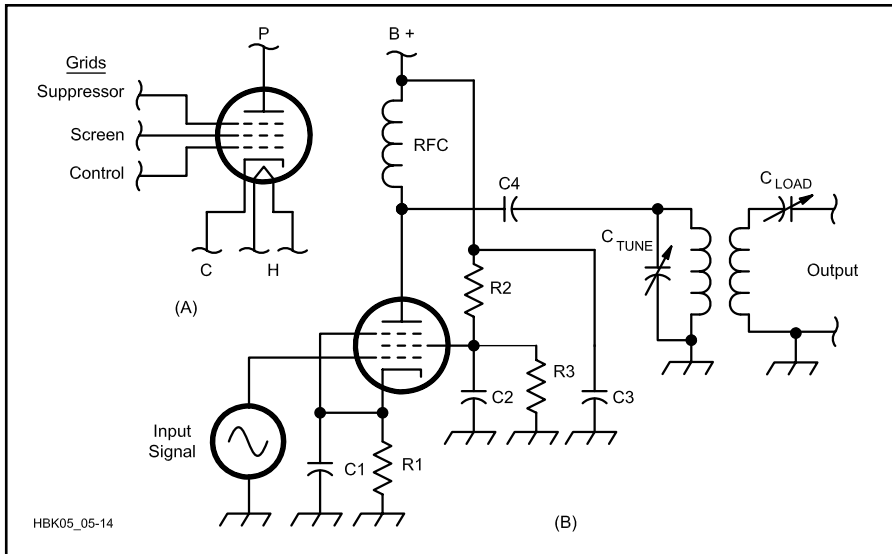

Fig 5.14 — Vacuum tube pentode. (A) Schematic symbol detailing heater (H), cathode (C), the three grids: control, screen and suppressor, and plate (P). (B) RF amplifier circuit using a pentode. C1, C2 and C3 are bypass (filter) capacitors and C4 is a dc blocking capacitor to isolate the plate voltage from the tank circuit components. R1 is the cathode bias resistor. R2 and R3 comprise a screen-dropping voltage divider. The plate tank circuit is tuned to the desired frequency bandpass. As is common, the heater circuit is not shown.

efficiency of the tube. *Beam tetrodes* permit higher plate currents with lower plate voltages and large power outputs with smaller grid driving power. RF power amplifiers are usually made with this type of vacuum tube.

Another unwanted effect in vacuum tubes is the emission of electrons from the plate. The electrons flowing within the tube have so much energy that they are capable of dislodging electrons from the metal atoms in the plate. These *secondary emission* electrons are repelled back to the plate by the negative bias of the grid in a triode and are of no concern. In the tetrode, the screen grid is positively biased and attracts the secondary emission electrons, causing a reverse current from the plate to the screen grid.

A third grid, called the *suppressor grid*, can be added between the screen grid and the plate. This overcomes the effects of secondary emission in tetrodes. A vacuum tube with three grids is called a *pentode* (penta for five components). See Fig 5.14. The suppressor grid is negatively biased with respect to the screen grid and the plate. In some tube designs it is internally connected to the cathode. The suppressor grid repels the secondary emission electrons back to the plate.

As the number of grids is increased between the cathode and the plate, the effect of the electrical field from the positive plate voltage at the cathode is decreased. This limits the number of electrons that can be emitted from the cathode and the

characteristic curves tend to flatten out as the grid bias becomes less negative. This flattening is another nonlinearity of the tube as an amplifier, since the response saturates at a given plate current and will go no higher. Tube saturation can be used advantageously in some circuits if a constant current source is desired, since the current does not change within the saturation region regardless of changes in plate voltage.

Types of Vacuum Tube Amplifiers

The descriptions of vacuum tube amplifiers up to this point have been for only one configuration, the common cathode, where the cathode is connected to the signal reference point, the grid is the input and the plate is the output. Although this is the most common configuration of the vacuum tube as an amplifier, other configurations exist. If the signal is introduced into the cathode and the grid is at a reference level (still negatively biased but with no ac component), with the output at the plate, the amplifier is called a *grounded-grid* (Fig 5.15). This amplifier is characterized by a very low input impedance, on the order of a few hundred ohms, and a low output impedance, that is mainly determined by the plate resistance of the tube.

The third configuration is called the *cathode follower* (Fig 5.16). The plate is the common element, the grid is the input and the cathode is the output. This type of amplifier is often used as a buffer stage

Fig 5.15 — Grounded grid amplifier schematic. The input signal is connected to the cathode, the grid is biased to the appropriate operating point by a dc bias voltage, $-V_G$, and the output voltage is obtained by the voltage drop through R_L that is developed by the plate current, I_p .

Fig 5.16 — Cathode follower schematic. The input signal is biased by $-V_G$ and fed into the grid. The plate bias, $B+$ is fed directly into the plate terminal. The output is derived by the cathode current (which is equal to the plate current, I_p) dropping the voltage through the load resistor, R_L .

due to its high input impedance, similar to that of the common cathode amplifier, and its very low output impedance. The output impedance (Z_o) can be calculated from the tube characteristics as:

$$Z_o = \frac{r_p}{1 + \mu} \quad (8)$$

where:

r_p = tube plate resistance

μ = tube amplification factor.

For a close approximation, we can simplify this equation as:

$$Z_o \approx \frac{r_p}{\mu} = \frac{1}{g_m}$$

Other Types of Tubes

Vacuum tube identifiers do not generally indicate the tube type. The format is typically a number, one or two letters and a number (such as 6AU6 or 12AT7). The first number in the identifier indicates the heater voltage (usually either 6 or 12 V). The last number often indicates the number of elements, including the heater. Some tubes also have an additional letter following the identifier (usually A or B) that indicates a revision of the tube design that represents an improvement in its operating parameters. There are also tubes that do not follow this naming convention, many of which are power amplifiers or military-type tubes (such as 6146 and 811).

To reduce stray reactances, some tubes do not have the plate connection in the tube base, where all the other connections are located. Rather, a connection is made at the top of the tube through a metallic cap. This requires an additional connector for the plate circuitry.

Tubes may share components in a single envelope to reduce size and incidental power requirements. A very common example of this is the dual triode tube (such as 12AT7 or 12AU7) that contains a single heater circuit and two complete triode tubes in the same device. Other configurations of multiple devices contained in a single vacuum tube also exist. The 6GW8 and 6EA8 tubes each contain both a triode and a pentode. The 6BN8 contains three distinct devices, one triode and two diodes.

Most common vacuum tubes are encased in glass. It is also possible to encase them in metal or ceramic materials to attain higher tube power and smaller size. Since heat dissipation from the plate is one

of the major limiting factors for vacuum tube power amplifiers, the alternate materials remove heat more efficiently. These tubes can be cooled by convection, with the casing connected to a large heat sink, or with water flowing past the tube for hydraulic cooling.

A variation of the vacuum tube that is widely used in oscilloscopes and television monitors is the *cathode ray tube (CRT)*, diagrammed in **Fig 5.17**. The CRT has a cathode and grid much like a triode tube. The plate, usually referred to as the *anode* in this device, is designed to accelerate the electrons to very high velocities, with anode voltages that can be as high as tens of thousands of volts. The anode of the CRT differs from the plates of other vacuum tubes, since it is designed as a set of plates that are parallel to the electron beam. The anode voltage accelerates the electrons but does not absorb them. The electron beam passes by the anode and continues to the face of the tube. The cathode, grid and anode are all located in the neck of the CRT and are collectively referred to as the *electron gun*.

The electron beam is deflected from its path by either magnetic deflectors that surround the yoke of the tube or by electrostatic deflection plates that are built into the tube neck just beyond the electron gun. A CRT typically has two sets of deflectors: vertical and horizontal. When a potential is applied to a set of deflectors, the passing electron beam is bent, altering its path. In an oscilloscope, the time base typically drives the horizontal deflectors and the input signal drives the vertical deflectors, although in many oscilloscopes it is possible to connect another input signal to the horizontal deflectors to

obtain an X-Y, or vector, display. In televisions and some computer monitors the deflectors typically are driven by a raster generator. The horizontal deflectors are driven by a sawtooth pattern that causes the beam to move repeatedly from left to right and then retrace quickly to the left. The vertical deflectors are driven by a slower sawtooth pattern that causes the beam to move repeatedly from top to bottom and then retrace quickly to the top. The relative timing of the two sawtooth patterns is such that the beam scans from left to right, retraces to the left and then begins the next horizontal trace just below the previous one.

Beyond the deflectors, the CRT flares out. The front face is coated with a phosphorescent material that glows when struck by the electron beam. To prevent spurious phosphorescence, a conductive layer along the sides of the tube absorbs any electrons that reflect off the glass.

Vector displays have better resolution than raster scanning. The trace lines are clearer, which is the reason oscilloscope displays use this technique. It is faster to fill the screen using raster scanning, however. This is why TVs use raster scanning.

Some CRT tubes are designed with multiple electron beams. The beams are sometimes generated by different electron guns that are placed next to each other in the neck of the tube. They can also be generated by splitting the output of a single electron gun into two or more beams. Very high quality oscilloscopes use two electron beams to trace two input channels rather than the more common method of alternating a single beam between the two inputs. Color television tubes use three electron beams for the three primary colors (red, green and blue). Each beam is focused on only one of these colored phosphors, which are interleaved on the face of the tube. A metal shadow mask keeps the colors separate as the beams scan across the tube.

A variation of the CRT is the *vidicon tube*. The vidicon is used in many video cameras and operates in a similar fashion to the CRT. The vidicon absorbs light from the surroundings, which charges the plate at the location of the light. This charge causes the cathode-to-plate current to increase when the raster scan points the electron beam at that location. The current increase is converted to a voltage that is proportional to the amount of light absorbed. This results in an electrical signal that represents the pattern of a visual image.

Standard vacuum tubes work well for frequencies up to hundreds of megahertz. At frequencies higher than this, the

Fig 5.17 — Cross section of CRT. The electron gun generates a stream of electrons and is made up of a heater, cathode, grid and anode (plate). The electron beam passes by two pairs of deflection plates that deviate the path of the beam in the vertical (y) direction and then the horizontal (x) direction. The deflected electron beam strikes a phosphor screen and causes it to glow at that spot. Any electrons that bounce off the screen are absorbed by the conductive layer along the sides of the tube, preventing spurious luminescence.

amount of time that it takes for the electrons to move between the cathode and the plate becomes a limiting factor. There are several special tubes designed to work at microwave frequencies. The *klystron* tube uses the principle of velocity modulation of the electrons to avoid transit time limitations. The beam of electrons travels down a metal drift tube that has interaction gaps along its sides. RF voltages are applied to the gaps and the electric fields that they generate accelerate or decelerate the passing electrons. The relative positions of the electrons shift due to their changing velocities causing the electron density of the beam to vary. The modulation of the electron density is used to perform amplification or oscillation. Klystron tubes tend to be relatively large, with lengths ranging from 10 cm to 2 m and weights ranging from as little as 150 g to over 100 kg. Unfortunately, klystrons have relatively narrow bandwidths, and are not retunable by amateurs for operation on different frequencies.

The *magnetron* tube is an efficient oscillator for microwave frequencies. Magnetrons are most commonly found in microwave ovens and high-powered radar equipment. The anode of a magnetron is made up of a number of coupled resonant cavities that surround the cathode. The magnetic field causes the electrons to rotate around the cathode and the energy that they give off as they approach the anode adds to the RF electric field. The RF power is obtained from the anode through a vacuum window. Magnetrons are self-oscillating with the frequency determined by the construction of their anodes; however, they can be tuned by coupling either inductance or capacitance to the resonant anode. The range of frequencies depends on how fast the tuning must be accomplished. The tube may be tuned slowly over a range of approximately 10% of the center frequency. If faster tuning is necessary, such as is required for frequency modulation, the range decreases to about 5%.

A third type of tube capable of operating in the microwave range is the *traveling wave tube*. For wide band amplifiers in the microwave range this is the tube of choice. Either permanent magnets or electromagnets are used to focus the beam of electrons that emerges from an electron gun similar to the one described for the CRT tube. The electron beam passes through a helical *slow-wave structure*, in which electrons are accelerated or decelerated, providing density modulation due to the applied RF signal, similar to that in the klystron. The modulated electron beam induces voltages in the helix that provides an amplified tube output whose

gain is proportional to the length of the slow-wave structure. After the RF energy is extracted from the electron beam by the helix, the electrons are collected and recycled to the cathode. Traveling wave tubes can often be operated outside their designed frequencies by carefully optimizing the beam voltage.

PHYSICAL ELECTRONICS OF SEMICONDUCTORS

Every atom of matter consists of, among other things, an equal number of protons and electrons. These two subatomic particles must match in number to neutralize the electric charge: one positive charge for a proton and one negative charge for an electron.

Electrons orbit the nucleus, which contains the protons, at different energy levels. The binding of the electrons to the nucleus determines how an atom will behave electrically. Loosely bound electrons are easily liberated from their nuclei; atoms with this property are called *conductors*. In contrast, tightly bound electrons require considerable energy to be dislodged from their atoms; these atoms are called *insulators*. In between these two extremes is a class of elements called *semiconductors*, or partial conductors. As energy is added to a semiconductor atom, electrons are more easily freed. This property leads to many potential applications for this type of material.

In a conductor, such as a metal, the outer, or *valence*, electrons of each atom are shared with the adjacent atoms so there are many electrons that can move about freely between atoms. The moving free electrons are the constituents of electrical current. In a good conductor, the concentration of these free electrons is very high, on the order of 10^{22} electrons/cm³. In an insulator, nearly all the electrons are tightly held by their atoms; the concentration of free electrons is very small, on the order of 10 electrons/cm³.

Semiconductor atoms (germanium — Ge and silicon — Si) share their valence electrons in a chemical bond that holds adjacent atoms together. The electrons are not free to leave their atom in order to move into the sphere of the adjacent atom, as in a conductor. They can be shared by the adjacent atom, however. The sharing of electrons means that the adjacent atoms are attracted to each other, forming a bond that gives the semiconductor its physical structure.

When energy is added to a semiconductor lattice, generally in the form of heat, some electrons are liberated from their bonds and move freely throughout the structure. The bond that loses an electron

is then unbalanced and the space that the electron came from is referred to as a *hole*. Electrons from adjacent bonds can leave their positions and fill the holes, thus creating new holes in the adjacent bonds. Two opposite movements can be said to occur: negatively charged electrons move from bond to bond in one direction and positively charged holes move from bond to bond in the opposite direction. Both of these movements represent forms of electrical current, but this is very different from the current in a conductor. While the conductor has *free electrons* that flow regardless of the crystalline structure, the current in a semiconductor is constrained to move only along the crystalline lattice between adjacent bonds.

Crystals formed from pure semiconductor atoms (Ge or Si) are called *intrinsic* semiconductors. In these materials the number of free electrons is equal to the number of holes. Each atom has four valence electrons that form bonds with adjacent atoms. Impurities can be added to the semiconductor material to enhance the formation of electrons or holes. These are *extrinsic* semiconductors. There are two types of impurities that can be added: one kind with five valence electrons *donates* free electrons to the crystalline structure; this is called an *N-type* impurity, for the negative charge that it adds. Some examples are antimony (Sb), phosphorus (P) and arsenic (As). N-type extrinsic semiconductors have more electrons and fewer holes than intrinsic semiconductors. Impurities with three valence electrons accept free electrons from the lattice, adding holes to the overall structure. These are called P-type impurities, for the net positive charge; some examples are boron (B), gallium (Ga) and indium (In).

Intrinsic semiconductor material can be formed by combining equal amounts of N-type and P-type impurity materials. Some examples of this include gallium-arsenide (GaAs), gallium-phosphate (GaP) and indium-phosphide (InP). To make an N-type compound semiconductor, a slightly higher amount of N-type material is used in the mixture. A P-type compound semiconductor has a little more P-type material in the mixture.

The conductivity of an extrinsic semiconductor depends on the charge density (in other words, the concentration of free electrons in N-type, and holes in P-type, semiconductor material). As the energy in the semiconductor increases, the charge density also increases. This is the basis of how all semiconductor devices operate: the major difference is the way in which the energy level is increased. Variations are: The *transistor*, where conductivity is

altered by injecting current into the device via a wire; the *thermistor*, where the level of heat in the device is detected by its conductivity, and the *photoconductor*, where light energy that is absorbed by the semiconductor material increases the conductivity.

The PN Semiconductor Junction

If a piece of N-type semiconductor material is placed against a piece of P-type semiconductor material, the location at which they join is called a *PN semiconductor junction*. The junction has characteristics that make it possible to develop diodes and transistors. The action of the junction is best described by a diode operating as a rectifier. Initially, when the two types of semiconductor material are placed in contact, each type of material will have only its majority carriers: P-type will have only holes and N-type will have only free electrons. The net positive charge of the P-type material attracts free electrons from across the junction and the opposite is true in the N-type material. These attractions lead to diffusion of some of the majority carriers across the junction, which neutralize the carriers immediately on the other side. The region close to the junction is then *depleted* of carriers, and, as such, is named the *depletion region* (or the *space-charge region* or the *transition region*). The width of the depletion region is very small, on the order of $0.5\ \mu\text{m}$.

If the N-type material is placed at a more negative voltage than the P-type material, current will pass through the junction because electrons are attracted from the lower potential to the higher potential and holes are attracted in the opposite direction. When the polarity is reversed, current does not flow because the electrons that are trying to enter the N-type material are repelled, as are the holes trying to enter the P-type material. This unidirectional current is what allows a semiconductor diode to act as rectifier.

Diodes are commonly made of silicon or germanium. Although they act similarly, they have slightly different characteristics. The *junction threshold voltage*, or *junction barrier voltage*, is the forward bias voltage at which current begins to pass through the device. This voltage is different for the two kinds of diodes. In the diode response curve of **Fig 5.18**, this value corresponds to the voltage at which the positive portion of the curve begins to rise sharply from the x axis. Most silicon diodes have a junction threshold voltage of about $0.7\ \text{V}$, while the value for germanium diodes typically is $0.3\ \text{V}$. The reverse biased leakage current is much lower for

Fig 5.18 — Semiconductor diode (PN junction) response curve. (A) Forward biased (anode voltage higher than cathode) response for Germanium (Ge) and Silicon (Si) devices. Each curve breaks away from the x-axis at its junction threshold voltage. The slope of each curve is its forward resistance. (B) Reverse biased response. Very small reverse current increases until it reaches the reverse saturation current (I_0). The reverse current increases suddenly and drastically when the reverse voltage reaches the reverse breakdown voltage, V_{BR} .

silicon diodes than for germanium diodes. The forward resistance of a diode is typically very low and varies with the amount of forward current.

Multiple Junctions

A bipolar transistor is formed when two PN junctions are placed next to each other. If N-type material is surrounded by P-type material, the result is a PNP transistor. Alternatively, if P-type material is in the middle of two layers of N-type material, the NPN transistor is formed (**Fig 5.19**).

Physically, we can think of the transistor as two PN junctions back-to-back, such as two diodes connected at their *anodes* (the positive terminal) for an NPN transistor or two diodes connected at their *cathodes* (the negative terminal) for a PNP

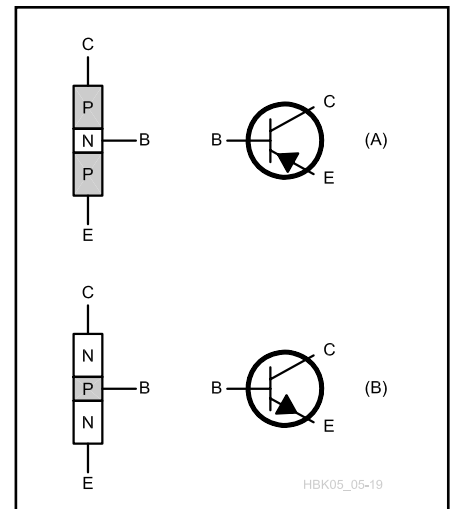

Fig 5.19 — Bipolar transistors. (A) A layer of N-type semiconductor sandwiched between two layers of P-type semiconductor makes a PNP device. The schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing in toward the base. (B) A layer of P-type semiconductor sandwiched between two layers of N-type semiconductor makes an NPN device. The schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing out away from the base.

transistor. The connection point is the base of the transistor. (You can't actually *make* a transistor this way.) A transistor conducts when the base-emitter junction is forward biased and the base-collector is reverse biased. Under these conditions, the emitter region emits majority carriers into the base region, where they are minority carriers because the materials of the emitter and base regions have opposite polarity. The excess minority carriers in the base are attracted across the base-collector junction, where they are collected and are once again considered majority carriers. The flow of majority carriers from emitter to collector can be modified by the application of a bias current to the base terminal. If the bias current has the same polarity as the base material (for example holes flowing into a P-type base) the emitter-collector current increases. A transistor allows a small base current to control a much larger collector current.

As in a semiconductor diode, the forward biased base-emitter junction has a threshold voltage (V_{BE}) that must be exceeded before the emitter current increases.

PNPN Diode

If four alternate layers of P-type and N-type material are placed together, a PNPN (usually pronounced like *pinpin*) diode with three junctions is obtained (see Fig 5.20). This device, when the anode is at a higher potential than the cathode, has its first and third junctions forward biased and its center junction reverse biased. In this state, there is little current, just as in the reverse biased diode. As the forward bias voltage is increased, the current through the device increases slowly until the *breakover (or firing) voltage*, V_{BO} , is reached and the flow of current abruptly increases. The PNPN diode is often considered to be a switch that is off below V_{BO} and on above it.

Bilateral Diode Switch

A semiconductor device similar to two

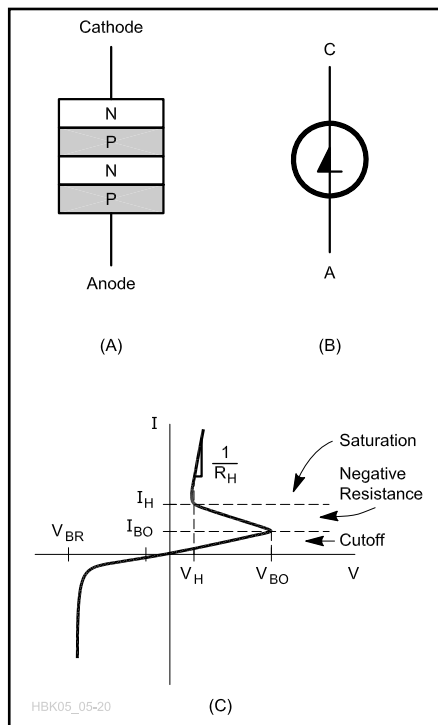

Fig 5.20 — PNPN diode. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol with cathode (C) and anode (A) leads. (C) Voltage-current response curve. Reverse biased response is the same as normal PN junction diodes. Forward biased response acts as a hysteresis switch. Resistance is very high until the bias voltage reaches V_{BO} and exceeds the cutoff current, I_{BO} . The device exhibits a negative resistance when the current increases as the bias voltage decreases until a voltage of V_H and saturation current of I_H is reached. After this, the resistance is very low, with large increases in current for small voltage increases.

PNPN diodes facing in opposite directions and attached in parallel is the *bilateral diode switch* or *diac*. This device has the characteristic curve of the PNPN diode for both positive and negative bias voltages. Its construction, schematic symbol and characteristic curve are shown in Fig 5.21.

Silicon Controlled Rectifier

Another device with four alternate layers of P-type and N-type semiconductor is the *silicon controlled rectifier (SCR)*, or *thyristor*. In addition to the connections to the outer two layers, two other terminals can be brought out for the inner two layers. The connection to the P-type material near the cathode is called the *cathode gate* and the N-type material near the anode is called the *anode gate*. In nearly all commercially available SCRs, only the cathode gate is connected (Fig 5.22).

Like the PNPN diode switch, the SCR is used to abruptly start conducting when the voltage exceeds a given level. By biasing the gate terminal appropriately, the

breakover voltage can be adjusted. The SCR is highly efficient and is used in power control applications. SCRs are available that can handle currents of greater than 100 A and voltage differentials of greater than 1000 V, yet can be switched with gate currents of less than 50 mA.

Triac

A five-layered semiconductor whose operation is similar to a bidirectional SCR is the *triac* (Fig 5.23). This is also similar to a bidirectional diode switch with a bias control gate. The gate terminal of the triac can control both positive and negative breakover voltages and the devices can pass both polarities of voltage.

SCRs and triacs are often used to modify ac power sources. A sine wave with a given RMS value can be switched on and off at preset points during the cycle to decrease the RMS voltage. When conduction is delayed until after the peak (as Fig 5.24 shows) the peak-to-peak voltage is reduced. If conduction starts before the

Fig 5.21 — Bilateral switch. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol. (C) Voltage-current response curve. The right-hand side of the curve is identical to the PNPN diode response in Fig 5.20. The device responds identically for both forward and reverse bias so the left-hand side of the curve is symmetrical with the right-hand side.

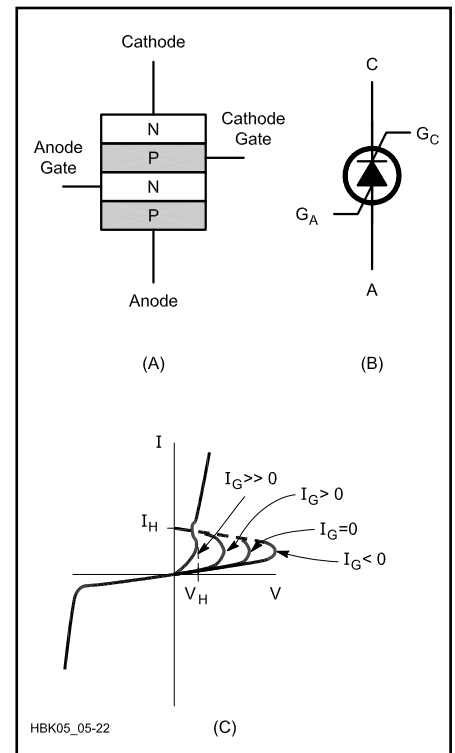

Fig 5.22 — SCR. (A) Alternating layers of P-type and N-type semiconductor. This is similar to a PNPN diode with gate terminals attached to the interior layers. (B) Schematic symbol with anode (A), cathode (C), anode gate (G_A) and cathode gate (G_C). Many devices are constructed without G_A . (C) Voltage-current response curve with different responses for various gate currents. $I_G = 0$ has the same response as the PNPN diode.

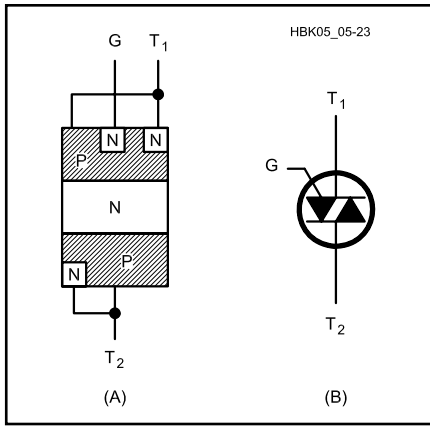

Fig 5.23 — Triac. (A) Alternating layers of P-type and N-type semiconductor. This behaves as two SCR devices facing in opposite directions with the anode of one connected to the cathode of the other and the cathode gates connected together. (B) Schematic symbol.

Fig 5.24 — Triac operation on sine wave. The dashed line is the original sine wave and the solid line is the portion that conducts through the triac. The relative delay and conduction period times are controlled by the amount or timing of gate current, I_G . The response of an SCR is the same as this for positive voltages (above the x-axis) and with no conduction for negative voltages.

peak, the RMS voltage is reduced, but the peak-to-peak value remains the same. This method is used to operate light dimmers and 240 V ac to 120 V ac converters. The sharp switching transients created when these devices switch are common sources of RF interference. SCRs are used as “crowbars” in power supply circuits, to short the output to ground and blow a fuse when an overvoltage condition exists.

FIELD-EFFECT TRANSISTORS

The *field-effect transistor (FET)* controls the current between two points but does so differently than the bipolar transistor. The FET operates by the effects of an electric field on the flow of electrons through a single type of semiconductor material. This is why the FET is some-

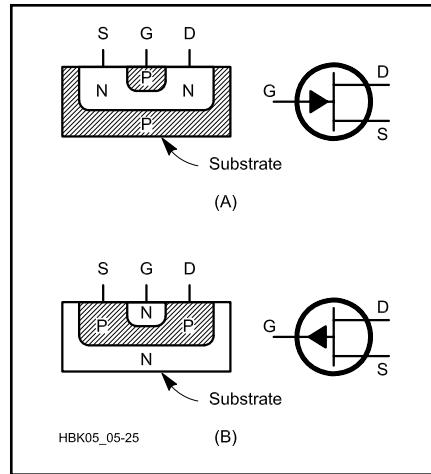

Fig 5.25 — JFET devices with terminals labeled: source (S), gate (G) and drain (D). (A) Pictorial of N-type channel embedded in P-type substrate and schematic symbol. (B) P-channel embedded in N-type substrate and schematic symbol.

times called a *unipolar* transistor. Also, unlike bipolar semiconductors that can be arranged in many configurations to provide diodes, transistors, photoelectric devices, temperature sensitive devices and so on, the field effect is usually only used to make transistors, although FETs are also available as special-purpose diodes, for use as constant current sources.

Current moves within the FET in a channel, from the source connection to the drain connection. A gate terminal generates an electric field that controls the current (see Fig 5.25). The channel is made of either N-type or P-type semiconductor material; an FET is specified as either an N-channel or P-channel device. Majority carriers flow from source to drain. In N-channel devices, electrons flow so the drain potential must be higher than that of the source ($V_{DS} > 0$). In P-channel devices, the flow of holes requires that $V_{DS} < 0$. The polarity of the electric field that controls current in the channel is determined by the majority carriers of the channel, ordinarily positive for P-channel FETs and negative for N-channel FETs.

Variations of FET technology are based on different ways of generating the electric field. In all of these, however, electrons at the gate are used only for their charge in order to create an electric field around the channel, and there is a minimal flow of electrons through the gate. This leads to a very high dc input resistance in devices that use FETs for their input circuitry. There may be quite a bit of capacitance between the gate and the other FET terminals, however. The input impedance

may be quite low at RF.

The current through an FET only has to pass through a single type of semiconductor material. There is very little resistance in the absence of an electric field (no bias voltage). The drain-source resistance ($r_{DS(ON)}$) is between a few hundred ohms to less than an ohm. The output impedance of devices made with FETs is generally quite low. If a gate bias voltage is added to operate the transistor near cutoff, the circuit output impedance may be much higher.

FET devices are constructed on a *substrate* of doped semiconductor material. The channel is formed within the substrate and has the opposite polarity (a P-channel FET has N-type substrate). Most FETs are constructed with silicon. In order to achieve a higher gain-bandwidth product, other materials have been used. Gallium Arsenide (GaAs) has electron mobility and drift velocities that are far higher than the standard doped silicon. Amplifiers designed with *GaAs FET* devices have much higher frequency response and lower noise factor at VHF and UHF than those made with standard FETs.

JFET

There are two basic types of FET. In the *junction FET (JFET)*, the gate material is made of the opposite polarity semiconductor to the channel material (for a P-channel FET the gate is made of N-type semiconductor material). The gate-channel junction is similar to a diode’s PN junction. As with the diode, current is high if the junction is forward biased and is extremely small when the junction is reverse biased. The latter case is the way that JFETs are used, since any current in the gate is undesirable. The magnitude of the reverse bias at the junction is proportional to the size of the electric field that “pinches” the channel. Thus, the current in the channel is reduced for higher reverse gate bias voltage.

Because the gate-channel junction in a JFET is similar to a bipolar junction diode, this junction must never be forward biased; otherwise large currents will pass through the gate and into the channel. For an N-channel JFET, the gate must always be at a lower potential than the source ($V_{GS} < 0$). The channel is as fully open as it can get when the gate and source voltages are equal ($V_{GS} = 0$). The prohibited condition is when $V_{GS} > 0$. For P-channel JFETs these conditions are reversed (in normal operation $V_{GS} > 0$ and the prohibited condition is when $V_{GS} < 0$).

MOSFET

Placing an insulating layer between the gate and the channel allows for a wider

range of control (gate) voltages and further decreases the gate current (and thus increases the device input resistance). The insulator is typically made of an oxide (such as silicon dioxide, SiO_2). This type of device is called a *metal-oxide-semiconductor FET (MOSFET)* or *insulated-gate FET (IGFET)*. The substrate is often connected to the source internally. The insulated gate is on the opposite side of the channel from the substrate (see **Fig 5.26**). The bias voltage on the gate terminal either attracts or repels the majority carriers of the substrate across the PN junction with the channel. This narrows (depletes) or widens (enhances) the channel, respectively, as V_{GS} changes polarity. For N-channel MOSFETs, positive gate voltages with respect to the substrate and the source ($V_{GS} > 0$) repel holes from the channel into the substrate, thereby widening the channel and decreasing channel resistance. Conversely, $V_{GS} < 0$ causes holes to be attracted from the substrate, narrowing the channel and increasing the channel resistance. Once again, the polarities discussed in this example are reversed for P-channel devices. The common abbreviation for an N-channel MOSFET is *NMOS*, and for a P-channel MOSFET, *PMOS*.

Because of the insulating layer next to the gate, input resistance of a MOSFET is usually greater than $10^{12} \Omega$ (a million megohms). Since MOSFETs can both deplete the channel, like the JFET, and also enhance it, the construction of MOSFET devices differs based on the channel size in the resting state, $V_{GS} = 0$. A *depletion mode* device (also called a *normally on MOSFET*) has a channel in resting state that gets smaller as a reverse bias is applied; this device conducts current with no bias applied (see Fig 5.26 A and B). An *enhancement mode* device (also called a *normally off MOSFET*) is built without a channel and does not conduct current when $V_{GS} = 0$; increasing forward bias forms a channel that conducts current (see Fig 5.26 C and D).

Semiconductor Temperature Effects

The number of excess holes and electrons is increased as the temperature of a semiconductor increases. Since the conductivity of a semiconductor is related to the number of excess carriers, this also increases with temperature. With respect to resistance, semiconductors have a negative temperature coefficient. The resistance of silicon *decreases* by about $8\% / ^\circ\text{C}$ and by about $6\% / ^\circ\text{C}$ for germanium. Semiconductor temperature properties are the opposite of most metals, which *increase* their

Fig 5.26 — MOSFET devices with terminals labeled: source (S), gate (G) and drain (D). N-channel devices are pictured. P-channel devices have the arrows reversed in the schematic symbols and the opposite type semiconductor material for each of the layers. (A) N-channel depletion mode device schematic symbol and (B) pictorial of P-type substrate, diffused N-type channel, SiO_2 insulating layer and aluminum gate region and source and drain connections. The substrate is connected to the source internally. A negative gate potential narrows the channel. (C) N-channel enhancement mode device schematic and (D) pictorial of P-type substrate, N-type source and drain wells, SiO_2 insulating layer and aluminum gate region and source and drain connections. Positive gate potential forms a channel between the two N-type wells.

resistance by about $0.4\% / ^\circ\text{C}$. These opposing temperature characteristics permit the design of circuits with opposite temperature coefficients that cancel each other out, making a temperature insensitive circuit. Left alone, the semiconductor can experience an effect called *thermal runaway* as the current causes an increase in temperature. The increased temperature decreases resistance and may lead to a further increase in current (depending on the circuit) that leads to an additional temperature increase. This sequence of events can continue until the semiconductor destroys itself.

Semiconductor Failure

There are several common failure modes for semiconductors that are related to heat. The semiconductor material is connected to the outside world through metallic leads. The point at which the metal and the semiconductor are connected is one common place for the semi-

conductor device to fail. As the device heats up and cools down, the materials expand and contract. The rate of expansion and contraction of semiconductor material is different from that of metal. Over many cycles of heating and cooling the bond between the semiconductor and the metal can break. Some experts have suggested that the lifetime of semiconductor equipment can be extended by leaving the devices powered on all the time. While this would decrease the type of failure just described, inadequate cooling can lead to another type of semiconductor failure.

Impurities are introduced into intrinsic semiconductors by diffusion, the same physical property that lets you smell cookies baking from several rooms away. Smells diffuse through air much faster than molecules diffuse through solids. Once the impurities diffuse into the semiconductor, they tend to stay in place. Rates of diffusion are proportional to temperature, and semiconductors are doped with

impurities at high temperature to save time. Once the doped semiconductor material is cooled, the rate of diffusion of the impurities is so low that they are essentially immobile for many years to come.

A common failure mode of semiconductors is due to the heat generated during semiconductor use. If the temperatures at the junctions rise to high enough levels for long enough periods of time, the impurities start to diffuse across the PN junctions.

When enough of these atoms get across the junction, it stops functioning properly and the semiconductor device fails.

Thermistors

A *thermistor* is an intrinsic (no N or P doping) semiconductor metal-oxide compound device that has a large negative temperature coefficient (NTC) of resistance. Thermally generated free electrons and holes become available as current carriers

in thermistors. Metal oxides, such as nickel-oxide (NiO), dimanganese-trioxide (Mn₂O₃) and cobalt-trioxide (Co₂O₃), are chosen for their stable electrical properties. Silicon and Germanium are not used as thermistors because their temperature properties are very sensitive to impurities.

A related device, the *sensistor*, uses large amounts of doping materials to achieve a large positive temperature coefficient (PTC) of resistance, usually over some restricted temperature range.

Practical Semiconductors

SEMICONDUCTOR DIODES

Although many types of semiconductor diodes are available, there are not many differences between them. The diode is made of a single PN junction that affects current differently depending on its direction. This leads to a large number of applications in electronic circuitry.

The diode symbol is shown in Fig 5.27. Current passes most easily from anode to cathode, in the direction of the arrow. This is often referred to as the *forward* direction and the opposite is the *reverse* direction. Remember that *current* refers to the flow of electricity from higher to lower potentials and is in the opposite direction to the flow of electrons (current moves from anode to cathode and electrons flow from cathode to anode, as based on the definitions of the words, *anode* and *cathode*). The anode of a semiconductor junction diode is made of P-type material and the cathode is made of N-type material, as indicated in Fig 5.27. Most diodes are marked with a band on the cathode end (Fig 5.27). The ideal diode would have zero resistance in the forward direction and infinite resistance in the reverse direction. This is not the case for actual devices, which behave as shown in the plot of a diode response in Fig 5.18. Note that the scales of the two parts of the graph are drastically different. The inverse of the slope of the line (the change in voltage between two points on a straight portion of the line divided by the corresponding change in current) on the upper right is the resistance of the diode in the forward direction. The range of voltages is small and the range of currents is large since the forward resistance is very small (in this example, about 2 Ω). The lower left portion of the curve illustrates a much higher resistance that increases from tens of kilohms to thousands of megohms as the reverse voltage gets larger, and then decreases to near zero (a nearly vertical line) very suddenly at the peak inverse

Fig 5.27 — Practical semiconductor diodes. All devices are aligned with anode on the left and cathode on the right. (A) Standard PN junction diode. (B) Point-contact or “cat’s whisker” diode. (C) PIN diode formed with heavily doped P-type (P⁺), undoped (intrinsic) and heavily doped N-type (N⁺) semiconductor material. (D) Diode schematic symbol. (E) Diode package with marking stripe on the cathode end.

voltage (PIV = 100 V in this example).

There are five major characteristics that distinguish standard junction diodes from one another: the PIV, the current or power handling capacity, the response speed, reverse leakage current and the junction barrier voltage. Each of these characteristics can be manipulated during manufacture to produce special purpose diodes.

The most common application of a diode is to perform rectification; that is, allowing positive voltages to pass and stopping negative voltages. Rectification is used in power supplies that convert ac to dc and in amplitude demodulation. The most important diode parameters to consider for power rectification are the PIV and current ratings. The peak negative voltages that are stopped by the diode must be smaller in magnitude than the PIV and the peak current through the diode when it is forward biased must be less than the maximum amount for which the device

was designed. Exceeding the current rating in a diode will cause excessive heating (based on $P = I \times V_F$) that leads to PN junction failure as described earlier.

Fast Diodes

The speed of a diode affects the frequencies on which it can act. The diode response in Fig 5.18 is a steady state response, showing how that diode will act at dc. As the frequency increases, the diode may not be able to keep up with the changing polarity of the signal and its response will not be as expected. Diode speed mainly depends on charge storage in the depletion region. Under reverse bias, excess charges move away from the junction, forming a larger space-charge region that is the equivalent of a dielectric. The diode thus exhibits capacitance, which is inversely proportional to the width of the dielectric and directly proportional to the cross-sectional surface area of the junction.

One way to decrease charge storage time in the depletion region is to form a metal-semiconductor junction. This can be accomplished with a point-contact diode, where a thin piece of aluminum wire, often called a *whisker*, is placed in contact with one face of a piece of lightly doped N-type material. In fact, the original diodes used for detecting radio signals (“cat’s whisker diodes”) were made this way. A more recent improvement to this technology, the *hot-carrier diode*, is like a point-contact diode with more ideal characteristics attained by using more efficient metals, such as platinum and gold, that act to lower forward resistance and increase PIV. This type of contact is known as a *Schottky barrier*, and diodes made this way are called *Schottky diodes*.

The PIN diode, shown in Fig 5.27C is a *slow response* diode that is capable of passing microwave signals when it is forward biased. This device is constructed with a layer of intrinsic (undoped) semi-

conductor placed between very highly doped P-type and N-type material (called P⁺-type and N⁺-type material to indicate the high level of doping), creating a PIN junction. These devices provide very ef-

fective switches for RF signals and are often used in TR switches in transceivers. PIN diodes have longer than normal carrier lifetimes, resulting in a slow switching process that causes them to act more

like resistors than diodes at high radio frequencies.

Varactors

If the PN junction capacitance is controlled rather than reduced, a diode can be made to act as a variable capacitor. As the reverse bias voltage on a diode increases, the width of the junction increases, which decreases its capacitance. A *varactor* is a diode whose junction is specially formulated to have a relatively large range of capacitance values for a modest range of reverse bias voltages (Fig 5.28). Although special forms of varactors are available from manufacturers, other types of diodes may be used as inexpensive varactor diodes, but the relationship between reverse voltage and capacitance is not always reliable. When designing with varactor diodes, the reverse bias voltage must be absolutely free of noise since any variations in the bias voltage will cause changes in capacitance. Unwanted frequency shifts or instability will result if the reverse bias voltage is noisy. It is possible to frequency modulate a signal by adding the audio signal to the reverse bias on a varactor diode used in the carrier oscillator.

Zener Diodes

When the PIV of a reverse biased diode is exceeded, the diode begins to conduct current as it does when it is forward biased. This current does not destroy the diode if it is limited to less than the device's maximum allowable value. When the PIV is controlled during manufacture to be at desired levels, the device is called a *Zener diode*. Zener diodes (named after the American physicist Clarence Zener) provide accurate voltage references and

Fig 5.28 — Varactor diode. (A) Schematic symbol. (B) Equivalent circuit of the reverse biased varactor diode. R_S is the junction resistance, R_J is the leakage resistance and C_J is the junction capacitance, which is a function of the magnitude of the reverse bias voltage. (C) Plot of junction capacitance, C_J , as a function of reverse voltage, V_R , for three different varactor devices. Both axes are plotted on a logarithmic scale. (D) Oscillator circuit with varactor tuning. D1-L1 is a tuned circuit with a dual varactor diode that is controlled by the voltage from potentiometer R2. C1 is a filter capacitor to ensure that the varactor bias voltage is clean dc. C2 and C6 are dc blocking capacitors. Q1 is an N-channel JFET in common drain configuration with feedback to the gate through C3. R3 is the gate bias resistor. R4 is the drain resistor with filter capacitor C5.

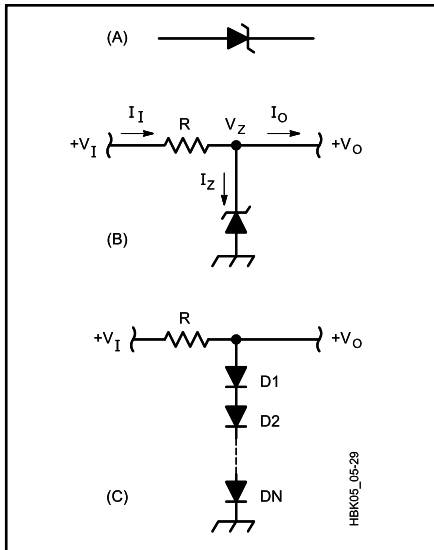

Fig 5.29 — Zener diode. (A) Schematic symbol. (B) Basic voltage regulating circuit. V_Z is the Zener reverse breakdown voltage. The Zener diode draws more current until $V_I - I_I R = V_Z$. The circuit design should select R so that when the maximum current is drawn, $R < (V_I - V_Z) / I_O$. The diode should be capable of passing the same current when there is no output current drawn. (C) For small voltages, several forward biased diodes can be used in place of Zener diodes. Each diode will drop the voltage by about 0.7 V for silicon or 0.3 V for germanium.

Fig 5.30 — Current regulator diode. (A) Schematic symbol and package with line marking cathode end. (B) Diode characteristic curve (1N5283 device). When forward bias voltage exceeds about 4 V the current passing through the device is held constant regardless of the voltage across the device.

are often used for this purpose in power supply regulators.

When the reverse breakdown voltage is exceeded, the reverse voltage drop across the Zener diode remains constant. With an appropriate current limiting resistor in series with it, the Zener diode provides an accurate voltage reference (**Fig 5.29**). Zener diodes are rated by their reverse-breakdown voltage and their power-handling capacity. The power is a product of the current passing through the reverse-biased Zener diode “in breakdown” (that is, in the breakdown mode of operation) and the breakdown voltage. Since the same current must always pass through the resistor to drop the source voltage down to the reference voltage, with that current divided between the Zener diode and the load, this type of power source is very wasteful of current. The Zener diode does make an excellent and efficient voltage reference in a larger voltage regulating circuit where the load current is provided from another device whose voltage is set by the reference. (See the **Power Supplies** chapter for more information about using Zener diodes as voltage regulators.) The major sources of error in Zener-diode derived voltages are the variation with load current and the variation due to heat. Temperature compensated Zener diodes are available with temperature coefficients as low as 0.0005 % / °C. If this is unacceptable, voltage reference integrated circuits based on Zener diodes have been developed that include additional circuitry to counteract temperature effects.

Constant Current Diodes

A form of diode, called a *field-effect regulator diode*, provides a constant current over a wide range of forward biased voltages. The schematic symbol and characteristic curve for this type of device are shown in **Fig 5.30**. Constant current diodes are very useful in any application where a constant current is desired. Some part numbers are 1N5283 through 1N5314.

Common Diode Applications

Standard semiconductor diodes have many uses in analog circuitry. Several examples of diode circuits are shown in **Fig 5.31**. Rectification has already been described. There are three basic forms of rectification using semiconductor diodes: half wave (1 diode), full-wave center-tapped (2 diodes) and full-wave bridge (4 diodes). These are more fully described in the **Power Supplies** chapter.

Diodes are commonly used to protect circuits. In battery powered devices a forward biased series diode is often used

to protect the circuitry from the user inadvertently inserting the batteries backwards. Likewise, when a circuit is powered from an external dc source, a diode is often placed in series with the power connector in the device to prevent incorrectly wired power supplies from destroying the equipment. Diodes are commonly used to protect analog meters from both reverse voltage and over voltage conditions that would destroy the delicate needle movement.

Zener diodes are sometimes used to protect low-current (a few amps) circuits from over-voltage conditions. A reverse biased Zener diode connected between the positive power lead and ground will conduct excessive current if its breakdown voltage is exceeded. Used in conjunction with a fuse in series with the power lead, the Zener diode will cause the fuse to blow when an over-voltage condition exists.

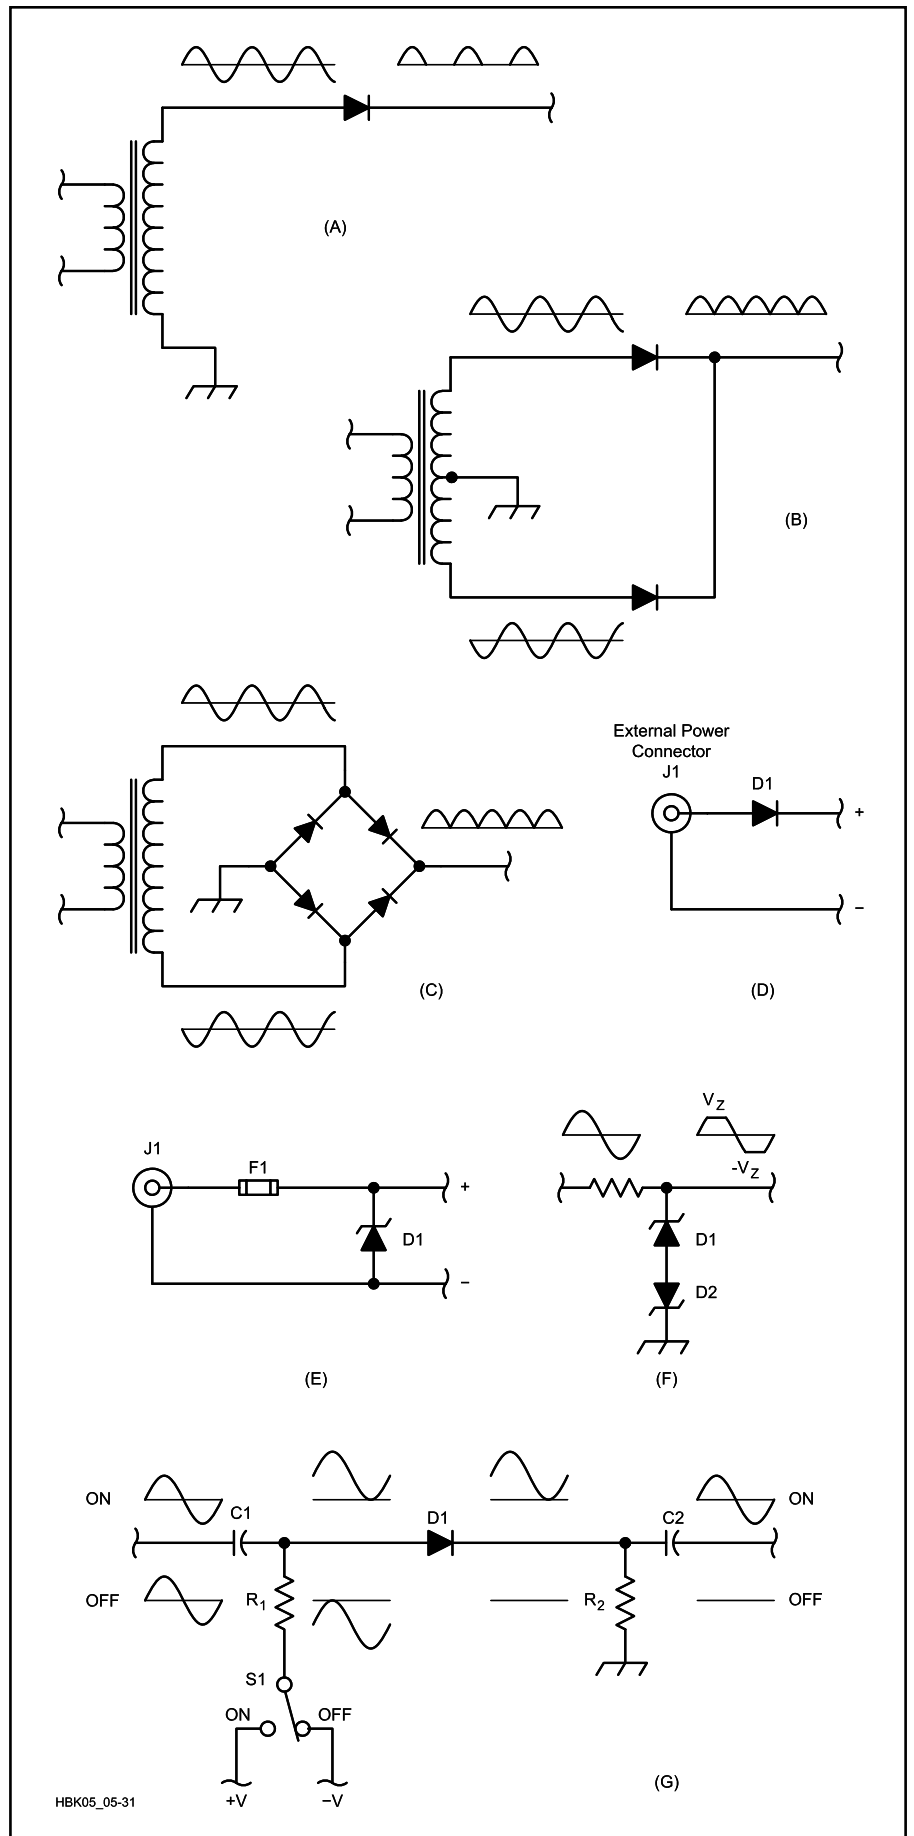

Very high, short-duration voltage spikes can destroy certain semiconductors, particularly MOS devices. Standard Zener diodes can't handle the high pulse powers found in these voltage spikes. Special Zener diodes are designed for this purpose, such as the *mosorb*. (General Semiconductor Industries, Inc calls these devices *TransZorbs*.) A reverse biased TransZorb with a low-value series resistor can decrease the voltage reaching the sensitive device. Since the polarity of the spike can be positive, negative, or both, over voltage transient suppressor circuits can be designed with two devices wired back-to-back. They protect a circuit over a range of voltages rather than just suppressing positive peaks.

Diodes can be used to clip signals, similar to rectification. If the signal is appropriately biased it can be clipped at any level. Two Zener diodes placed back-to-back can be used to clip both the positive and negative peaks of a signal. Such an arrangement is used to convert a sine wave to an approximate square wave.

Care must be taken when using Zener diodes to process signals. The Zener diode is a relatively noisy device and can add excessive noise to the signals if it operates in breakdown. The Zener diode is often specified for at intentionally generate noise, such as the noise bridge (see the **Test Procedures** chapter). The reverse biased Zener diode in breakdown generates wide band (nearly white) noise levels as high as $2000 \mu V / \sqrt{Hz}$. The noise voltage is determined by multiplying this value by the square root of the circuit bandwidth in Hz.

Diodes are used as switches for ac coupled signals when a dc bias voltage can be added to the signal to permit or inhibit

Fig 5.31 — Diode circuits. (A) Half wave rectifier circuit. Only when the ac voltage is positive does current pass through the diode. Current flows only during half of the cycle. (B) Full-wave center-tapped rectifier circuit. Center-tap on the transformer secondary is grounded and the two ends of the secondary are 180° out of phase. During the first half of the cycle the upper diode conducts and during the second half of the cycle the lower diode conducts. There is conduction during the full cycle with only positive voltages appearing at the output. (C) Full-wave bridge rectifier circuit. In each half of the cycle two diodes conduct. (D) Polarity protection for external power connection. J1 is the connector that power is applied to. If polarity is correct, the diode will conduct and if reversed the diode will block current, protecting the circuit that is being powered. (E) Over-voltage protection circuit. If excessive voltage is applied to J1, D1 will conduct current until fuse, F1, is blown. (F) Bipolar voltage clipping circuit. In the positive portion of the cycle, D2 is forward biased, but no current is shunted to ground because D1 is reverse biased. D1 starts to conduct when the voltage exceeds the Zener breakdown voltage, and the positive peak is clipped. When the negative portion of the cycle is reached, D1 is forward biased, but no current is shunted to ground because D2 is reverse biased. When the voltage exceeds the Zener breakdown voltage of D2, it also begins to conduct, and the negative peak is clipped. (G) Diode switch. The signal is ac coupled to the diode by C1 at the input and C2 at the output. R2 provides a reference for the bias voltage. When switch S1 is in the ON position, a positive dc voltage is added to the signal so it is forward biased and is passed through the diode. When S1 is in the OFF position, the negative dc voltage added to the signal reverse biases the diode, and the signal does not get through.

the signal from passing through the diode. In this case the bias voltage must be added to the ac signal and be of sufficient magnitude so that the entire envelope of the ac signal is above or below the junction barrier voltage, with respect to the cathode, to pass through the diode or inhibit the signal. Special forms of diodes, such as the PIN diode described earlier, which are capable of passing higher frequencies, are used to switch RF signals.

BIPOLAR TRANSISTORS

The bipolar transistor is a *current-controlled device*. The current between the emitter and the collector is governed by the current that enters the base. The convention when discussing transistor opera-

Fig 5.32 — Transistor response curve. The x-axis is the output voltage, and the y-axis is the output current. Different curves are plotted for various values of input current. The three regions of the transistor are its cutoff region, where no current flows in any terminal, its active region, where the output current is nearly independent of the output voltage and there is a linear relationship between the input current and the output current, and the saturation region, where the output current has large changes for small changes in output voltage.

tion is that the three currents into the device are positive (I_c into the collector, I_b into the base and I_e into the emitter). Kirchhoff's current law applies to transistors just as it does to passive electrical networks: the total current entering the device must be zero. Thus, the relationship between the currents into a transistor can be generalized as

$$0 = I_c + I_b + I_e \quad (9)$$

which can be rearranged as necessary. For example, if we are interested in the emitter current,

$$I_e = -(I_c + I_b) \quad (10)$$

The back-to-back diode model is appropriate for visualization of transistor construction. In actual transistors, however, the relative sizes of the collector, base and emitter regions differ. A common transistor configuration that spans a distance of 3 mm between the collector and emitter contacts typically has a base region that is only 25 μm across.

Current conduction between collector and emitter is described by regions in the common-base response curves of the transistor device (see **Fig 5.32**). The transistor is in its *active region* when the base-collector junction is reverse biased and the base-emitter junction is forward biased. The slope of the output current (I_O) versus the output voltage (V_O) is virtually flat, indicating that the output current is nearly independent of the output voltage. The slight slope that does exist is due to base-

width modulation (known as the "Early effect"). Under these conditions, there is a linear relationship between the input current (I_I) and I_O . When both the junctions in the transistor are forward biased, the transistor is said to be in its *saturation region*. In this region, V_O is nearly zero and large changes in I_O occur for very small changes in V_O . The *cutoff region* occurs when both junctions in the transistor are reverse biased. Under this condition, there is very little current in the output, only the nanoamperes or microamperes that result from the very small leakage across the input-to-output junction. These descriptions of junction conditions are the basis for the use of transistors. Various configurations of the transistor in circuitry make use of the properties of the junctions to serve different purposes in analog signal processing.

In the common base configuration, where the input is at the emitter and the output is at the collector, the current gain is defined as

$$\alpha = -\frac{\Delta I_C}{\Delta I_E} = 1 \quad (11)$$

In the common emitter configuration, with the input at the base and the output at the collector, the current gain is

$$\beta = \frac{\Delta I_C}{\Delta I_B} \quad (12)$$

and the relationship between α and β is defined as

$$\alpha = \frac{\beta}{1 + \beta} \quad (13)$$

Since the common-emitter configuration is the most used transistor-amplifier configuration, another designation for β is often used: h_{FE} , the forward dc current gain. (The "h" refers to "h parameters," a set of parameters for describing a two-port network.) The symbol, h_{fe} , is used for the forward current gain of ac signals. Other transistor transfer function relationships that are measured are h_{ie} , the input impedance, h_{oe} , the output admittance (reciprocal of impedance) and h_{re} , the voltage feedback ratio.

The behavior of a transistor can be defined in many ways, depending on which type of amplifier it is wired to be. A complete description of a transistor must include characteristic curves for each configuration. Typically, two sets of characteristic curves are presented: one describing the input behavior and the other describing the output behavior in each amplifier configuration. Different transistor amplifier configurations have different gains, input and output impedances. At low frequencies, where parasitic capacitances aren't a factor, the common emitter configuration has a high current gain (about -50 , with the negative sign indicating a 180° phase shift), medium to high input impedance (about 50 k Ω) and a medium to low output impedance (about 1 k Ω). The common collector has a high current gain (about 50), a high input impedance (about 150 k Ω) and a low output impedance (about 80 Ω). The common base amplifier has a low current gain (about 1), a low input impedance (about 25 Ω) and a very high output impedance (about 2 M Ω). Depending on the intended use of the transistor amplifier in an analog circuit, one configuration will be more appropriate than others. Once the common lead of the transistor amplifier configuration is chosen, the input and output impedances are functions of the device bias levels and circuit loading (**Fig 5.33**). The actual input and output impedances of a transistor amplifier are highly dependent on the input, biasing and load resistors that are used in the circuit.

A typical general-purpose bipolar-transistor data sheet lists important device specifications. Parameters listed in the ABSOLUTE MAXIMUM RATINGS section are the three junction voltages (V_{CEO} , V_{CBO} and V_{EBO}), the continuous collector current (I_C), the total device power dissipation (P_D) and the operating and storage temperature range. In the OPERATING PARAMETERS section, the three guaranteed minimum junction breakdown voltages

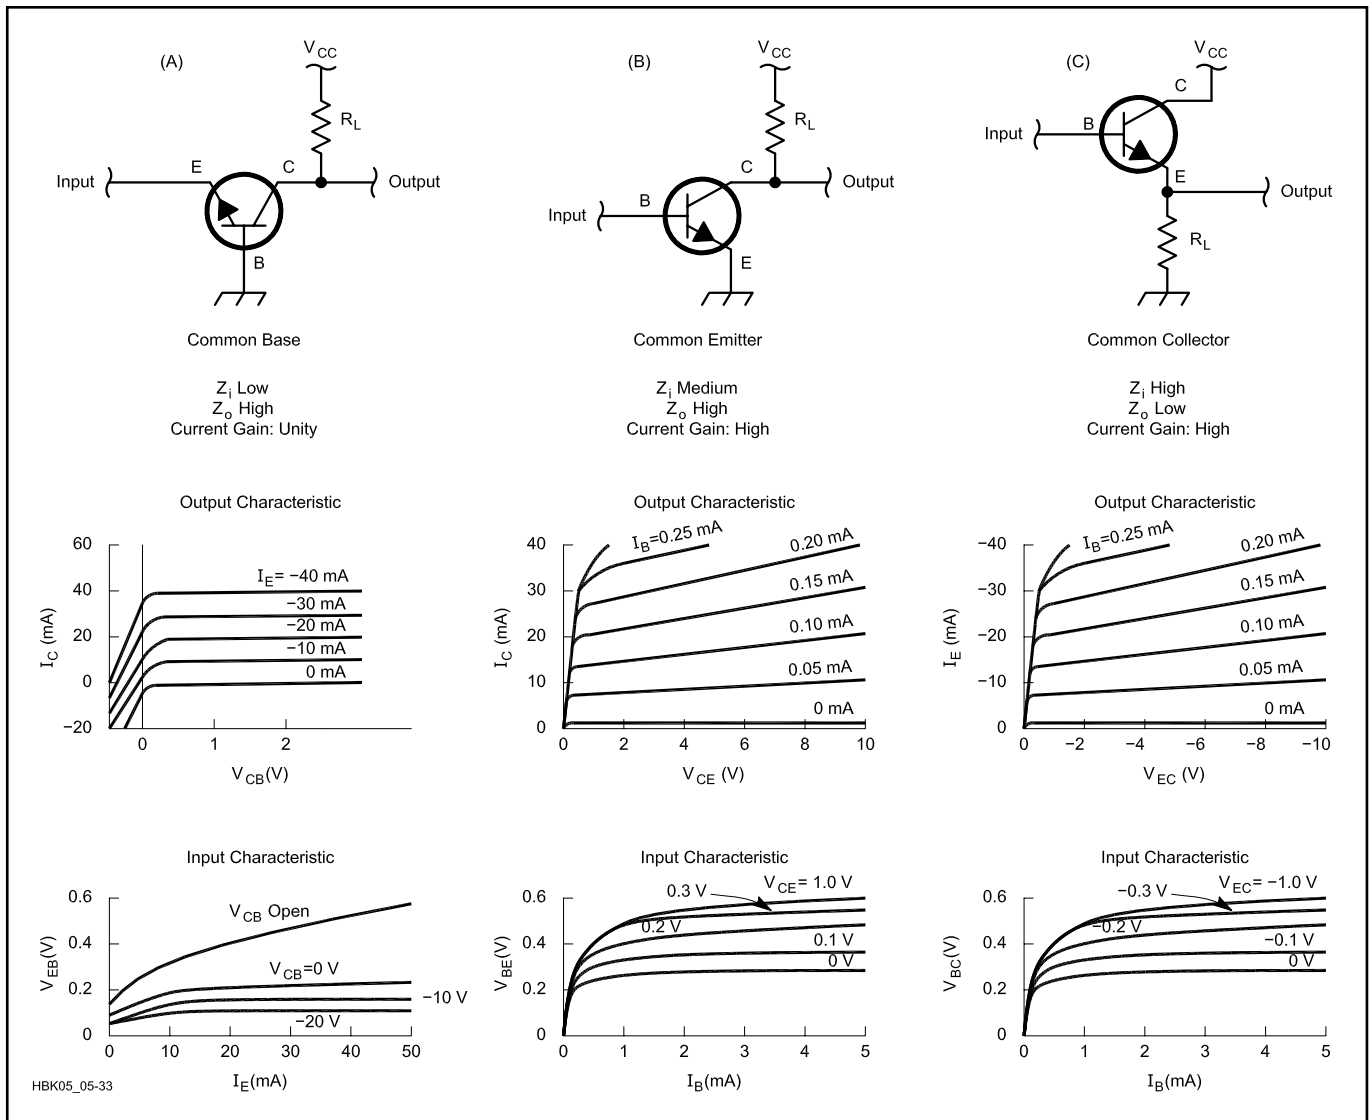

Fig 5.33 — The three configurations of transistor amplifiers. Each has a table of its relative impedance and current gain. The output characteristic curve is plotted for each, with the output voltage along the x-axis, the output current along the y-axis and various curves plotted for different values of input current. The input characteristic curve is plotted for each configuration with input current along the x-axis, input voltage along the y-axis and various curves plotted for different values of output voltage. (A) Common base configuration with input terminal at the emitter and output terminal at the collector. (B) Common emitter configuration with input terminal at the base and output terminal at the collector. (C) Common collector with input terminal at the base and output terminal at the emitter.

are listed $V_{(BR)CEO}$, $V_{(BR)CBO}$ and $V_{(BR)EBO}$ — along with the two guaranteed maximum collector cutoff currents — I_{CEO} and I_{CBO} — under OFF CHARACTERISTICS. Under ON CHARACTERISTICS are the guaranteed minimum dc current gain (h_{FE}), guaranteed maximum collector-emitter saturation voltage — $V_{CE(SAT)}$ — and the guaranteed maximum base-emitter on voltage — $V_{BE(ON)}$. The next section is SMALL-SIGNAL CHARACTERISTICS, where the guaranteed minimum current gain-bandwidth product — f_T , the guaranteed maximum output capacitance — C_{obo} , the guaranteed maximum input capacitance — C_{ibo} , the guaranteed range of

input impedance — h_{ie} , the small-signal current gain — h_{fe} , the guaranteed maximum voltage feedback ratio — h_{re} and output admittance — h_{oe} are listed. Finally, the SWITCHING CHARACTERISTICS section lists absolute maximum ratings for delay time — t_d , rise time — t_r , storage time — t_s and fall time — t_f .

Transistor Biasing

Biasing in a transistor adds or subtracts a fixed amount of current from the signal at the input port. This differs from vacuum tube, FET and operational amplifier biasing where a bias *voltage* is added to the input signal. Fixed bias is the simplest

form, as shown in **Fig 5.34A**. The operating point is determined by the intersection between the characteristic curves, the load line and the quiescent current bias line (Fig 5.34B). The problem with fixing the bias current is that if the transistor parameters drift due to heat, the operating point will change. The operating point can be stabilized by self biasing, also called emitter biasing, as pictured in Fig 5.34C. If I_C increases due to temperature changes, the current in R_E increases. The larger current through R_E increases the voltage drop across that resistor, causing a decrease in the base current, I_B . This, in turn, leads to a decreasing I_C , minimizing its variation

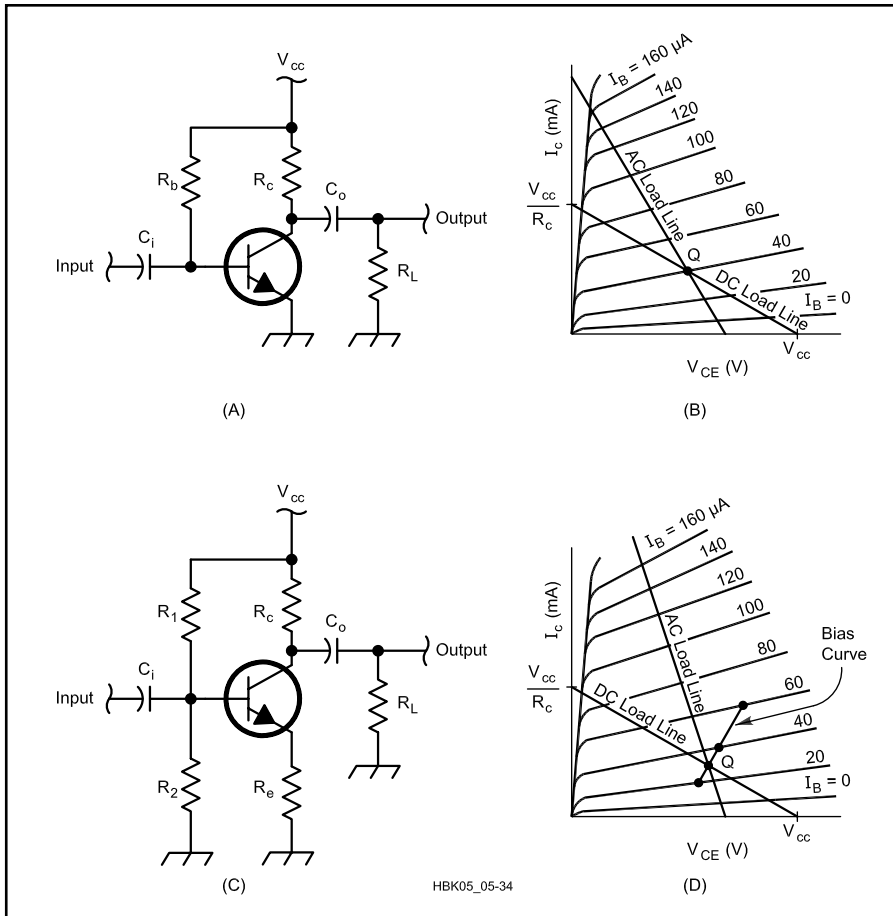

Fig 5.34 — Transistor biasing circuits. (A) Fixed bias. Input signal is ac coupled through C_i . The output has a voltage that is equal to $V_{CC} - I_C \times R_C$. This signal is ac coupled to the load, R_L , through C_o . For dc signals, the entire output voltage is based on the value of R_C . For ac signals, the output voltage is based on the value of R_C in parallel with R_L . (B) Characteristic curve for the transistor amplifier pictured in (A). The slope of the dc load line is equal to $-1 / R_C$. For ac signals, the slope of the ac load line is equal to $-1 / (R_C \parallel R_L)$. The quiescent operating point, Q, is based on the base bias current with no input signal applied and the point where this characteristic line crosses the dc load line. The ac load line must also pass through point Q. (C) Self-bias. Similar to fixed bias circuit with the base bias resistor split into two: R_1 connected to V_{CC} and R_2 connected to ground. Also an emitter bias resistor, R_E , is included to compensate for changing device characteristics. (D) This is similar to the characteristic curve plotted in (B) but with an additional “bias curve” that shows how the base bias current varies as the device characteristics change with temperature. The operating point, Q, moves along this line and the load lines continue to intersect it as it changes.

due to heat. The operating point for this type of biasing is plotted in Fig 5.34D.

FIELD-EFFECT TRANSISTORS

FET devices are more closely related to vacuum tubes than are bipolar transistors. Both the vacuum tube and the FET are controlled by the voltage level of the input rather than the input current, as in the bipolar transistor. FETs have three basic terminals, the gate, the source and the drain. These are related to both vacuum tube and bipolar transistor terminals: the gate to the grid and the base, the source to the cathode and the emitter, and the drain to the plate and the collec-

tor. Different forms of FET devices are pictured in Fig 5.35.

The characteristic curves for FETs are similar to those of vacuum tubes. The two most useful relationships are called the transconductance and output curves (Fig 5.36). Transconductance curves give the drain current, I_D , due to different gate-source voltage differences, V_{GS} , for various drain-source voltages, V_{DS} . The same parameters are interrelated in a different way in the output curve. For different values of V_{GS} , I_D is plotted against V_{DS} . In both of these representations, the device output is the drain current and these curves describe the FET in the common-source

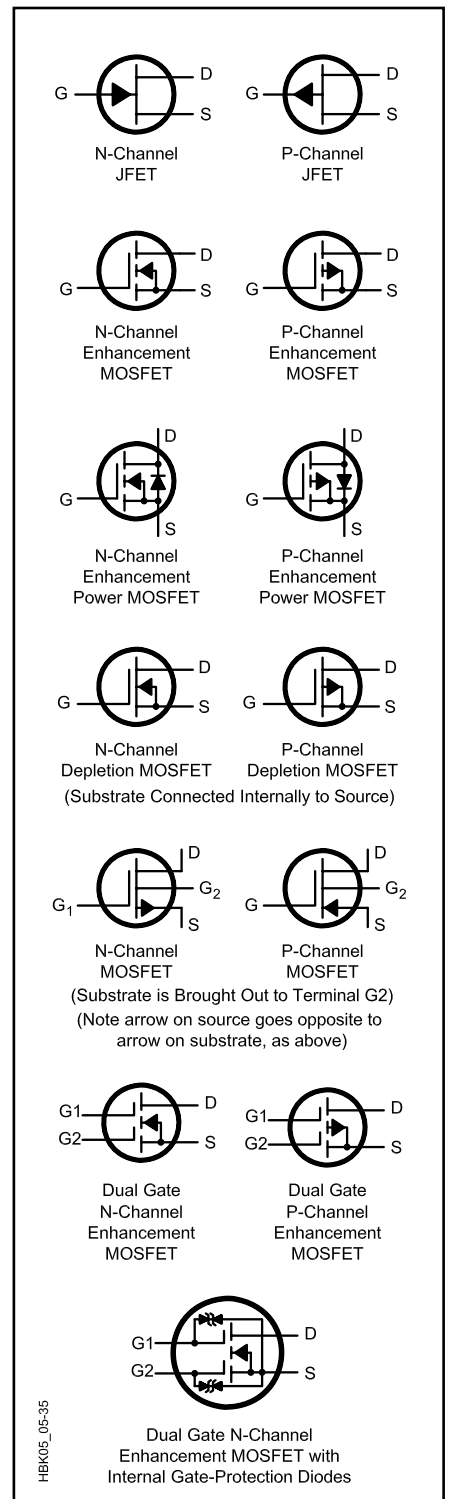

Fig 5.35—FET schematic symbols.

configuration. The action of the FET channel is so nearly ideal that, as long as the JFET gate does not become forward biased, the drain and source currents are virtually identical. For JFETs the gate leakage current, I_G , is a function of V_{GS} and this is often expressed with an input curve (Fig 5.37). The point at which there

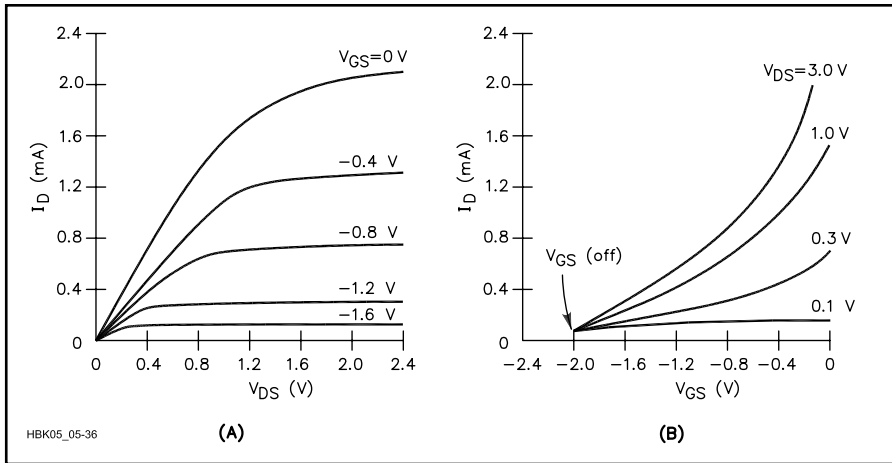

Fig 5.36 — JFET output and transconductance response curves for common source amplifier configuration. (A) Output voltage (V_{DS}) on the x-axis versus output current (I_D) on the y-axis, with different curves plotted for various values of input voltage (V_{GS}). (B) Transconductance curve has the same three variables rearranged, V_{GS} on the x-axis, I_D on the y-axis and curves plotted for different values of V_{DS} .

is a great increase in I_G is called the *junction breakpoint voltage*. The insulated gates in MOSFET devices do away with any appreciable gate leakage current. MOSFETs do not need input and reverse transconductance curves. Their output curves (Fig 5.38) are similar to those of the JFET.

The parameters used to describe a FET's performance are also similar to those of vacuum tubes. The dc channel resistance, r_{DS} , is specified in data sheets to be less than a maximum value when the device is biased on ($r_{DS(on)}$). For ac signals, $r_{ds(on)}$ is not necessarily the same as $r_{DS(on)}$, but it is not very different as long as the frequency is not so high that capacitive reactance becomes significant. The common source forward transconductance, g_{fs} , is obtained as the slope of one of the lines in the forward transconductance curve,

$$g_{fs} = \frac{\Delta I_D}{\Delta V_{GS}} \quad (14)$$

When the gate voltage is maximum ($V_{GS} = 0$ for a JFET), $r_{DS(on)}$ is minimum. This describes the effectiveness of the device as an analog switch.

A typical FET data sheet gives ABSOLUTE MAXIMUM RATINGS for V_{DS} , V_{DG} , V_{GS} and I_D , along with the usual device dissipation (P_D) and storage temperature range. The OFF CHARACTERISTICS listed are the gate-source breakdown voltage, $V_{GS(BR)}$, the reverse gate current, I_{GSS} and the gate-source cutoff voltage, $V_{GS(OFF)}$. The ON CHARACTERISTIC is the zero-gate-voltage drain current (I_{DSS}). The SMALL SIGNAL CHARACTERISTICS include the forward transfer admittance, y_{fs} ,

the output admittance, y_{os} , the static drain-source on resistance, $r_{ds(on)}$ and various capacitances such as input capacitance, C_{iss} , reverse transfer capacitance, C_{rss} , the drain-substrate capacitance, $C_{d(sub)}$. FUNCTIONAL CHARACTERISTICS include the noise

figure, NF and the common source power gain G_{ps} .

The relatively flat regions in the MOSFET output curves are often used to provide a constant current source. As is plotted in these curves, the drain current,

Fig 5.37 — JFET input leakage curves for common source amplifier configuration. Input voltage (V_{GS}) on the x-axis versus input current (I_G) on the y-axis, with two curves plotted for different operating temperatures, 25°C and 125°C . Input current increases greatly when the gate voltage exceeds the junction breakpoint voltage.

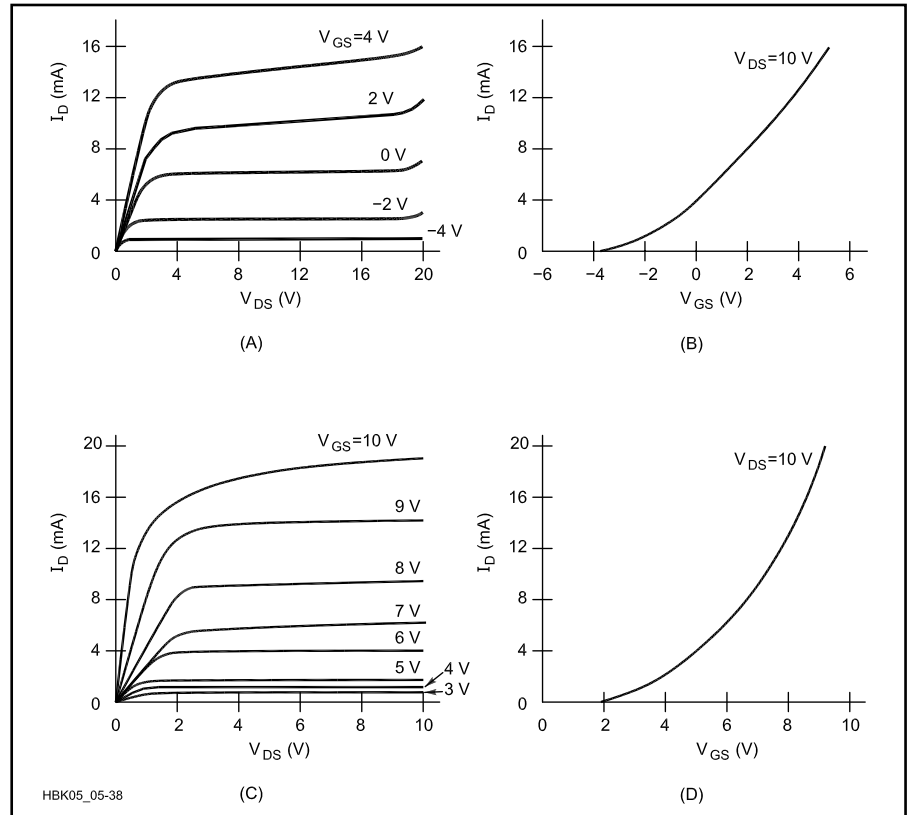

Fig 5.38 — MOSFET output [(A) and (C)] and transconductance [(B) and (D)] response curves. Plots (A) and (B) are for an N-channel depletion mode device. Note that V_{GS} varies from negative to positive values. Plots (C) and (D) are for an N-channel enhancement mode device. V_{GS} has only positive values.

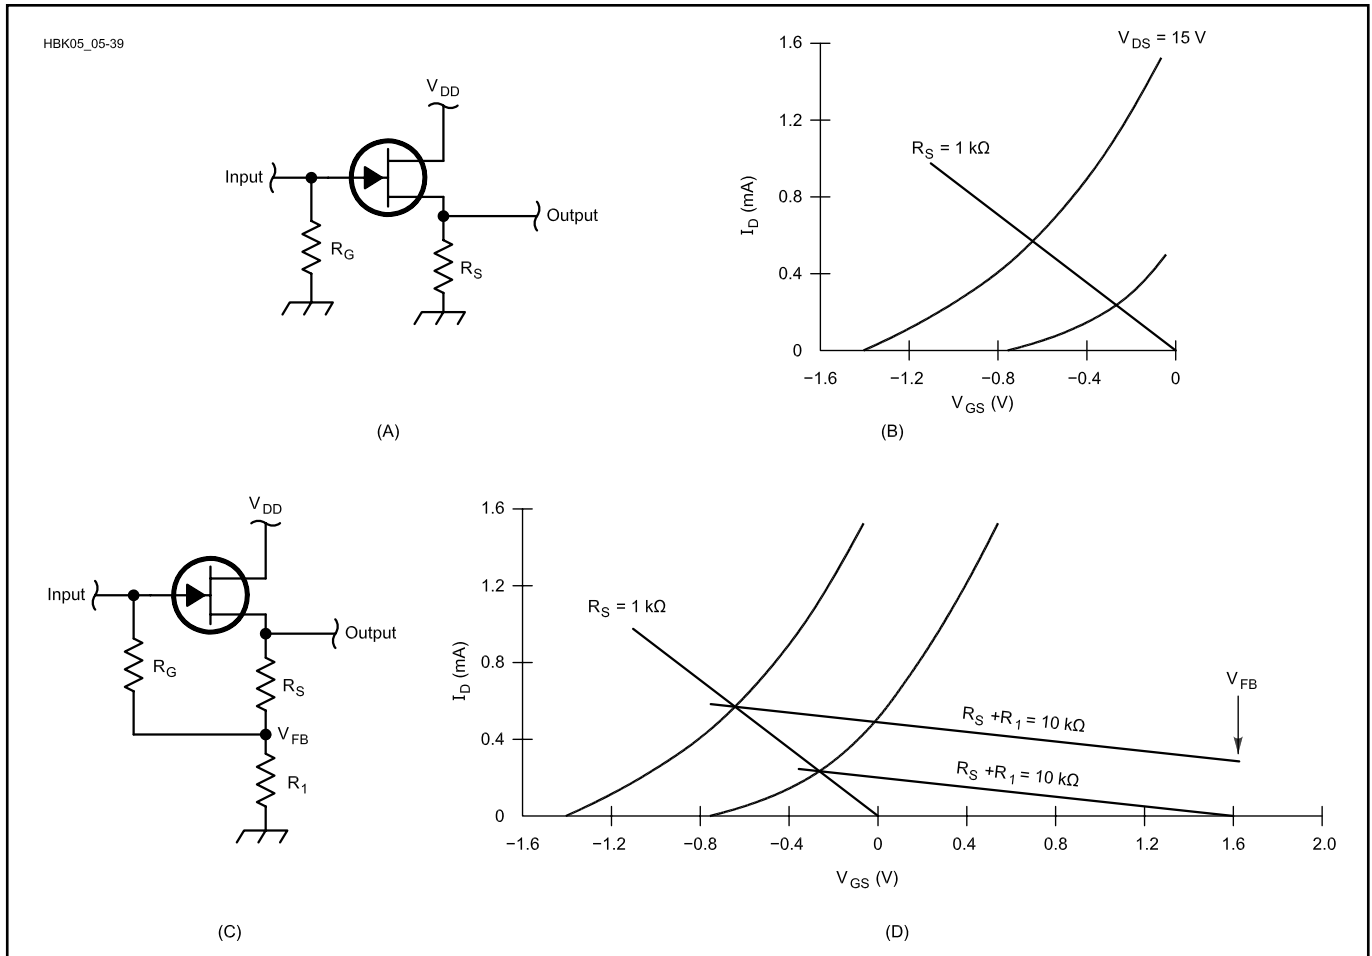

Fig 5.39 — FET biasing circuits. (A) Self-biased common drain JFET circuit. (B) Transconductance curve for self-biased JFET in (A). Gate bias is determined by current through R_S . Load line has a slope of $-1/R_S$, and gate bias voltage can vary between where the load line crosses the characteristic curves. (C) Feedback bias common drain JFET circuit.

I_D , changes very little as the drain-source voltage, V_{DS} , varies in this portion of the curve. Thus, for a fixed gate-source voltage, V_{GS} , the drain current can be considered to be constant over a wide range of drain-source voltages.

Multiple gate MOSFETs are also available (MFE130, MPF201, MPF211, MPF521). Due to the insulating layer, the two gates are isolated from each other and allow two signals to control the channel simultaneously with virtually no loading of one signal by the other. A common application of this type of device is an automatic gain control (AGC) amplifier. The signal is applied to one gate and a rectified, low-pass filtered form of the output (the AGC voltage) is fed back to the other gate. Another common application is for mixers.

FET Biasing

There are two ways to bias an FET, with and without feedback. Source self biasing for an N-channel JFET is pictured in **Fig 5.39A**. In this common-drain ampli-

fier circuit, bias level is determined by the current through R_S , since I_G is very small and there is essentially no voltage drop across R_G . The characteristic curve for this configuration is plotted in **Fig 5.39B**. The operating points of the amplifier are where the load line intersects the curves. An example of feedback biasing is shown in **Fig 5.39C**. R_1 is generally much larger than R_S and the load line is determined by the sum of these resistors, as shown in **Fig 5.39D**. Feedback biasing increases the input impedance of the amplifier, but is rarely required, since input resistance (R_G) can be made very large.

MOSFET Gate Protection

The MOSFET is constructed with a very thin layer of SiO_2 for the gate insulator. This layer is extremely thin in order to improve the gain of the device but this makes it susceptible to damage from high voltage levels. If enough charge accumulates on the gate terminal, it can punch through the gate insulator and destroy it. The insulation of the gate terminal is so

good that virtually none of this potential is eased by leakage of the charge into the device. While this condition makes for nearly ideal input impedance (approaching infinity), it puts the device at risk of destruction from even such seemingly innocuous electrical sources as static electricity in the air.

Some MOSFET devices contain an internal Zener diode with its cathode connected to the gate and its anode to the substrate. If the voltage at the gate rises to a damaging level the Zener junction breaks down and bleeds the excess charges off to the substrate. When voltages are within normal operating limits the Zener has little effect on the signal at the gate, although it may decrease the input impedance of the MOSFET. This solution will not work for all MOSFETs. The Zener diode must always be reverse biased to be effective. In the enhancement-mode MOSFET, $V_{GS} > 0$ for all valid uses of the part. In depletion mode devices V_{GS} can be both positive and negative; when negative, a protection Zener diode would be

Transistor Amplifier Design — a Practical Approach

The design of a transistorized amplifier is a straightforward process. Just as you don't need a degree in mechanical engineering to drive an automobile, neither do you need detailed knowledge of semiconductor physics in order to design a transistor amplifier with predictable and repeatable properties.

This sidebar will describe how to design a small-signal "Class A" transistor amplifier, following procedures detailed in one of the best books on the subject — *Solid State Design for the Radio Amateur*, by Wes Hayward, W7ZOI, and Doug DeMaw, W1FB. For many years, both hams and professional engineers have used this classic ARRL book to design untold numbers of working amplifiers.

How Much Gain?

One of the simple, yet profound, observations made in *Solid State Design for the Radio Amateur* is that a designer should *not* attempt to extract every last bit of gain from a single amplifier stage. Trying to do so virtually guarantees that the circuit will be "touchy" — it may end up being more oscillator than amplifier! While engineers might debate the exact number, modern semiconductor circuits are inexpensive enough that you should try for no more than 25 dB of gain in a single stage.

For example, if you are designing a high-gain amplifier system to follow a direct-conversion receiver mixer, you will need a total of about 100 dB of audio amplification. We would recommend a conservative approach where you use four stages, each with 25 dB of gain. You might risk oscillation and instability by using only two stages, with 50 dB gain each. The component cost will not be greatly different between these approaches, but the headaches and lack of reproducibility of the "simpler" two-stage design will very likely far outweigh any small cost advantages!

Biasing the Transistor Amplifier

The first step in amplifier design is to *bias* the transistor properly. A small-signal linear amplifier is biased properly when there is current at all times. Once you have biased the stage, you can then use several simple rules of thumb to determine all the major properties of the resulting amplifier.

Solid State Design for the Radio Amateur introduces several elegant transistor models. We won't get into that much detail here, except to say that the most fundamental property of a transistor is this: When there is current in the base-emitter junction, a larger current will flow in the collector-emitter junction. When the base-emitter junction is thus *forward biased*, the voltage across the base and emitter leads of a silicon transistor will be relatively constant, at 0.7 V. For most modern transistors, the dc current in the collector-emitter junction will be at least 50 to 100 times greater than the base-emitter current. This dc current gain is called the transistor's *Beta* (β).

See Fig A, which shows a simple capacitively coupled low-frequency amplifier suitable for use at 1 MHz.

Resistors R1 and R2 form a voltage divider feeding the base of the transistor. The amount of current in the resistive voltage divider is purposely made large enough so the base current is small in comparison, thus creating a "stiff" voltage supply for the base. As stated above, the voltage at the emitter will be 0.7 V less than the base voltage for this NPN transistor. The emitter voltage V_E appears across the series combination of R4 and R5. Note that R5 is bypassed by capacitor C4 for ac current.

By Ohm's Law, the emitter current is equal to the emitter voltage V_E divided by the sum of R4 plus R5. Now, the emitter current is made up of both the base-emitter and the collector-emitter current, but since the base current is much smaller than the collector current, the amount of collector current is essentially equal to the emitter current, at $V_E / (R4 + R5)$.

Our design process starts by specifying the amount of current we want to flow in the collector, with the dc collector voltage equal to half the supply voltage. For good bias stability with temperature variation, the total emitter resistor should be at least 100 Ω for a small-signal amplifier. Let's choose a collector current of 5 mA, and use a total emitter resistance of 200 Ω , with R4 = R5 = 100 Ω each. The voltage across 200 Ω for 5 mA of current is 1.0 V. This means that the voltage at the base must be 1.0 V + 0.7 V = 1.7 V, provided by the voltage divider R1 and R2.

The dc base current requirements for a collector current of 5 mA is approximately 5 mA / 50 = 0.1 mA if the transistor's dc Beta is at least 50, a safe assumption for modern transistors. To provide a "stiff" base voltage, we want the current through the voltage divider to be about five to ten times greater than the base current. For convenience then, we choose the current through R1 to be 1 mA. This is a convenient current value, because the math is simplified — we don't have to worry about decimal points for current or resistance:

$1 \text{ mA} \times 1.8 \text{ k}\Omega = 1.8 \text{ V}$. This is very close to the

1.7 V we are seeking. We thus choose a standard value of 1.8 k Ω for R2. The voltage drop across R1 is 12 V – 1.8 V = 10.2 V. With 1 mA in R1, the necessary value is 10.2 k Ω , and we choose the closest standard value, 10 k Ω .

Let's now look at what is happening in the collector part of the circuit. The collector resistor R3 is 1 k Ω , and the 5 mA of collector current creates a 5 V drop across R3. This means that the collector dc voltage must be 12 V – 5 V = 7 V. The dc power dissipated in the transistor will be essentially all in the collector-emitter junction, and will be the collector-emitter voltage (7 V – 1 V = 6 V) times the collector current of 5 mA = 0.030 W, or 30 mW. This dissipation is well within the 0.5 W rating typical of small-signal transistors.

Now, let's calculate more accurately the result from using standard values for R1 and R2. The actual

Fig A — Example of a simple low-frequency capacitively coupled transistorized small-signal amplifier. The voltages shown are the preliminary values desired for a collector current of 5 mA. The ac voltage gain is the ratio of the collector load resistor, R3, divided by the unbypassed portion of the emitter resistor, R4.

base voltage will be $12\text{ V} \times [1.8\text{ k}\Omega / (1.8\text{ k}\Omega + 10\text{ k}\Omega)] = 1.83\text{ V}$, rather than 1.7 V . The resulting emitter voltage is $1.83\text{ V} - 0.7\text{ V} = 1.13\text{ V}$, resulting in $1.13\text{ V} / 200\ \Omega = 5.7\text{ mA}$ of collector current, rather than our desired 5 mA . We are close enough — we have finished designing the bias circuitry!

Performance: Voltage Gain

Now we can analyze how our little amplifier will work. The use of the unbypassed emitter resistor R_4 results in *emitter degeneration* — a fancy word describing a form of negative feedback. The bottom line for us is that we can use several handy rules of thumb. The first is for the ac voltage gain of an amplifier: $A_v = R_3 / R_4$, where A_v is shorthand for *voltage gain*. The ac voltage gain of such an amplifier is simply the ratio of the collector load resistor and the unbypassed emitter resistor. In this case, the gain is $1000 / 100 = 10$, which is 20 dB of voltage gain. This expression for gain is true virtually without regard for the exact kind of transistor used in the circuit, provided that we design for moderate gain in a single stage, as we have done.

Performance: Input Resistance

Another useful rule of thumb stemming from use of an unbypassed emitter resistor is the expression for the ac input resistance: $R_{in} = \beta \times R_4$. If the ac β at low frequencies is about 50, then the input resistance of the transistor is $50 \times 100\ \Omega = 5000\ \Omega$. The actual input resistance includes the shunt resistance of voltage divider R_2 and R_1 , about $1.5\text{ k}\Omega$. Thus the biasing resistive voltage divider essentially sets the input resistance of the amplifier.

Performance: Overload

We can accurately predict how this amplifier will perform. If we were to supply a peak positive 1 V signal to the base, the voltage at the collector will try to fall by the voltage gain of 10. However, since the dc voltage at the collector is only 7 V , it is clear that the collector voltage cannot fall 10 V . In theory, the collector voltage could fall as low as the 1.13 V dc level at the emitter. This amplifier will “run out of voltage” at a negative collector voltage swing of about $6.3\text{ V} - 1.13\text{ V} = 5.17\text{ V}$, when the input voltage is 5.17 divided by the gain of $10 = 0.517\text{ V}$.

When a negative-going ac voltage is supplied to the base, the collector current falls, and the collector voltage will rise by the voltage gain of 10. The maximum amount of voltage possible is the 12 V supply voltage, where the transistor is cut off with no collector current. The maximum positive collector swing is from the standing collector dc voltage to the supply voltage: $12\text{ V} - 6.3\text{ V} = 5.7\text{ V}$ positive swing. This occurs with a peak negative input voltage of $5.7\text{ V} / 10 = 0.57\text{ V}$. Our amplifier will overload rather symmetrically on both negative and positive peaks. This is no accident — we biased it to

Fig B — Output IMD (intermodulation distortion) as a function of input. In the region below the 1-dB compression point, a decrease in input level of 10 dB results in a drop of IMD products by 30 dB below the level of each output tone in a two-tone signal.

have a collector voltage halfway between ground and the supply voltage.

When the amplifier “runs out of output voltage” in either direction, another useful rule of thumb is that this is the *1 dB compression point*. This is where the amplifier just begins to depart from linearity, where it can no longer provide any more output for further input. For our amplifier, this is with a peak-to-peak output swing of approximately $5.1\text{ V} \times 2 = 10.2\text{ V}$, or 3.6 V rms. The output power developed in output resistor R_3 is $(3.6)^2 / 1000 = 0.013\text{ W} = 13\text{ mW}$, which is $+11.1\text{ dBm}$ (referenced to 1 mW on $50\ \Omega$).

At the 1 dB compression point, the third-order *IMD* (intermodulation distortion) will be roughly 25 dB below the level of each tone. **Fig B** shows a graph of output versus input levels for both the desired signal and for third-order *IMD* products. The rule of thumb for *IMD* is that if the input level is decreased by 10 dB , the *IMD* will decrease by 30 dB . Thus, if input is restricted to be 10 dB below the 1 dB compression point, the *IMD* will be $25\text{ dB} + 30\text{ dB} = 55\text{ dB}$ below each output tone.

With very simple math we have thus designed and characterized a simple amplifier. This amplifier will be stable for both dc and ac under almost any thermal and environmental conditions conceivable. That wasn’t too difficult, was it? — *R. Dean Straw, N6BV, ARRL Senior Assistant Technical Editor*

forward biased and the MOSFET would not work properly. In some depletion mode MOSFET devices, back-to-back Zener diodes are used to protect the gate.

MOSFET devices are at greatest risk of damage from static electricity when they are out of circuit. Even though static electricity is capable of delivering little current, it can generate thousands of volts. When storing MOSFETs, the leads should be placed into conductive foam. When working with MOSFETs, it is a good idea to minimize static by wearing a grounded wrist strap and working on a grounded table. A humidifier may help to decrease the static electricity in the air. Before inserting a MOSFET into a circuit board it helps to first touch the device leads with your hand and then touch the circuit board. This serves to equalize the excess charge so that when the device is inserted into the circuit board little charge will flow into the gate terminal.

OPTICAL SEMICONDUCTORS

In addition to electrical energy and heat energy, light energy also affects the behavior of semiconductor materials. If a device is made to allow light to fall on the surface of the semiconductor material, the light energy will break covalent bonds and increase the number of electron-hole pairs, decreasing the resistance of the material.

Photoconductors

In commercial *photoconductors* (also called *photoresistors*) the resistance can change by as much as several kilohms for a light intensity change of 100 ft-candles. The most common material used in photoconductors is cadmium sulfide

(CdS), with a resistance range of more than 2 M Ω in total darkness to less than 10 Ω in bright light. Other materials used in photoconductors respond best at specific colors. Lead sulfide (PbS) is most sensitive to infrared light and selenium (Se) works best in the blue end of the visible spectrum.

A similar effect is used in some diodes and transistors so that their operation can be controlled by light instead of electrical current biasing. These devices are called *photodiodes* and *phototransistors*. The flow of minority carriers across the reverse biased PN junction is increased by light falling on the doped semiconductor material. In the dark, the junction acts the same as any reverse biased PN junction, with a very low current (on the order of 10 μ A) that is nearly independent of reverse voltage. The presence of light not only increases the current but also provides a resistance-like relationship (reverse current increases as reverse voltage increases). See Fig 5.40 for the characteristic response of a photodiode. Even with no reverse voltage applied, the presence of light causes a small reverse current, as indicated by the points at which the lines in Fig 5.40 intersect the left side of the graph. Photoconductors and photodiodes are generally used to produce light-related analog signals that require further processing. The phototransistor can often be used to serve both purposes, acting as an amplifier whose gain varies with the amount of light present. It is also more sensitive to light than the other devices. Phototransistors have lots of gain, but photodiodes normally have less noise, so they make sensitive detectors.

Photovoltaic Effect

When illuminated, the reverse biased photodiode has a reverse current due to excess minority carriers. As the reverse voltage is reduced, the potential barrier to the forward flow of majority carriers is also reduced. Since light energy leads to the generation of both majority and minority carriers, when the resistance to the flow of majority carriers is decreased these carriers form a forward current. The voltage at which the forward current equals the reverse current is called the *photovoltaic potential* of the junction. If the illuminated PN junction is not connected to a load, a voltage equal to the photovoltaic potential can be measured across it. Devices that use light from the sun to produce electricity in this way are called *solar cells* or *solar batteries*. Common operating characteristics of silicon photovoltaic cells are an open circuit voltage of about 0.6 V and a conversion efficiency of about 10 to 15%.

Light Emitting Diodes

In the photodiode, energy from light falling on the semiconductor material is absorbed to make additional electron-hole pairs. When the electrons and holes recombine, the same amount of energy is given off. In normal diodes the energy from recombination of carriers is given off as heat. In certain forms of semiconductor material, the recombination energy is given off as light with a mechanism called *electroluminescence*. Unlike the incandescent light bulb, electroluminescence is a cold light source that typically operates with low voltages and currents (such as 1.5 V and 10 mA). Devices made for this purpose are called *light emitting diodes (LEDs)*. They have the advantages of low power requirements, fast switching times (on the order of 10 ns) and narrow spectra (relatively pure color). The LED emits light when it is forward biased and excess carriers are present. As the carriers recombine, light is produced with a color that depends on the properties of the semiconductor material used. Gallium arsenide (GaAs) generates light in the infrared region, gallium phosphide (GaP) gives off red light when doped with oxygen or green light when doped with nitrogen. Orange light is attained with a mixture of GaAs and GaP (GaAsP). Silicon doped with carbon gives off yellow light but does not produce much illumination. Other colors are also possible with different types and concentrations of dopants but usually have lower illumination efficiencies.

The LED is very simple to use. It is connected across a voltage source with a series resistor that limits the current to the

Fig 5.40 — Photodiode response curve. Reverse voltage is plotted on the x-axis and current through diode is plotted on the y-axis. Various response lines are plotted for different illumination. Except for the zero illumination line, the response does not pass through the origin since there is current generated at the PN junction by the light energy. A load line is shown for a 50 k Ω resistor in series with the photodiode.

desired level for the amount of light to be generated. The cathode lead is connected to the lower potential, and is usually specially marked (flattening of the lead near the package, a dot of paint next to the lead, and a flat portion of the round device located next to the lead are all common methods).

Optoisolators

An interesting combination of optoelectronic components proves very useful in many analog signal processing applications. An *optoisolator* consists of an LED optically coupled to a phototransistor, usually in an enclosed package. The optoisolator, as its name suggests, isolates different circuits from each other. Typically, isolation resistance is on the order of $10^{11} \Omega$ and isolation capacitance is less than 1 pF. Maximum voltage isolation varies from 1,000 to 10,000 V ac. The most common optoisolators are available in 6-pin DIP packages.

Optoisolators are used for voltage level shifting and signal isolation. The isolation has two purposes: to protect circuitry from excessive voltage spikes and to isolate noisy circuitry from noise sensitive circuitry. A disadvantage of an optoisolator is that it adds a finite amount of noise and is not appropriate for use in many applications with low-level signals. Optoisolators also cannot transfer signals with high power levels. The power rating of the LED in a 4N25 device is 120 mW. Optoisolators have a limited frequency response due to the high capacitance of the LED. A typical bandwidth for the 4N25 series is 300 kHz.

As an example of voltage level shifting, the input to an optoisolator can be derived from a tube amplifier that has a signal varying between 0 and 150 V by using a series current limiting resistor. In order to drive a semiconductor circuit that operates in the -1 to 0 V range, the output of the optoisolator can be biased to operate in that range. This conversion of voltage levels, without a common ground connection between the circuits, is not easily performed in any other way.

A 1000 V spike that is high enough to destroy a semiconductor circuit will only saturate the LED in the optoisolator and will not propagate to the next stage. The worst that will happen is the LED will be destroyed, but very often it is capable of surviving even very high voltage spikes.

Optoisolators are also useful for isolating different ground systems. The input and output signals are totally isolated from each other, even with respect to the references for each signal. A common application for optoisolation is when a computer is used to control radio equipment. The

computer signal, and even its ground reference, typically contains considerable wide band noise due to the digital circuitry. The best way to keep this noise out of the radio is to isolate both the signal and its reference; this is easily done with an optoisolator.

The design of circuits with optoisolators is not different from the design of circuits with LEDs and with transistors. The LED is forward biased and usually driven with a series current limiting resistor whose value is set so that the forward current will be less than the maximum value for the device (such as 60 mA in a 4N25). Signals must be appropriately dc shifted so that the LED is always forward biased. The phototransistor typically has all three leads available for connection. The base lead is used for biasing, since the signal is usually derived from the optics, and the collector and emitter leads are used as they would be in any transistor amplifier circuit.

Fiber Optics

An interesting variation of the optoisolator is the *fiber-optic* connection. Like the optoisolator, the signal is introduced to an LED device that modulates light. The signal is recovered by a photodetecting device (photoresistor, photodiode, or phototransistor). Instead of locating the input and output devices next to each other, the light is transmitted in a fiber optic cable, an extruded glass fiber that efficiently carries light over long distances and around fairly sharp bends. The fiber optic cable isolates the two circuits and provides an interesting transmission line. Fiber optics generally have far less loss than coaxial cable transmission lines. They do not leak RF energy, nor do they pick up electrical noise. Fiber optic cables are virtually immune from electromagnetic interference! Special forms of LEDs and phototransistors are available with the appropriate optical couplers for connecting to fiber optic cables. These devices are typically designed for higher frequency operation with bandwidths in the tens and hundreds of megahertz.

LINEAR INTEGRATED CIRCUITS

If you look into a transistor, the actual size of the semiconductor is quite small compared to the size of the packaging. For most semiconductors, the packaging takes considerably more space than the actual semiconductor device. Thus, an obvious way to reduce the physical size of circuitry is to combine more of the circuit inside a single package.

Hybrid Integrated Circuits

It is easy to imagine placing several

small semiconductor chips in the same package. This is known as *hybrid circuitry*, a technology in which several semiconductor chips are placed in the same package and miniature wires are connected between them to make complete circuits.

Hybrid circuits miniaturize analog electronic circuits by replacing much of the packaging that is inherent in discrete electronics. The term *discrete* refers to the use of individual components to make a circuit, each in its own package. One application that still exists for hybrid circuitry is microwave amplifiers. The components of the amplifier are placed in a standard TO-39 package that is only 1 cm in diameter. The small dimensions of these circuits permit operation at VHF. For example, the Motorola MWA5157 can provide over 23 dB of gain at 1 GHz.

Both discrete and hybrid circuitry require that connections be made between the leads of the components. This takes space, is relatively expensive to construct and is the source of most failures in electronic circuitry. If multiple components could be placed on a single piece of semiconductor with the connections between them as part of the semiconductor chip, these three disadvantages would be overcome.

Monolithic Integrated Circuits

In order to build entire circuits on a single piece of semiconductor, it must be possible to fabricate other devices, such as resistors and capacitors, as well as transistors and diodes. The entire circuit is combined into a single unit, or chip, that is called a *monolithic integrated circuit*.

An integrated circuit (IC) is fabricated in layers. An example of a semiconductor circuit schematic and its implementation in an IC is pictured in **Fig 5.41**. The base layer of the circuit, the *substrate*, is made of P-type semiconductor material. Although less common, the polarity of the substrate can also be N-type material. Since the mobility of electrons is about three times higher than that of holes, bipolar transistors made with N-type collectors and FETs made with N-type channels are capable of higher speeds and power handling. Thus, P-type substrates are far more common. For devices with N-type substrates, all polarities in the ensuing discussion would be reversed. Other substrates have been used, one of the most successful of which is the silicon-on-sapphire (SOS) construction that has been used to increase the bandwidth of integrated circuitry. Its relatively high manufacturing cost has impeded its use, however.

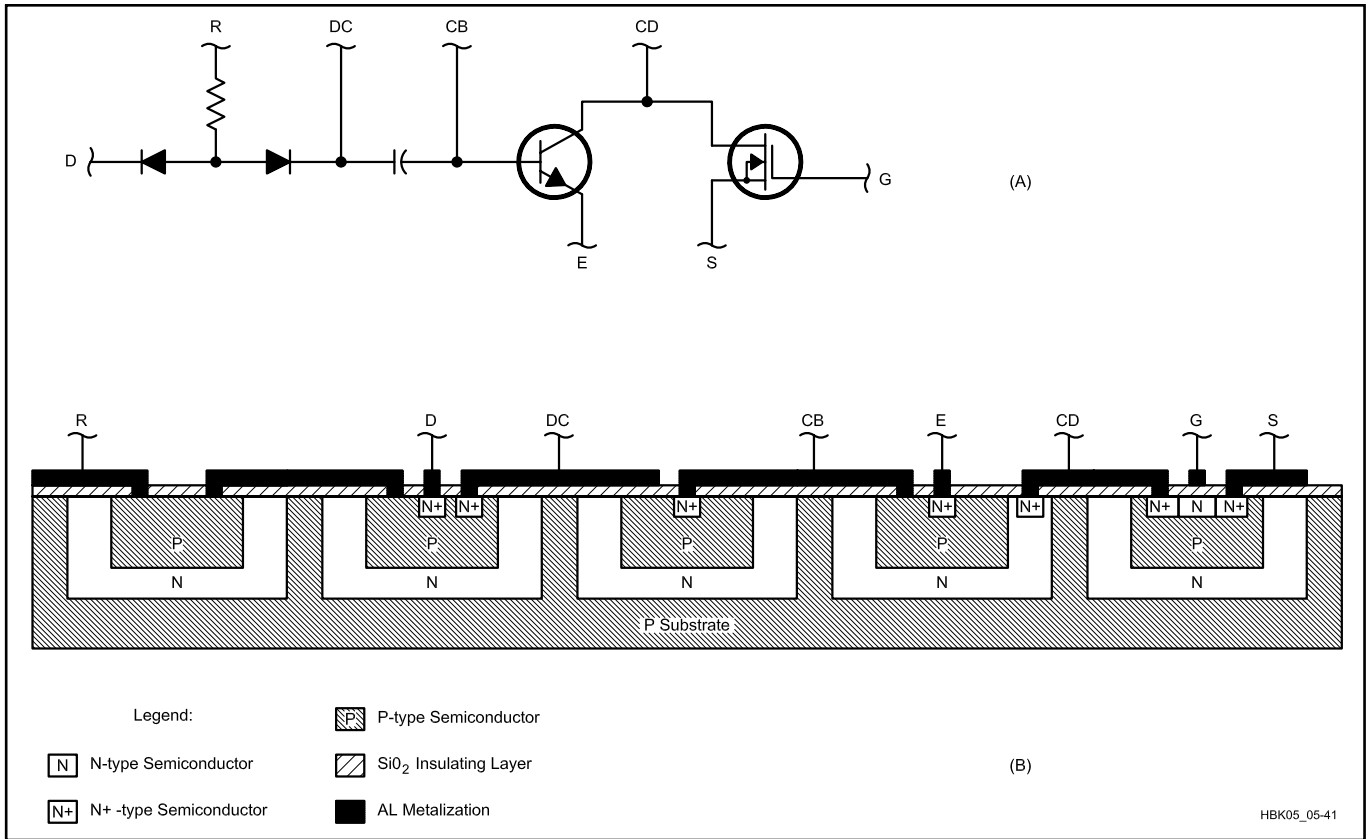

Fig 5.41 — Integrated circuit layout. (A) Circuit containing two diodes, a resistor, a capacitor, an NPN transistor and an N-channel MOSFET. Labeled leads are D for diode, R for resistor, DC for diode-capacitor, E for emitter, S for source, CD for collector-drain and G for gate. (B) Integrated circuit that is identical to circuit in (A). Same leads are labeled for comparison. Circuit is built on a P-type semiconductor substrate with N-type wells diffused into it. An insulating layer of SiO₂ is above the semiconductor and is etched away where aluminum metal contacts are made with the semiconductor. Most metal-to-semiconductor contacts are made with heavily doped N-type material (N⁺-type semiconductor).

On top of the P-type substrate is a thin layer of N-type material in which the active and passive components are built. Impurities are diffused into this layer to form the appropriate component at each location. To prevent random diffusion of impurities into the N-layer, its upper surface must be protected. This is done by covering the N-layer with a layer of silicon dioxide (SiO₂). Wherever diffusion of impurities is desired, the SiO₂ is etched away. The precision of placing the components on the semiconductor material depends mainly on the fineness of the etching. The fourth layer of an IC is made of metal (usually aluminum) and is used to make the interconnections between the components.

Different components are made in a single piece of semiconductor material by first diffusing a high concentration of acceptor impurities into the layer of N-type material. This process creates P-type semiconductor — often referred to as P⁺-type semiconductor because of its high concentration of acceptor atoms — that iso-

lates regions of N-type material. Each of these regions is then further processed to form single components. A component is produced by the diffusion of a lesser concentration of acceptor atoms into the middle of each isolation region. This results in an N-type *isolation well* that contains P-type material, is surrounded on its sides by P⁺-type material and has P-type material (substrate) below it. The cross sectional view in Fig 5.41B illustrates the various layers. Connections to the metal layer are often made by diffusing high concentrations of donor atoms into small regions of the N-type well and the P-type material in the well. The material in these small regions is N⁺-type and facilitates electron flow between the metal contact and the semiconductor. In some configurations, it is necessary to connect the metal directly to the P-type material in the well.

An isolation well can be made into a resistor by making two contacts into the P-type semiconductor in the well. Resistance is inversely proportional to the cross-sectional area of the well. An alter-

nate type of resistor that can be integrated in a semiconductor circuit is a *thin film resistor*, where a metallic film is deposited on the SiO₂ layer, masked on its upper surface by more SiO₂ and then etched to make the desired geometry, thus adjusting the resistance.

There are two ways to form capacitors in a semiconductor. One is to make use of the PN junction between the N-type well and the P-type material that fills it. Much like a varactor diode, when this junction is reverse biased a capacitance results. Since a bias voltage is required, this type of capacitor is polarized, like an electrolytic capacitor. Nonpolarized capacitors can also be formed in an integrated circuit by using thin film technology. In this case, a very high concentration of donor ions is diffused into the well, creating an N⁺-type region. A thin metallic film is deposited over the SiO₂ layer covering the well and the capacitance is created between the metallic film and the well. The value of the capacitance is adjusted by varying the thickness of the SiO₂ layer and the cross-

sectional size of the well. This type of thin film capacitor is also known as a metal oxide semiconductor (MOS) capacitor.

Unlike resistors and capacitors, it is very difficult to create inductors in integrated circuits. Generally, RF circuits that need inductance require external inductors to be connected to the IC. In some cases, particularly at lower frequencies, the behavior of an inductor can be mimicked by an amplifier circuit. In many cases the appropriate design of IC amplifiers can obviate the need for external inductors.

Transistors are created in integrated circuitry in much the same way that they are fabricated in their discrete forms. The NPN transistor is the easiest to make since the wall of the well, made of N-type semiconductor, forms the collector, the P-type material in the well forms the base and a small region of N⁺-type material formed in the center of the well becomes the emitter. A PNP transistor is made by diffusing donor ions into the P-type semiconductor in the well to make a pattern with P-type material in the center (emitter) surrounded by a ring of N-type material that connects all the way down to the well material (base), and this is surrounded by another ring of P-type material (collector). This configuration results in a large base width separating the emitter and collector, causing these devices to have much lower current gain than the NPN form. This is one reason why integrated circuitry is designed to use many more NPN transistors than PNP transistors.

The simplest form of diode is generated by connecting to an N⁺-type connection point in the well for the cathode and to the P-type well material for the anode. Diodes are often converted from NPN transistor configurations. Integrated circuit diodes made this way can either short the collector to the base or leave the collector unconnected. The base contact is the anode and the emitter contact is the cathode.

FETs can also be fabricated in IC form. Due to its many functional advantages, the MOSFET is the most common form used for digital ICs. MOSFETs are made in a semiconductor chip much the same way as MOS capacitors, described earlier. In addition to the signal processing advantages offered by MOSFETs over other transistors, the MOSFET device can be fabricated in 5% of the physical space required for bipolar transistors. MOSFET ICs can contain 20 times more circuitry than bipolar ICs with the same chip size. Just as discrete MOSFETs are at risk of gate destruction, IC chips made with MOSFET devices have a similar risk. They should be treated with the same care to protect

them from static electricity as discrete MOSFETs. Integrated circuits need not be made exclusively with MOSFETs or bipolar transistors. It is common to find IC chips designed with both technologies, taking advantage of the strengths of each.

Complementary Metal Oxide Semiconductors

Power dissipation in a circuit can be reduced to very small levels (on the order of a few nW) by using the MOSFET devices in complementary pairs (CMOS). Each amplifier is constructed of a series circuit of MOSFET devices, as in Fig 5.42. The gates are tied together for the input signal, as are the drains for the output signal. In saturation and cutoff, only one of the devices conducts. The current drawn by the circuit under no load is equal to the OFF leakage current of either device and the voltage drop across the pair is equal to V_{DD} , so the steady state power used by the circuit is always equal to $V_{DD} \times I_{D(OFF)}$. For ac signals, power consumption is proportional to frequency.

CMOS circuitry could be built with discrete components; however, the number of extra parts and the need for the complementary components to be matched has made it an unusual design technique. Although CMOS is most commonly used in digital integrated circuitry, its low power consumption has been put to advantage by several manufacturers of analog ICs.

Integrated Circuit Advantages

There are many advantages of monolithic integrated circuitry over similar circuitry implemented with discrete

components. The integration of the interconnections is one that has already been mentioned. This procedure alone serves to greatly decrease the physical size of the circuit and to improve its reliability. In fact, in one study performed on failures of electronic circuitry, it was found that the failure rate is not necessarily related to the complexity of the circuit, as had been previously thought, but is more closely a function of the number of interconnections between packages. Thus, the more circuitry that can be integrated onto a single piece of semiconductor material, the more reliable the circuit should be.

The amount of circuitry that can be placed onto a single semiconductor chip is a function of two factors: the size of the chip and how closely the various components are spaced. A revolution in IC manufacture occurred when semiconductor material was created in the laboratory rather than found in nature. The man-made semiconductor wafers are more pure and allow for larger wafer sizes. This, along with the steady improvement of the etching resolution on the chips, has caused an exponential increase over the past two decades in the amount of circuitry that can be placed in a single IC package. Currently, it is not unusual to find chips with more than one million transistors on them.

Decreased circuit size and improved reliability are only two of the advantages of monolithic integrated circuitry. The uncertainty of the exact behavior of the integrated components is the same as it is for discrete components, as discussed earlier. The relative properties of the devices on a single chip are very predictable, how-

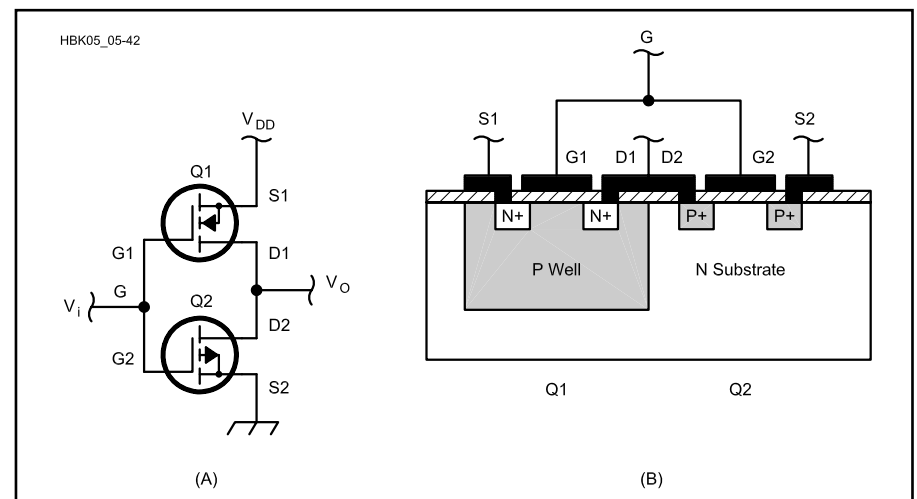

Fig 5.42 — Complementary metal oxide semiconductor (CMOS). (A) CMOS device is made from a pair of enhancement mode MOS transistors. The upper is an N-channel device, and the lower is a P-channel device. When one transistor is biased on, the other is biased off; therefore, there is minimal current from V_{DD} to ground. (B) Implementation of a CMOS pair as an integrated circuit.

ever. Since adjacent components on a semiconductor chip are made simultaneously (the entire N-type layer is grown at once, a single diffusion pass isolates all the wells and another pass fills them), the characteristics of identically formed components on a single chip of silicon should be identical. Even if the exact characteristics of the components are unknown, very often in analog circuit design the major concern is how components interact. For instance, push-pull amplifiers require perfectly matched transistors, and the gain of many amplifier configurations is governed by the ratio between two resistors and not their absolute values of resistance.

Integrated circuits often have an advantage over discrete circuits in their temperature behavior. The variation of performance of the components on an integrated circuit due to heat is no better than that of discrete components. While a discrete circuit may be exposed to a wide range of temperature changes, the entire semiconductor chip generally changes temperature by the same amount; there are fewer “hot spots” and “cold spots.” Thus, integrated circuits can be designed to better compensate for temperature changes.

A designer of analog devices implemented with integrated circuitry has more freedom to include additional components that could improve the stability and performance of the implementation. The inclusion of components that could cause a prohibitive increase in the size, cost or complexity of a discrete circuit would have very little effect on any of these factors in an integrated circuit.

Once an integrated circuit is designed and laid out, the cost of making copies of it is very small, often only pennies per chip. Integrated circuitry is responsible for the incredible increase in performance with a corresponding decrease in price of electronics over the last 20 years. While this trend is most obvious in digital computers, analog circuitry has also benefited from this technology.

The advent of integrated circuitry has also improved the design of high frequency circuitry. One problem in the design and layout of RF equipment is the radiation and reception of spurious signals. As frequencies increase and wavelengths approach the dimensions of the wires in a circuit board, the interconnections act as efficient antennas. The dimensions of the circuitry within an IC are orders of magnitude smaller than in discrete circuitry, thus greatly decreasing this problem and permitting the processing of much higher frequencies with fewer problems of interstage interference. Another related advantage of the smaller

interconnections in an IC is the lower inherent inductance of the wires, and lower stray capacitance between components and traces.

Integrated Circuit Disadvantages

Despite the many advantages of integrated circuitry, disadvantages also exist. ICs have not replaced discrete components, even tubes, in some applications. There are some tasks that ICs cannot perform, even though the list of these continues to decrease over time as IC technology improves.

Although the high concentration of components on an IC chip is considered to be an advantage of that technology, it also leads to a major limitation. Heat generated in the individual components on the IC chip is often difficult to dissipate. Since there are so many heat generating components so close together, the heat can build up and destroy the circuitry. It is this limitation that currently causes many power amplifiers to be designed with discrete components.

Integrated circuits, despite their short interconnection lengths and lower stray inductance, do not have as high a frequency response as similar circuits built with appropriate discrete components. (There are exceptions to this generalization, of course. Monolithic microwave integrated circuits — MMICs — are available for operation on frequencies up through 10 GHz.) The physical architecture of an integrated circuit is the cause of this limitation. Since the substrate and the walls of the isolation wells are made of opposite types of semiconductor material, the PN junction between them must be reverse biased to prevent current from passing into the substrate. Like any other reverse biased PN junction, a capacitance is created at the junction and this limits the frequency response of the devices on the IC. This situation has improved over the years as isolation wells have gotten smaller, thus decreasing the capacitance between the well and the substrate, and techniques have been developed to decrease the PN junction capacitance at the substrate. One such technique has been to create an N⁺-type layer between the well and the substrate, which decreases the capacitance of the PN junction as seen by the well. As an example, in the 1970s the LM324 operational amplifier IC package was developed by National Semiconductor and claimed a gain-bandwidth product of 1 MHz. In the 1990s the HFA1102 operational amplifier IC, developed by Harris Semiconductor, was introduced with a gain-bandwidth product of 600 MHz.

A major impediment to the introduction

of new integrated circuits, particularly with special applications, is the very high cost of development of new designs. The masking cost alone for a designed and tested integrated circuit can exceed \$100,000. Adding the design, layout and debugging costs motivates IC manufacturers to produce devices that will be widely used so that they can recoup the development costs by volume of sales. While a particular application would benefit from customization of circuitry on an IC, the popularity of that application may not be wide enough to compel an IC manufacturer to develop that design. A designer who wishes to use IC chips must often settle for circuits that do not behave exactly as desired for the specific application. This trade-off between the advantages afforded by the use of integrated circuitry and the loss of performance if the available IC products do not exactly meet the desired specifications must be considered by equipment designers. It often leads to the use of discrete circuitry in sensitive applications. Once again, the improvements afforded by technology have mitigated this problem somewhat. The design and layout of ICs has been made more affordable by computer-based aids. Interaction between the computer aided design (CAD) software and modern chip masking hardware has also decreased the masking costs. As these development costs decrease, we are seeing an increase in the number of specialty chips that are being marketed and also of small companies that are created to fill the needs of the niche markets.

Common Types of Linear Integrated Circuits

The three main advantages of designing a circuit into an IC are to take advantage of the matched characteristics of like components, to make highly complex circuitry more economical, and to miniaturize the circuit. As a particular technology becomes popular, a rash of integrated circuitry is developed to service that technology. A recent example is the cellular telephone industry. Cellular phones have become so pervasive that IC manufacturers have developed a large number of devices targeted toward this technology. Space limitations prohibit a comprehensive listing of all analog special function ICs but a sampling of those that are more useful in the radio field is presented.

Component Arrays

The most basic form of linear integrated circuit is the component array. The most common of these are the resistor, diode

and transistor arrays. Though capacitor arrays are also possible, they are used less often. Component arrays usually provide space saving but this is not the major advantage of these devices. They are the least densely packed of the integrated circuits, limited mainly by the number of off-chip connections needed. While it may be possible to place over a million transistors on a single semiconductor chip, individual access to these would require a total of three million pins and this is beyond the limits of practicability. More commonly, resistor and diode arrays contain from five to 16 individual devices and transistor arrays contain from three to six individual transistors. The advantage of these arrays is the very close matching of component values within the array. In a circuit that needs matched components, the component array is often a good method of obtaining this feature. The components within an array can be internally combined for special functions, such as termination resistors, diode bridges and Darlington pair transistors. A nearly infinite number of possibilities exists for these combinations of components and many of these are available in arrays.

Multivibrators

A *multivibrator* is a circuit that oscillates, usually with a square wave output in the audio frequency range. The frequency of oscillation is accurately controlled with the addition of appropriate values of external resistance and capacitance. The most common multivibrator in use today is the 555 (NE555 by Signetics [now Philips] or LM555 by National Semiconductor). This very simple eight-pin DIP device has a frequency range from less than one hertz to several hundred kilohertz. Such a device can also be used in *monostable* operation, where an input pulse generates an output pulse of a different duration, or in *astable* operation, where the device freely oscillates. Some other applications of a multivibrator are as a frequency divider, a delay line, a pulse width modulator and a pulse position modulator.

Operational Amplifiers

An *operational amplifier*, or *op amp*, is one of the most useful linear devices that has been developed in integrated circuitry. While it is possible to build an op amp with discrete components, the symmetry of this circuit requires a close match of many components and is more effective, and much easier, to implement in integrated circuitry. Fig 5.43 shows a basic op-amp circuit. The op amp approaches a perfect analog circuit building block.

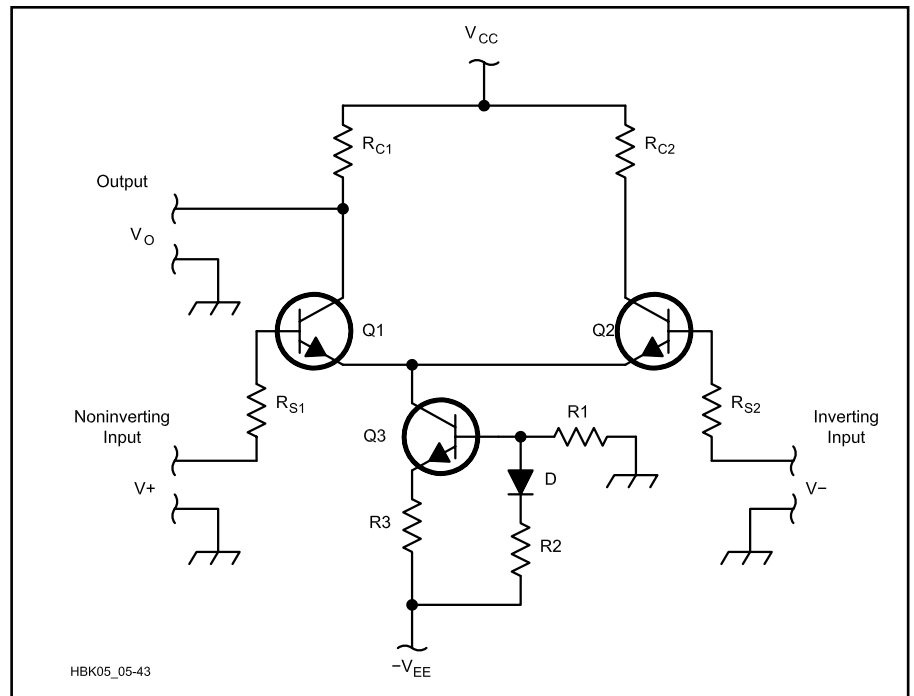

Fig 5.43 — Schematic of the components that make up an operational amplifier. Q1 and Q2 are matched emitter-coupled amplifiers. Q3 provides a constant current source. The symmetry of this device makes the matching of the components critical to its operation. This is why this circuit is usually implemented only in integrated circuitry. This simple op amp design has a large dc offset voltage at the output. Most practical designs include a level-shifting circuit, so the output voltage can exist near ground potential.

Ideally, an op amp has an infinite input impedance (Z_i), a zero output impedance (Z_o) and an open loop voltage gain (A_v) of infinity. Obviously, practical op amps do not meet these specifications, but they do come closer than most other types of amplifiers. An older op amp that is based on bipolar transistor technology, the LM324, has the following characteristics: guaranteed minimum CMRR of 65 dB, guaranteed minimum A_v of 25000, an input bias current (related to Z_i) guaranteed to be below 250 nA (2.5×10^{-7} A), output current capability (which determines Z_o) guaranteed to be above 10 mA and a gain-bandwidth product of 1 MHz. The TL084, which is a pin compatible replacement for the LM324 but is made with both JFET and bipolar transistors, has a guaranteed minimum CMRR of 80 dB, an input bias current guaranteed to be below 200 pA (2.0×10^{-10} A, almost 1000 times smaller than the LM324) and a gain-bandwidth product of 3 MHz. Philips has recently introduced the LMC6001 op amp with an input bias current of 25 fA (2.5×10^{-14} A, almost 10,000 times smaller than the TL084). This is equivalent to 156 electrons entering the device every millisecond and corresponds to nearly infinite input impedance. Op amps can be custom-

ized to perform a large variety of functions by the addition of external components.

The typical op amp has three signal terminals (see Fig 5.44). There are two input terminals, the noninverting terminal marked with a + sign and the inverting terminal marked with a - sign. The output of the amplifier has a single terminal and

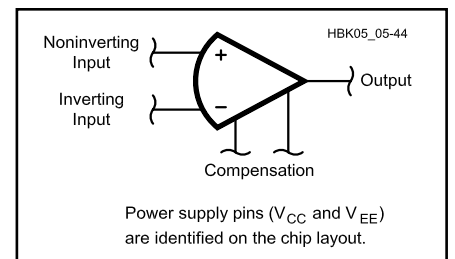

Fig 5.44 — Operational amplifier schematic symbol. The terminal marked with a + sign is the noninverting input. The terminal marked with a - sign is the inverting input. The output is to the right. On some op amps, external compensation is needed and leads are provided, pictured here below the device. Usually, the power supply leads are not shown on the op amp itself but are specified in the data sheet.

Fig 5.45 — Operational amplifiers arranged as an instrumentation amplifier. The balanced and cascaded series of op amps work together to perform differential amplification with good common-mode rejection and very high input impedance (no load resistor required) on both the inverting (V_1) and noninverting (V_2) inputs.

all signal levels within the op amp float, which means they are not tied to a specific reference. Rather, the reference of the input signals becomes the reference for the output signal. In many circuits this reference level is ground. Older operational amplifiers have an additional two connections for *compensation*. To keep the amplifier from going into oscillation at very high gains (increase its stability) it is often necessary to place a capacitor across the compensation terminals. This also decreases the frequency response of the op amp. Most modern op amps are internally compensated and do not have separate pins to add compensation capacitance. Additional compensation can be attained by connecting a capacitor between the op amp output and the inverting input.

One of the major advantages of using an op amp is its very high common mode rejection ratio (CMRR). Since there are two input terminals to an op amp, anything that is common to both terminals will be subtracted from the signal during amplification. The CMRR is a measure of the effectiveness of this removal. High CMRR results from the symmetry between the circuit halves. The rejection of power-supply noise is also an important parameter of an op amp. This is attained similarly, since the power supply is connected equally to both symmetrical halves of the op amp circuit. Thus, the power supply rejection ratio (PSRR) is similar to the CMRR and is often specified on the device data sheets.

Just as the symmetry of the transistors making up an op amp leads to a device with high values of Z_i , A_v and CMRR and a low value of Z_o , a symmetric combination of op amps is used to further improve these parameters. This circuit, shown in **Fig 5.45**, is called an instrumentation amplifier.

The op amp is capable of amplifying signals to levels limited mainly by the power supplies. Two power supplies are required, thus defining the range of signal voltages that can be processed. In most op amps the signal levels that can be handled are less than the power supply limits (rails), usually one or two diode drops (0.7 V or 1.4 V) away from each rail. Thus, if an op amp has 15 V connected as its upper rail (usually denoted V^+) and ground connected as its lower rail (V^-), input signals can be amplified to be as high as 13.6 V and as low as 1.4 V in most amplifiers. Any values that would be amplified beyond those limits are clamped (output voltages that should be 1.4 V or less appear as 1.4 V and those that should be 13.6 V or more appear as 13.6 V). This clamping action is illustrated in Fig 5.1. Op amps have been developed to handle signals all the way out to the power supply rails (for example, the MAX406, from Maxim Integrated Products).

If a signal is connected to the input terminals of an op amp, it will be amplified as much as the device is able (up to A_v), and will probably grow so large that it clamps, as described above. Even if such large gains are desired, A_v varies from one device to the next and cannot be guaranteed. In most applications the op amp gain is limited to a more reasonable value and this is usually realized by providing a negative feedback path from the output terminal to the inverting input terminal. The *closed loop gain* of an op amp depends solely on the values of the passive components used to form the loop (usually resistors and, for frequency-selective circuits, capacitors). Some examples of different circuit configurations that manipulate the loop gain follow.

The op amp is often used as either an

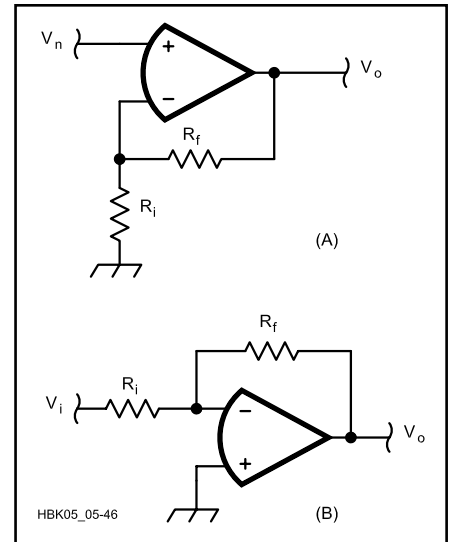

Fig 5.46 — Operational amplifier circuits. (A) Noninverting configuration. (B) Inverting configuration.

inverting or a noninverting amplifier. Accurate amplification can be achieved with just two resistors: the feedback resistor, R_f , and the input resistor, R_i (see **Fig 5.46**). If connected in the noninverting configuration, the input signal is connected to the noninverting terminal. The feedback resistor is connected between the output and the inverting terminal. The inverting terminal is connected to R_i , which is connected to ground. The gain of this configuration is:

$$\frac{V_o}{V_n} = \left(1 + \frac{R_f}{R_i} \right) \quad (15)$$

where:

V_o is the output voltage, and
 V_n is the input voltage to the noninverting terminal.

In the inverting configuration, the input signal (V_i) is connected through R_i to the inverting terminal. The feedback resistor is again connected between the inverting terminal and the output. The noninverting terminal can be connected to ground or to a dc-offset voltage. The gain of this circuit is:

$$\frac{V_o}{V_i} = - \frac{R_f}{R_i} \quad (16)$$

where V_i represents the voltage input to R_i .

The negative sign in equation 16 indicates that the signal is inverted. For ac signals, inversion represents a 180° phase shift. The gain of the noninverting op amp can vary from a minimum of $\times 1$ to the

maximum of which the device is capable. The gain of the inverting op amp configuration can vary from a minimum of $\times 0$ (gains from $\times 0$ to $\times 1$ attenuate the signal while gains of $\times 1$ and higher amplify the signal) to the maximum of which the device is capable, as indicated by A_v for dc signals, or the gain-bandwidth product for ac signals. Both parameters are usually specified in the manufacturer's data sheet.

A voltage follower is a type of op amp that is commonly used as a buffer stage. The voltage follower has the input connected directly to the noninverting terminal and the output connected directly to the inverting terminal (Fig 5.47). This configuration has unity gain and provides the maximum possible input impedance and the minimum possible output impedance of which the device is capable.

A *differential amplifier* is a special application of an operational amplifier (see Fig 5.48). It amplifies the difference between two analog signals and is very useful to cancel noise under certain conditions. For instance, if an analog signal and a reference signal travel over the same cable they may pick up noise, and it is likely that both signals will have the same amount of noise. When the differential amplifier subtracts them, the signal will be unchanged but the noise will

be completely removed, within the limits of the CMRR. The equation for differential amplifier operation is

$$V_o = \frac{R_f}{R_i} \left[\frac{1}{\frac{R_n}{R_g} + 1} \left(\frac{R_i}{R_f} + 1 \right) V_n - V_i \right] \quad (17)$$

which, if the ratios

$$\frac{R_i}{R_f} \quad \text{and} \quad \frac{R_n}{R_g}$$

are equal, simplifies to

$$V_o = \frac{R_f}{R_i} (V_n - V_i) \quad (18)$$

Note that the differential amplifier response is identical to the inverting op amp response (equation 16) if the voltage source to the noninverting terminal is equal to zero. If the voltage source to the inverting terminal (V_i) is set to zero, the analysis is a little more complicated but it is possible to derive the noninverting op amp response (equation 15) from the differential amplifier response by taking into account the influence of R_n and R_g .

DC offset is an important consideration in op amps for two reasons. Actual op amps have a slight mismatch between the

inverting and noninverting terminals that can become a substantial dc offset in the output, depending on the amplifier gain. The op amp output must not be too close to the clamping limits or distortion will occur. Introduction of a small dc correction voltage to the noninverting terminal is sometimes used to apply an offset voltage that counteracts the internal mismatch and centers the signal in the rail-to-rail range.

The high input impedance of an op amp makes it ideal for use as a *summing amplifier*. In either the inverting or noninverting configuration, the single input signal can be replaced by multiple input signals that are connected together through series resistors, as shown in Fig 5.49. For the inverting summing amplifier, the gain of each input signal can be calculated individually using equation 16 and, because of the superposition property, the output becomes the sum of each input signal multiplied by its gain. In the noninverting configuration, the output is the gain times the weighted sum of the m different input signals:

$$V_n = V_{n1} \frac{R_{p1}}{R_1 + R_{p1}} + V_{n2} \frac{R_{p2}}{R_2 + R_{p2}} + \dots + V_{nm} \frac{R_{pm}}{R_m + R_{pm}} \quad (19)$$

where R_{pm} is the parallel resistance of all m resistors excluding R_m . For example, with three signals being summed, R_{p1} is the parallel combination of R_2 and R_3 .

Other combinations of summing and difference amplification can be realized with a single op amp. The analyses of such circuits use the standard op amp equations coupled with the principle of superposition.

A *voltage comparator* is another special form of an operational amplifier. It takes in two analog signals and provides a binary output that is true if the voltage of one signal is bigger than that of the other, and false if not. A standard operational amplifier can be made to act as a comparator by connecting the two voltages to the noninverting and inverting inputs with no input or feedback resistors. If the voltage of the noninverting input is higher than that of the inverting input, the output voltage will be clamped to the positive clamping limit. If the inverting input is at a higher potential than the noninverting input, the output voltage will be clamped to the negative clamping limit (although this is not necessarily a negative voltage, depending on the value of the lower rail). Some applications of a voltage comparator are a zero crossing detector, a signal squarer (which turns other cyclical wave

Fig 5.47 — Voltage follower. This operational amplifier circuit makes a nearly ideal buffer with a voltage gain of about one, and with extremely high input impedance and extremely low output impedance.

Fig 5.48 — Differential amplifier. This operational amplifier circuit amplifies the difference between the two input signals.

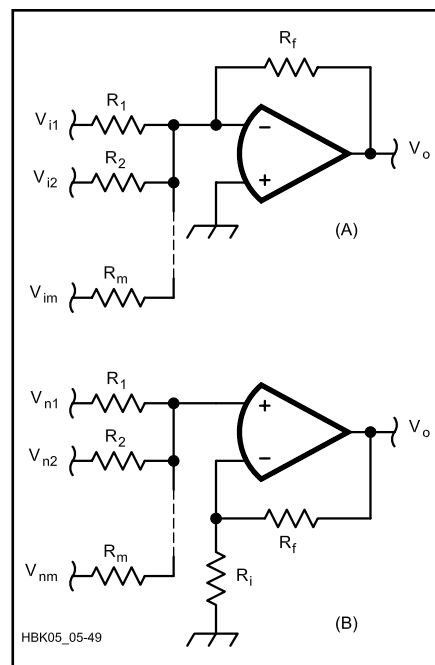

Fig 5.49 — Summing operational amplifier circuits. (A) Inverting configuration. (B) Noninverting configuration.

forms into square waves) and a peak detector.

Charge Coupled Devices

As the speed of integrated circuitry increases, it becomes possible to process some of the signals digitally while other processing occurs in analog form, all of this on the same IC chip. Such a chip is often called a *mixed modality* or *hybrid* chip (not to be confused with the hybrid circuitry discussed earlier). An example of this is the *charge-coupled device* (CCD). Pure digital analysis of signals requires digitization in two domains, namely the time sampling of a signal into individual packets and the amplitude sampling of each time packet into digital levels. CCDs perform time sampling but the time packets remain in analog form; they can take on any voltage value rather than a fixed number of discrete values. The CCD is often used to produce a delay filter. While most analog filters introduce some phase shift or delay into the signal, the relationship between the phase shift and the frequency is not always linear; different frequencies are delayed by different amounts of time. The goal of an ideal delay filter is to delay all parts of the signal by the same time. The CCD is used to realize this by sampling the signal, shifting the time packets through a series of capacitors and then reconstructing the continuous signal at the other end. The rate of shifting the time packets and the number of stages determines the amount of the delay. When originally introduced in the late 1970s, CCDs were described as bucket brigade devices (after the old fire fighting technique), where the buckets filled with signal packets are passed along the line until they are dumped at the end and recombined into an analog signal. These devices are simply constructed in an IC where each bucket is a MOS capacitor that is surrounded by two MOSFETs. When the transistors are biased to conduct, the charge moves from one bucket to the next and, while biased off, the charges are held in their capacitors. Very accurate filters, called *switched capacitor filters*, can be made with CCDs (see the **RF and AF Filters** chapter).

A special form of CCD has also become quite popular in recent years, replacing the vidicon in modern camera circuitry. A two dimensional array of CCD elements has been developed with light sensitive semiconductor material; the charge that enters the capacitors is proportional to the amount of light incident on that location of the chip. The charges are held in their array of capacitors until shifted out, one horizontal line at a time, in a raster format.

The CCD array mimics the operation of the vidicon camera and has many advantages. CCD response linearity across the field is superior to that of the vidicon. Very bright light at one location saturates the CCD elements only at that location rather than the blooming effect in vidicons where bright light spreads radially from the original location. CCD imaging elements do not suffer from image retention, which is another disadvantage of vidicon tubes.

Balanced Mixers

The *balanced mixer* is a device with many applications in modern radio transceivers (see the **Mixers, Modulators and Demodulators** chapter). Audio signals can be modulated onto a carrier or demodulated from the carrier with a balanced mixer. RF signals can be downconverted to intermediate frequency (IF) or IF can be upconverted to RF with a balanced mixer. This device is made with a bridge of four matched Schottky diodes and the necessary transformers packaged in a small metal, plastic or ceramic container. The consequence of unmatched diodes is poor isolation between the local oscillator (LO) and the two signals. IC mixers often use a “Gilbert cell” to provide LO isolation as high as -30 dB at 500 MHz. The isolation improves with decreasing frequency.

Receiver Subsystems

High performance ICs have been designed that make up complete receivers with the addition of only a few external components. Two examples that are very similar are the Motorola MC3363 and the Philips NE627. Both of these chips have all the active RF stages necessary for a double conversion FM receiver. The MC3363 has an internal local oscillator (LO) with varactor diodes that can generate frequencies up to 200 MHz, although the rest of the circuit is capable of operating at frequencies up to 450 MHz with an external oscillator. The RF amplifier has a low noise factor and gives this chip a 0.3 μ V sensitivity. The intermediate frequency stages contain limiter amplifiers and quadrature detection. The necessary circuitry to implement receiver squelch and zero crossing detection of FSK modulation is also present. The circuit also contains received signal strength (“S-meter”) circuitry (RSSI). The input and output of each stage are also brought out of the chip for versatility. The audio signal out of this chip must be appropriately amplified to drive a low-impedance speaker. This chip can be driven with a dc power source from 2 to 7 V and it draws only 3 mA with a 2 V supply.

The Philips NE627 is a newer chip than

the MC3363 and has better performance characteristics even though it has essentially the same architecture. Its LO can generate frequencies up to 150 MHz and external oscillator frequencies up to 1 GHz can be used. The chip has a 4.6 dB noise figure and 0.22 μ V sensitivity. The circuit can be powered with a dc voltage between 4.5 and 8 V and it draws between 5.1 and 6.7 mA. This chip is also ESD hardened so it resists damage from electrostatic discharges, such as from nearby lightning strikes.

The various stages in the receiver subsystem ICs are made available by connections on the package. There are two reasons that this is done. Filtering that is added between stages can be performed more effectively with inductors and crystal or ceramic filters, which are difficult to fabricate in integrated circuitry, so the output of one stage can be filtered externally before being fed to the next stage. It also adds to the versatility of the device. Filter frequencies can be customized for different intermediate frequencies. Stages can be used individually as well, so these devices can be made to perform direct conversion or single conversion reception or other forms of demodulation instead of FM.

Older integrated circuits that are subsets of the receiver subsystems are popular. The NE602 contains one double balanced mixer and a local oscillator, along with voltage regulation and buffering (**Fig 5.50**). It contains almost everything required to construct a direct conversion receiver. Its small size, an 8-pin DIP, makes it more desirable for this purpose than using part of an MC3363, which is in a 24-pin DIP and is more expensive. The NE604 contains the IF amplifiers and quadrature detector that, together with two NE602s and an RF amplifier, could almost duplicate the functions of the MC3363 or the NE367.

Transmitter Subsystems

Single chips are available to implement FM transmitters. One implementation is the Motorola MC2831A. This chip contains a mike preamplifier with limiting, a tone generator for CTCSS or AFSK, and a frequency modulator. It has an internal voltage controlled oscillator that can be controlled with a crystal or an LC circuit. This chip also contains circuitry to check the power supply voltage and produce a warning if it falls too low. Together with an FM receiver IC, an entire transceiver can be fabricated with very few parts.

Monolithic Microwave Integrated Circuit

A class of bipolar IC that is capable of higher frequency responses is the *mono-*

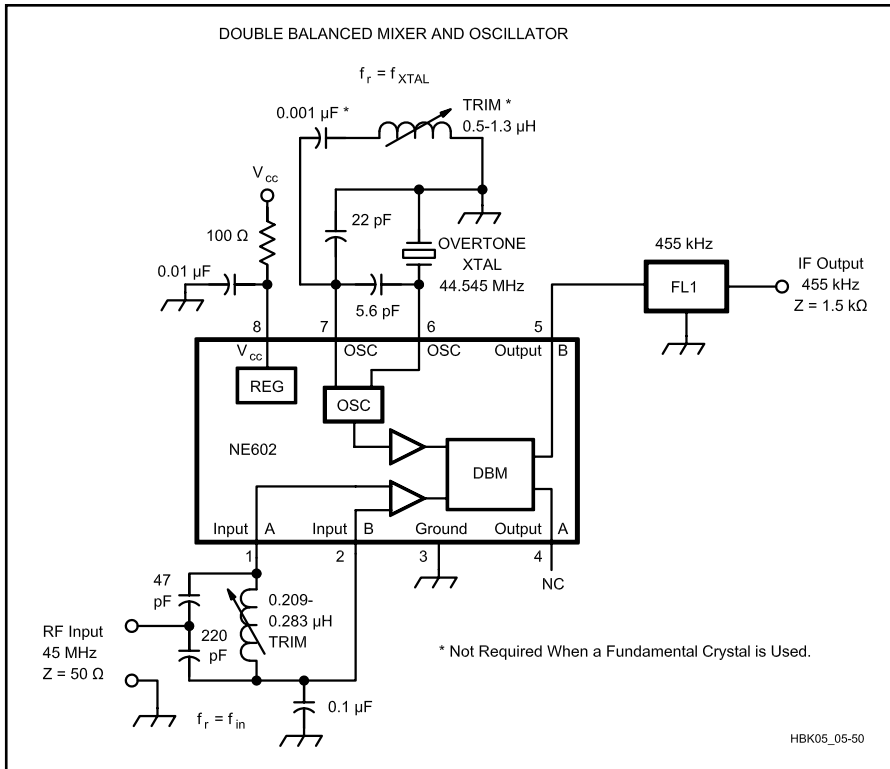

Fig 5.50 — The NE602 functional block diagram in circuit. This device contains a doubly balanced mixer, a local oscillator, buffers and a voltage regulator. This application uses the NE602 to convert an RF signal in a receiver to IF.

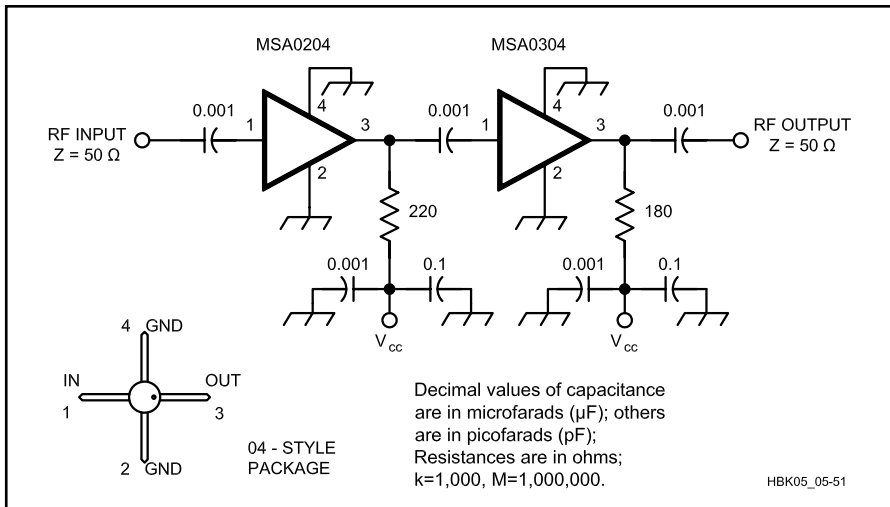

Fig 5.51 — The MSA0204 and MSA0304 MMICs in circuit. Both amplifiers have both input and output impedance of 50 Ω and a bandwidth of more than 2.5 GHz.

lithic microwave integrated circuit (MMIC). There is no formal definition of when an IC amplifier becomes an MMIC and, as the performance of IC devices improves, particularly MOS based devices, the distinction is becoming blurred. MMIC devices typically have predefined operating characteristics and require few external components. An example of an MMIC is a fixed gain amplifier, the

MSA0204 (Fig 5.51), which can deliver 12 dB of gain up to 1 GHz. More modern MMIC devices are being developed with bandwidths in the tens of GHz.

Comparison of Analog Signal Processing Components

Analog signal processing deals with changing a signal to a desired form. Vacuum tubes, bipolar transistors, field-

effect transistors and integrated circuitry perform similar functions, each with specific advantages and disadvantages. These are summarized here.

Of the four component types, vacuum tubes are physically the largest and require the most operating power. They have more limited life spans, usually because the heater filament burns out just as a light bulb does. Regardless of its use, a vacuum tube always generates heat. Miniaturization is difficult with vacuum tubes both because of their size and because of the need for air space around them for cooling. Vacuum tubes do have advantages, however. They are electrically robust. You need not be as concerned about static charges destroying vacuum tubes. A transmitter with vacuum tube finals usually has a variable matching network built in, and can be loaded into a higher SWR than one with semiconductor finals. Tubes are generally able to withstand the high voltages generated by reflections under high SWR conditions. They are not as easily damaged by short-term overloads or the electromagnetic pulses generated by lightning. The relatively high plate voltages mean that the plate current is lower for a given power output; thus power supplies do not need as high a current handling capability. Vacuum tubes are capable of considerable heat dissipation and many high power applications still use them. Special forms of vacuum tubes are also still used. Most video displays use CRTs, and microwave transmitting tubes are still common.

Bipolar transistors have many advantages over vacuum tubes. When treated properly they can have virtually unlimited life spans. They are relatively small and, if they do not handle high currents, do not generate much heat, improving miniaturization. They make excellent high-frequency amplifiers. Compared to MOSFET devices they are less susceptible to damage from electrostatic discharge. RF amplifiers designed with bipolar transistors in their finals generally include circuitry to protect the transistors from the high voltages generated by reflections under high SWR conditions. Lightning strikes in the area (not direct hits) have been known to destroy all kinds of semiconductors, including bipolar transistors. Semiconductors have replaced almost all small-signal applications of tubes.

There are many performance advantages to FET devices, particularly MOSFETs. The extremely low gate currents allow the design of analog stages with nearly infinite input resistance. Signal distortion due to loading is minimized in this way. As these characteristics are

improved by technology, we are seeing an increase in FET design at the expense of bipolar transistors.

The current trend in electronics is portability. Transceivers are decreasing in size and in their power requirements. Integrated circuitry has played a large part in this trend. Extremely large circuits have been designed with microscopic proportions. It is more feasible to use MOSFETs within an IC chip than as discrete components since the devices at risk are usually those that are connected to the outside world. It is not necessary to use electrostatic discharge protection circuitry on the gate of every MOSFET in an IC; only the ones that connect to the pins on the chip need this protection. This arrangement both improves the performance of the internal MOSFETs and decreases the circuit size even further. Semiconductors are slowly replacing the last tube applications.

Digital Fundamentals

Radio Amateurs have been involved with digital technology since the first spark transmitters, a form of pulse-coded transmission, were connected to an “aerial.” Modern digital technology use by Radio Amateurs probably arrived first in automatic keyers, where hams learned about flip-flops and gates to replace their semi-automatic mechanical keyers (bugs). Amateur use of digital technology echoes public use of these new abilities, starting with using the first home computers for calculations and later as Teletype and data terminals.

The first PC hobbyists, on the west coast, worked on the idea that technology, and in particular software, should be free and available to all. It is not very surprising to learn that many of these PC pioneers were also Radio Amateurs, who were accustomed to seeing new technical ideas freely distributed in the pages of *QST*.

The remainder of this chapter, written by Christine Montgomery, KGØGN, with additional material by Paul Danzer, N1II, presents digital-theory fundamentals and some applications of that theory in Amateur Radio. The fundamentals introduce digital mathematics, including number systems, logic devices and simple digital circuits. Next, the implementation of these simple circuits is explored in integrated circuits, their families and interfacing. Integrated circuits continue with memory chips and microprocessors, culminating in a synthesis of these components in the modern digital computer. Where possible, this section mentions Amateur Radio applications associated with the technologies being discussed, as well as pointers to

CCD chips have been so successful in video cameras that it is difficult to find an application for vidicon tubes. The liquid crystal displays (LCDs) in laptop computers have given considerable competition to the CRT tube.

An important consideration in the use of analog components is the future availability of parts. At an ever increasing rate, as new components are developed to replace older technology, the older components are discontinued by the manufacturers and become unavailable for future use. This tends to be a fairly long term process but it is not unusual for a manufacturer to stop offering a component when demand for it falls. This has become evident with vacuum tubes, which are becoming more difficult to find and more expensive as fewer manufacturers produce them.

The major disadvantages of IC technology have been power handling capabil-

ity, frequency response and non-customized circuitry. These characteristics have improved at an amazing pace over recent years; it is a process that feeds itself. As ICs are improved they are used to make more powerful tools (such as computers and electronic test equipment) that are used in the design of further IC improvements. Entire transceivers are designed with just a few IC chips and the appropriate transistors for power amplification. The quiescent current draw of these devices has been reduced to the microampere level so they can operate effectively from small battery packs. The improved noise performance of circuitry has also decreased the need for high transmitter power, further decreasing the current requirements for these devices. If this trend continues, we should eventually see a near total switch to IC components with few discrete semiconductors and no vacuum tubes.

other chapters that discuss such applications in greater depth.

DIGITAL VS. ANALOG

An essential first step in understanding digital theory is to understand the difference between a *digital* and an *analog* signal. An analog value, a real number, has no end; for example, the number $1/3$ is $0.333\dots$ where the 3 can be repeated forever, or $3/4$ equals $0.7500\dots$ with infinite repeated 0s. A digital approximation of an analog number breaks the real number line into discrete steps, for example, the integers. This process of approximating a value with discrete steps either truncates or rounds an analog value to some number of decimal places. For example, rounding $1/3$ to an integer gives 0 and rounding $3/4$ gives 1.

For a simple physical example, look at your wristwatch. A watch with a face — with the hands of the watch rotating in a continuous, smooth motion — is an analog display. Here, the displayed time has a *continuous* range of values, such as from 12:00 exactly to 12:00 and $1/3$ second or any values in between. In contrast, a watch with a digital display is limited to *discrete* states. Here the displayed time jumps from 12:00 and 0 seconds to 12:00 and 1 second, without showing the time in between. (A watch with a second hand that jerks from one second to another could also fit the digital analogy.)

In the digital watch example, time is represented by ten distinct states (0, 1, 2, 3, 4, 5, 6, 7, 8 and 9). Digital electronic signals, however, will usually be much more limited in the number of states allowed.

The digital system used is also called the *binary* system, since only two values are allowed. By using coding, as discussed in the following pages, these two binary values can represent any number of real values. **Fig 5.52** illustrates the contrast of an analog signal (in this case a sine wave) and its digital approximation. Three positive and three negative values are shown as an approximation to the sine wave, but any number of coded value steps can be used as an approximation.

While the focus in this chapter will be on digital theory, many circuits and systems involve *both* digital and analog components. Often, a designer may choose between using digital technology, analog technology or a combination.

Fig 5.52 — An analog signal and its analog approximation. Note that the analog waveform has continuously varying voltage while the approximated waveform is composed of discrete steps.

Number Systems

In order to understand digital electronics, you must first understand the digital numbering system. Any number system has two distinct characteristics: a set of *symbols* (digits or numerals) and a *base* or radix. A *number* is a collection of these digits, where the left-most digit is the *most significant digit (MSD)* and the right-most digit is the *least significant digit (LSD)*. The value of this number is a weighted sum of its digits. The *weights* are determined by the system's base and the digit's position relative to the decimal point.

While these definitions may seem strange with all the technical terms, they will be more familiar when seen in a decimal system example. This is the "traditional" number system with which we are all familiar.

DECIMAL

The decimal system is a base-10 system, with ten symbols: {0, 1, 2, 3, 4, 5, 6, 7, 8, 9}. To count, we start at 0, and then work our way up to the highest single value allowed — 9. Therefore we count 0, 1, 2, 3, 4, 5, 6, 7, 8, 9.

Consider 3 digits, represented by XXX. We start at 000, and then fill up the first (least significant) column, on the right:

```

XXX
000
001
002
003
...
009
    
```

Table 5.1
Decimal Numbers

Example: 548

Digit = 5; Weight = 10; Position = 2

548	=	5(10 ²)	+	4(10 ¹)	+	8(10 ⁰)
	=	5(100)	+	4(10)	+	8(1)
	=	500	+	40	+	8
	=	5	+	4	+	8
		MSD				LSD

We now reset the first column to the lowest possible value, 0, and increase the second column by 1.

```

010
011
012
013
...
019
    
```

We have again filled up the first column, so again reset it to 0, and increase the second column by one.

```

020
021
022
023
...
029
    
```

We repeat this process, until we hit 099. At this point the second column is filled, so we reset the first two columns to 00 and increase the third column by 1, giving us 100. This is how our familiar decimal or 10-digit number system works; number systems working on other bases work the same way.

Each column in a number has a property called weight. As an example, look at the decimal number, 548. The digits are 5, 4, 8, where 5 is the most significant digit since it is positioned to the far left and 8 is the least significant digit since it is positioned to the far right. The value of this number is a weighted sum of its digits, as shown in **Table 5.1**.

Table 5.2
Decimal and Binary Number Equivalents

163	=	128	+	0	+	32	+	0	+	0	+	0	+	2	+	1	decimal
	=	1(2 ⁸)	+	0(64)	+	1(32)	+	0(16)	+	0(8)	+	0(4)	+	1(2)	+	1(1)	
	=	1(2 ⁷)	+	0(2 ⁶)	+	1(2 ⁵)	+	0(2 ⁴)	+	0(2 ³)	+	0(2 ²)	+	1(2 ¹)	+	1(2 ⁰)	
10100011	=	1		0		1		0		0		0		1		1	binary
		MSB														LSB	
		└──┘				└──┘											
		Nibble				Nibble											
		└──┘															
		Byte = 8 digits															

The weight of a position is the system's base raised to a power. In this case, for a decimal system the base is 10, so each position is weighted by 10^P with the power determined by the position relative to the decimal. For example, digit 8, immediately to the left of the decimal, is at position 0; therefore, its weight factor is 10⁰ = 1. Similarly, digit 5 is 2 positions to the left of the decimal and has a weight factor 10² = 100. The value of the number is the sum of each digit times its weight.

BINARY

Binary is a *base-2* number system and therefore limited to two symbols: {0, 1}. The weight factors are now powers of 2, like 2⁰, 2¹ and 2². For example, the decimal number, 163 and its equivalent binary number, 10100011, are shown in **Table 5.2**.

The digits of a binary number are now *bits* (short for binary digit). The MSD is the *most significant bit (MSB)* and the LSD is the *least significant bit (LSB)*. Four bits make a *nibble* and two nibbles, or eight bits, make a *byte*. A word can consist of two or four or more bytes. These groupings are useful when converting to hexadecimal notation, which is explained later.

Counting in binary follows the same pattern illustrated for decimal. Consider the three digit binary number XXX. First fill up the right-hand column.

```

XXX
000
001
    
```

The column has been filled, and much quicker than with decimal, since there are only two values instead of 10. But just like decimal, now reset the right-hand column to 0, increase the next column by 1, and continue.

```

XXX
000
001
010 ←
011
    
```

Now the first two columns are full, so reset both back to 0 and increase the next column by 1 and continue:

```

XXX
000
001
010
011
100 ←
101
110
111 and so on.

```

Examination of the set of binary numbers from 0 to 15 shows some important characteristics:

Binary Value	Decimal Value
0000	0
0001	1
0010	2
0011	3
0100	4
0101	5
0110	6
0111	7
1000	8
1001	9
1010	10
1011	11
1100	12
1101	13
1110	14
1111	15

Notice each column starts with 0. The first (right-most) column alternates; every other value is a 0 and a 1. The second column alternates every two values, that is there are two 0's followed by two 1's. The third column has groups of four 0's and four 1's, and the fourth column has groups of eight 0's and eight 1's. Thus you can make up a binary counting table by simply following this pattern.

HEXADECIMAL

The hexadecimal, or hex, *base-16* number system is widely used in personal computers for its ease in conversion to and from binary numbers and the fact that it is somewhat more human-friendly than long strings of 1's and 0's. A base-16 number requires 16 symbols. Since our normal mathematical number, as set up in the decimal system, has only 10 digits (0 through 9), a set of additional new symbols is required. Hex uses both numbers and characters in its set of sixteen symbols: {0,1,2,3,4,5,6,7,8,9,A,B,C,D,E,F}. Here, the letters A to F have the decimal equivalents of 10 to 15 respectively: A=10, B=11, C=12, D=13, E=14 and F=15. Again, the weights are powers of the base, such as 16^0 , 16^1 and 16^2 .

The four-bit binary listing in the previ-

ous paragraph shows that the individual 16 hex digits can be represented by a four-bit binary number. Four binary digits are called a *nibble*.

Since a byte is equal to eight binary digits, two hex digits provide a byte — the equivalent of 8 binary digits. Conversion from binary to hex is therefore simplified. Take a binary number, divide it into groups of four binary digits starting from the right, and convert each of the four binary digits to an individual value.

Conversion from hex to binary is equally convenient; replace each hex digit with its four-bit binary equivalent. As an example, the decimal number 163 is shown in Table 5.2 as binary 10100011. Divide the binary number in groups of four, so 1010 is equivalent to decimal 10 or "A" hex, and 0011 is equivalent to decimal 3, thus decimal number 163 is equivalent to hex A3.

BINARY CODED DECIMAL (BCD)

Scientists have experimented with many devices out of a desire for fast computations. Initially, analog computers were developed and used for many applications, especially military applications. It was not unusual to see analog computers aboard US navy ships as recently as the mid-1960s, where they were used to direct naval gunfire.

Analog computers have a very large disadvantage; they could not be readily reprogrammed. They did have a very great advantage; their output was more human readable than digital computers. Very few humans can get used to either binary or hexadecimal read-outs!

The binary number system representation is the most appropriate form for fast internal computations since there is a direct mathematical relationship for every bit in the number. To interface with a user — who usually wants to see I/O in terms of decimal numbers — other codes are more useful. The *Binary Coded Decimal (BCD)* system is the simplest and most widely used form for inputs and outputs of user-oriented digital systems.

In the Binary Coded Decimal (BCD) system, each decimal digit is expressed as a corresponding 4-bit binary number. In other words, the decimal digits 0 to 9 are

encoded as the bit strings 0000 to 1001. To make the number easier to read, a space is left between each 4-bit group. For example, the decimal number 163 is equivalent to the BCD number 0001 0110 0011, as shown in **Table 5.3**.

A generic code could use any n-bit string to represent a piece of information. BCD uses 4 bits because that is the minimum needed to represent a 9. All four bits are always written; even a decimal 0 is written as 0000 in BCD.

The important difference between BCD and the previous number systems is that, starting with decimal 10, BCD loses the standard mathematical relationship of a weighted sum. BCD is simply a cut-off hexadecimal. Instead of using the 4-bit code strings 1010 to 1111 for decimal 10 to 15, BCD uses 0001 0000 to 0001 0101. There are other n-bit decimal codes in use and, even for specifically 4 bits, there are millions of combinations to represent the decimal digits 0-9. BCD is the simplest way to convert between decimal and a binary code; thus it is the ideal form for I/O interfacing. The binary number system, since it maintains the mathematical relationship between bits, is the ideal form for the computer's internal computations.

CONVERSION TECHNIQUES

An easy way to convert a number from decimal to another number system is to do repeated division, recording the remainders in a tower just to the right. The converted number, then, is the remainders, reading up the tower. This technique is illustrated in **Table 5.4** for hexadecimal and binary conversions of the decimal number 163.

For example, to convert decimal 163 to hex, repeated divisions by 16 are performed. The first division gives $163/16 = 10$ remainder 3. The remainder 3 is written in a column to the right. The second division gives $10/16 = 0$ remainder 10. Since 10 decimal = A hex, A is written in the remainder column to the right. This division gave a divisor of 0 so the process is complete. Reading up the remainders column, the result is A3. The most common mistake in this technique is to forget that the Most Significant Digit ends up at the bottom.

Another technique that should be

Table 5.3
Binary Coded Decimal Number Conversion

	0 0 0 1	0 1 1 0	0 0 1 1	BCD
	$\underbrace{\hspace{1.5cm}}$	$\underbrace{\hspace{1.5cm}}$	$\underbrace{\hspace{1.5cm}}$	
=	$1(2^0)$	$1(2^2) + 1(2^1)$	$1(2^1) + 1(2^0)$	
=	(1)	(4 + 2)	(2 + 1)	
163 =	1	6	3	decimal

Table 5.4
Number System Conversions

Hex	Remainder	Binary	Remainder
16	$\begin{array}{r} 163 \\ 10 \\ 0 \end{array}$	3	LSB
		A	MSB
A3 hex		1010 0011 binary	

briefly mentioned can be even easier: get a calculator with a binary and/or hex mode option. One warning for this technique: this chapter doesn't discuss negative binary numbers. If your calculator does not give you the answer you expected, it may have interpreted the number as negative. This would happen when the number's binary form has a 1 in its MSB, such as the highest (leftmost) bit for the binary mode's default size. To avoid learning about negative binary numbers, always use a leading 0 when you enter a number in binary or hex into your calculator.

Physical Representation of Binary States

STATE LEVELS

Most digital systems use the binary number system because many simple physical systems are most easily described by two state levels (0 and 1). For example, the two states may represent "on" and "off," a punched hole or the absence of a hole in paper tape or a card, or a "mark" and "space" in a communications transmission. In electronic systems, state levels are physically represented by voltages. A typical choice is

state 0 = 0 V
state 1 = 5 V

Since it is unrealistic to obtain these exact voltage values, a more practical choice is a range of values, such as

state 0 = 0.0 to 0.4 V
state 1 = 2.4 to 5.0 V

Fig 5.53 illustrates this representation of states by voltage levels. The undefined region between the two binary states is also known as the *transition region* or *noise margin*.

Transition Time

The gap in **Fig 5.53**, between binary 0 and binary 1, shows that a change in state does not occur instantly. There is a *transition time* between states. This transition time is a result of the time it takes to charge or discharge the stray capacitance in wires and other components because voltage cannot change instantaneously across a capacitor. (Stray inductance in the wires also has an effect because the current through an inductor can't change instantaneously.) The transition from a 0 to a 1 state is called the *rise time*, and is usually specified as the time for the pulse to rise

from 10% of its final value to 90% of its final value. Similarly, the transition from a 1 to a 0 state is called the *fall time*, with a similar 10% to 90% definition. Note that these times need not be the same. **Fig 5.54A** shows an ideal signal, or *pulse*, with

Fig 5.53 — Representation of binary states 1 and 0 by a selected range of voltage levels.

Fig 5.54 — (A) An ideal digital pulse and (B) a typical actual pulse, showing the gradual transition between states.

zero-time switching. **Fig 5.54B** shows a typical pulse, as it changes between states in a smooth curve.

Rise and fall times vary with the logic family used and the location in a circuit. Typical values of transition time are in the microsecond to nanosecond range. In a circuit, distributed inductances and capacitances in wires or PC-board traces may cause rise and fall times to increase as the pulse moves away from the source.

Propagation Delay

Rise and fall times only describe a relationship within a pulse. For a circuit, a pulse input into the circuit must propagate through the circuit; in other words it must pass through each component in the circuit until eventually it arrives at the circuit output. The time delay between providing an input to a circuit and seeing a response at the output is the *propagation delay* and is illustrated by **Fig 5.55**.

For modern switching logic, typical propagation delay values are in the 1 to 15 nanosecond range. (It is useful to remem-

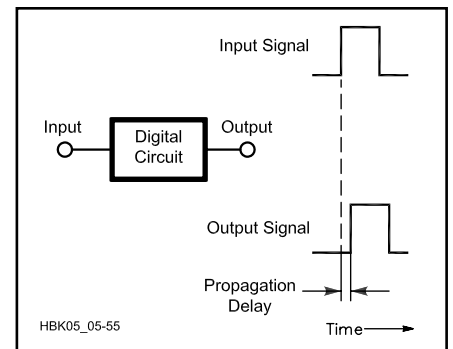

Fig 5.55 — Propagation delay in a digital circuit.

ber that the propagation delay along a wire or printed-circuit-board trace is about 1.0 to 1.5 ns per inch.) Propagation delay is the result of cumulative transition times as well as transistor switching delays, reactive element charging times and the time for signals to travel through wires. In complex circuits, different propagation delays through different paths can cause prob-

lems when pulses must arrive somewhere at exactly the same time.

The effect of these delays on digital devices can be seen by looking at the speed of the digital pulses. Most digital devices and all PCs use *clock pulses*, which are one of the more prominently advertised feature of new PCs. A PC having a 2-GHz clock rate translates into each clock pulse, if it is a

symmetrical square wave, being at a logic 1 and a logic 0 state for 2.5 ns as a 1 and 2.5 ns as a zero. Therefore if two pulses are supposed to arrive at a logic circuit at the same time, or very close to the same time, the path length for the two signals cannot be any different than two to three inches. This can be a very significant design problem for high-speed logic designs.

Combinational Logic

Having defined a way to use voltage levels to physically represent digital numbers, we can apply digital signal theory to design useful circuits. Digital circuits combine binary inputs to produce a desired binary output or combination of outputs. This simple combination of 0s and 1s can become very powerful, implementing everything from simple switches to powerful computers.

A digital circuit falls into one of two types: combinational logic or sequential logic. In a *combinational logic* circuit, the output depends only on the *present inputs*. (If we ignore propagation delay.) In contrast, in a *sequential logic* circuit, the output depends on the present inputs, the *previous sequence of inputs* and often a clock signal. The next section discusses combinational logic circuits. Later, we will build sequential logic circuits from the basics established here.

BOOLEAN ALGEBRA AND THE BASIC LOGICAL OPERATORS

Combinational circuits are composed of logic gates, which perform binary operations. Logic gates manipulate binary numbers, so you need an understanding of the algebra of binary numbers to understand how logic gates operate. *Boolean algebra* is the mathematical system to describe and design binary digital circuits. It is named after George Boole, the mathematician who developed the system. Standard algebra has a set of basic operations: addition, subtraction, multiplication and division. Similarly, Boolean algebra has a set of basic operations, called *logical operations*: NOT, AND and OR.

The function of these operators can be described by either a Boolean equation or a truth table. A Boolean *equation* describes an operator's function by representing the inputs and the operations performed on them. An equation is of the form "B = A," while an *expression* is of the form "A." In an assignment equation, the inputs and operations appear on the right and the result, or output, is assigned to the variable on the left.

A *truth table* describes an operator's function by listing all possible inputs and the corresponding outputs. Truth tables are sometimes written with Ts and Fs (for true and false) or with their respective equivalents, 1s and 0s. In company databooks (catalogs of logic devices a

company manufactures), truth tables are usually written with Hs and Ls (for high and low). In the figures, 1 will mean high and 0 will mean low. This representation is called *positive logic*. The meaning of different logic types and why they are useful is discussed in a later section.

Each Boolean operator also has two circuit symbols associated with it. The traditional symbol — used by ARRL and other US publications — appears on top in each of the figures; for example, the triangle and bubble for the NOT function in Fig 5.58. In the traditional symbols, a small circle, or *bubble*, always represents "NOT." (This *bubble* is called a state indicator.) Appearing just below the traditional symbol is the newer ANSI/IEEE Standard symbol. This symbol is always a square box with notations inside it. In these newer symbols, a small flag represents "NOT." The new notation is an attempt to replace the detailed logic drawing of a complex function with a simpler block symbol.

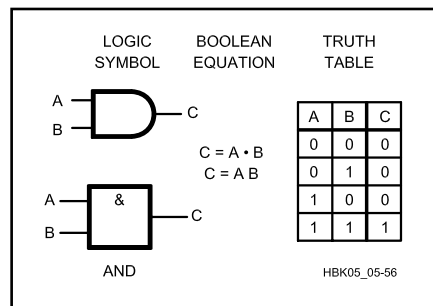

Fig 5.56 — Two-input AND gate.

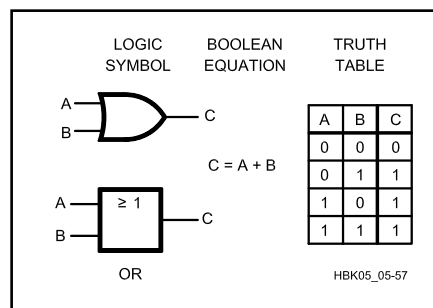

Fig 5.57 — Two-input OR gate.

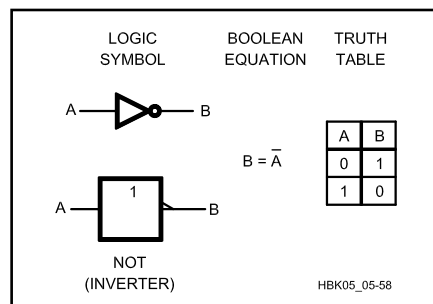

Fig 5.58 — Inverter.

COMMON GATES

Figs 5.56, 5.57 and 5.58 show the truth tables, Boolean algebra equations and circuit symbols for the three basic Boolean operations: AND, OR and NOT, respectively. All combinational logic functions, no matter how complex, can be described in terms of these three operators. Each truth table can be converted into words. The truth table for the two-input AND gate can be expressed as "the output C is a 1 only when the inputs are both 1's." This can be seen by examining the output column "C" — it remains at a 0 and becomes a 1 only when the input column "A" and the input column "B" are both 1's — the last line of the table.

The NOT operation is also called *inversion*, *negation* or *complement*. The circuit that implements this function is called an *inverter* or *inverting buffer*. The most common notation for NOT is a bar over a variable or expression. For example, NOT A is denoted \bar{A} . This is read as either "Not A" or as "A bar." A less common notation

is to denote Not A by A' , which is read as "A prime."

While the inverting buffer and the noninverting buffer covered later have only one input and output, many combinational logic elements can have multiple inputs. When a combinational logic element has two or more inputs and one output, it is called a *gate*. (The term "gate" has many different but specific technical uses. For a clarification of the many definitions of gate, see the section on Synchronicity and Control Signals, later in this chapter.) For simplicity, the figures and truth tables for multiple-input elements will show the operations for only two inputs, the minimum number.

The output of an AND function is 1 only if *all* of the inputs are 1. Therefore, if *any* of the inputs are 0, then the output is 0. The notation for an AND is either a dot (\bullet) between the inputs, as in $C = A \bullet B$, or nothing between the inputs, as in $C = AB$. Read these equations as "C equals A AND B."

The OR gate detects if one or more inputs are 1. In other words, if *any* of the inputs are 1, then the output of the OR gate is 1. Since this includes the case where more than one input may be 1, the OR operation is also known as an *INCLUSIVE OR*. The OR operation detects if *at least one* input is 1. Only if all the inputs are 0, then the output is 0. The notation for an OR is a plus sign (+) between the inputs, as in $C = A + B$. Read this equation as "C equals A OR B."

Additional Gates

More complex logical functions are derived from combinations of the basic logical operators. These operations — NAND, NOR, XOR and the noninverter or buffer — are illustrated in **Figs 5.59** through **5.62**, respectively. As before, each is described by a truth table, Boolean algebra equation and circuit symbols. Also as before, except for the noninverter, each could have more inputs than the two illustrated.

The NAND gate (short for NOT AND) is equivalent to an AND gate followed by a NOT gate. Thus, its output is the complement of the AND output: The output is a 0 only if all the inputs are 1. If any of the inputs is 0, then the output is a 1.

The NOR gate (short for NOT OR) is equivalent to an OR gate followed by a NOT gate. Thus, its output is the complement of the OR output: If any of the inputs are 1, then the output is a 0. Only if all the inputs are 0, then the output is a 1.

The operations so far enable a designer to determine two general cases: (1) if *all* inputs have a desired state or (2) if *at least one* input has a desired state. The XOR

and XNOR gates enable a designer to determine if *one and only one* input of a desired state is present.

The XOR gate (read as *EXCLUSIVE OR*) has an output of 1 if one and only one of the inputs is a 1 state. The output is 0 otherwise. The symbol for XOR is \oplus . This is easy to remember if you think of the "+" OR symbol enclosed in an "O" for *only one*.

The XOR gate is also known as a "half adder," because in binary arithmetic it does everything but the "carry" operation. The following examples show the possible binary additions for a two-input XOR.

0	0	1	1
<u>0</u>	<u>1</u>	<u>0</u>	<u>1</u>
0	1	1	0

The XNOR gate (read as *EXCLUSIVE NOR*) is the complement of the XOR gate. The output is 0 if one and only one of the inputs is a 1. The output is 1 either if all inputs are 0 or more than one input is 1.

Buffers

A *noninverter*, also known as a *buffer*, *amplifier* or *driver*, at first glance does not seem to do anything. It simply receives an input and produces the same output. In reality, it is changing other properties of the signal in a useful fashion, such as amplifying the current level. The practical uses of a noninverter include (A) providing sufficient current to drive a number of gates, (B) interfacing between two logic families, (C) obtaining a desired pulse rise time and (D) providing a slight delay to make pulses arrive at the proper time.

Tri-State Gates

Under normal circumstances, a logic element can drive or feed several other logic elements. A typical AND gate might be able to drive or feed 10 other gates. This is known as *fan-out*. However, only one gate output can be connected to a single wire. If you have two possible driving sources to feed one particular wire, some logic network that probably includes a number OR gates must be used. The symbol and truth table for a tri-state gate is in **Fig 5.63**.

In each PC data is routed internally on a set of wires called *buses*. A bus consists of a set of wires, and many input logic elements are connected to *listen* on the bus. However the data on the bus can come from many circuits or drivers. To eliminate the need for the network of OR gates to drive each bus wire, as set of gates known as *tri-state* gates are used.

A tri-state gate can be any of the common gates previously described, but with one additional control lead. When this lead is enabled (it can be designed to allow

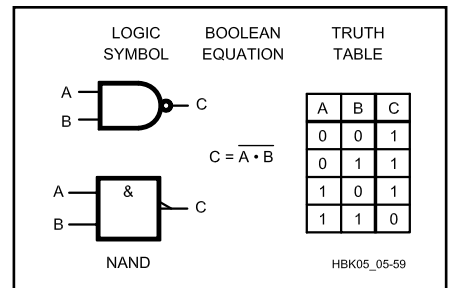

Fig 5.59 — Two-input NAND gate.

either a 0 or a 1 to enable it) the gate operates normally, according to the truth table for that type of gate. However, when the gate is not enabled, the output goes to a high impedance, and so far as the output wire is concerned, the gate does not exist.

Each device that has to send data down a bus wire is connected to the bus wire through a tri-state gate. However, as long as only one device, through its tri-state gate, is enabled, it is as though all the other connected tri-state gates do not exist.

BOOLEAN THEOREMS

The analysis of a circuit starts with a

logic diagram and then derives a circuit description. In digital circuits, this description is in the form of a truth table or logical equation. The *synthesis*, or design, of a circuit goes in the reverse: starting with an informal description, determining an equation or truth table and then expanding the truth table to components that will implement the desired response. In both of these processes, we need to either simplify or expand a complex logical equation.

To manipulate an equation, we use mathematical *theorems*. Theorems are statements that have been proven to be true. The theorems of Boolean algebra are very similar to those of standard algebra, such as commutivity and associativity. Proofs of the Boolean algebra theorems can be found in an introductory digital design textbook.

BASIC THEOREMS

Table 5.5 lists the theorems for a single variable and **Table 5.6** lists the theorems for two or more variables. These tables illustrate the *principle of duality* exhibited by the Boolean theorems: Each theo-

rem has a dual in which, after swapping all ANDs with ORs and all 1s with 0s, the statement is still true.

The tables also illustrate the *precedence* of the Boolean operations: the order in which operations are performed when not specified by parenthesis. From highest to lowest, the precedence is NOT, AND then OR. For example, the distributive law includes the expression " $A + B \cdot C$." This is equivalent to " $A + (B \cdot C)$." The parenthesis around $(B \cdot C)$ can be left out since an AND operation has higher priority than an OR operation. Precedence for Boolean algebra is similar to the convention of standard algebra: raising to a power, then multiplication, then addition.

DeMorgan's Theorem

One of the most useful theorems in Boolean algebra is DeMorgan's Theorem: $\overline{A \cdot B} = \bar{A} + \bar{B}$ and its dual $\overline{A + B} = \bar{A} \cdot \bar{B}$. The truth table in **Table 5.7** proves these statements. DeMorgan's Theorem provides a way to simplify the complement of a large expression. It also enables a designer to interchange a number of equivalent gates, as shown by **Fig 5.64**.

The equivalent gates show that the duality principle works with symbols the same as it does for Boolean equations: just swap ANDs with ORs and switch the bubbles. For example, the NAND gate — an AND gate followed by an inverter bubble — becomes an OR gate preceded by two inverter bubbles. DeMorgan's Theorem is important because it means any logical function can be implemented using either inverters and AND gates or inverters and OR gates. Also, the ability to change placement of the bubbles using DeMorgan's Theorem is useful in dealing with mixed logic, to be discussed next.

POSITIVE AND NEGATIVE LOGIC

The truth tables shown in the figures in this chapter are drawn for positive logic. In *positive logic*, or *high true*, a higher voltage means true (logic 1) while a lower

Fig 5.64 — Equivalent gates from DeMorgan's Theorem: Each gate in column A is equivalent to the opposite gate in column B. The Boolean equations in column C formally state the equivalences.

voltage means false (logic 0). This is also referred to as *active high*: a signal performs a named action or denotes a condition when it is “high” or 1. In *negative logic*, or *low true*, a lower voltage means true (1) and a higher voltage means false (0). An *active low* signal performs an action or denotes a condition when it is “low” or 0.

In both logic types, true = 1 and false = 0; but whether true means high or low differs. Company databooks are drawn for general truth tables: an “H” for high and

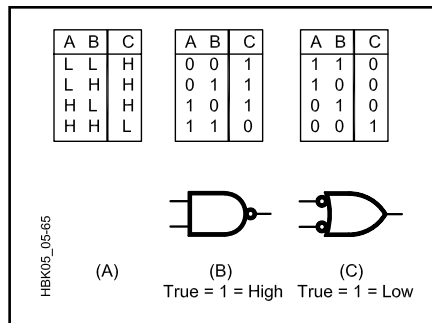

Fig 5.65 — (A) A general truth table, (B) a truth table and NAND symbol for positive logic and (C) a truth table and NOR symbol for negative logic.

an “L” for low. (Some tables also have an “X” for a “don’t care” state.) The function of the table can differ depending on whether it is interpreted for positive logic or negative logic.

*Device data sheets often show positive logic convention, or same is assumed. However, a signal into an IC is represented with a bar above it, indicating that the “enable” on that wire is active low — it does **not** mean negative logic (0 volts = a logical 1) is used! Similarly a bubble on the input of a logic element also usually means active low. These can be sources of confusion.*

Fig 5.65 shows how a general truth table differs when interpreted for different logic types. The same truth table gives two equivalent gates: positive logic gives the

function of a NAND gate while negative logic gives the function of a NOR gate.

Note that these gates correspond to the equivalent gates from DeMorgan’s Theorem. A bubble on an input or output terminal indicates an active low device. The absence of bubbles indicates an active high device.

Like the bubbles, signal names can be used to indicate logic states. These names can aid the understanding of a circuit by indicating control of an action (GO, /ENABLE) or detection of a condition (READY, /ERROR). The action or condition occurs when the signal is in its active state. When a signal is in its active state, it is called *asserted*; a signal not in its active state is called *negated* or *deasserted*. A prefix can easily indicate a signal’s active state: active low signals are preceded by a “/,” like /READY, while active high signals have no prefix. Standard practice is that the signal name and input pin match (have the same active level). For example, an input with a bubble (active low) may be called /READY while an input with no bubble (active high) is called READY. Output signal names should always match the device output pin.

In this chapter, positive logic is used unless indicated otherwise. Although using mixed logic can be confusing, it does have some advantages. Mixed logic combined with DeMorgan’s Theorem can promote more effective use of available gates. Also, well-chosen signal names and placement of bubbles can promote more understandable logic diagrams.

Sequential Logic

The previous section discussed combinational logic, whose outputs depend only on the present inputs. In contrast, in *sequential logic* circuits, the new output depends not only on the present inputs but also on the present outputs. The present outputs depended on the previous inputs and outputs and those earlier outputs depended on even earlier inputs and outputs and so on. Thus, the present outputs depend on the previous *sequence of inputs* and the system has *memory*. Having the outputs become part of the new inputs is known as *feedback*.

This section first introduces a number of terms necessary to understand sequential logic: types of synchronicity, types of control signals and ways to illustrate circuit function. Numerous sequential logic circuits are then introduced. These circuits provide an overview of the basic sequential circuits that are commercially avail-

able. Depending on your approach to learning, you may choose to either (1) read the material in the order presented, definitions then examples, or (2) start with the example circuits, which begin with the flip-flop, referring back to the definitions as needed.

SYNCHRONICITY AND CONTROL SIGNALS

When a combinational circuit is given a set of inputs, the outputs take on the expected values after a propagation delay during which the inputs travel through the circuit to the output. In a sequential circuit, however, the travel through the circuit is more complicated. After application of the first inputs and one propagation delay, the outputs take on the resulting state; but then the outputs start trickling back through and, after a second propagation delay, new outputs appear.

The same happens after a third propagation delay. With propagation delays in the nanosecond range, this cycle around the circuit is rapidly and continually generating new outputs. A user needs to know when the outputs are valid.

There are two types of sequential circuits: synchronous circuits and asynchronous circuits, which are analyzed differently for valid outputs. In *asynchronous* operation, the outputs respond to the inputs immediately after the propagation delay. To work properly, this type of circuit must eventually reach a *stable* state: the inputs and the fed back outputs result in the new outputs staying the same. When the nonfeedback inputs are changed, the feedback cycle needs to eventually reach a new stable state. Generally, the output of this type of logic is not valid until the last input has changed, and enough time has elapsed for all propagation delays to have occurred.

In *synchronous* operation, the outputs change state only at specific times. These times are determined by the presence of a particular input signal: a clock, toggle, latch or enable. Synchronicity is important because it ensures proper timing: all the inputs are present where needed when the control signal causes a change of state.

Some authors vary the meanings slightly for the different control signals. The following is a brief illustration of common uses, as well as showing uses for noun, verb and adjective. *Enabling* a circuit generally means the control signal goes to its asserted level, allowing the circuit to change state. *Latch* implies memory: (noun) a circuit that stores a bit of information or (verb) to hold at the same output state. *Gate* has many meanings, some unrelated to synchronous control: (A) a signal used to trigger the passage of other signals through a circuit (for example, “A gate circuit passes a signal only when a gating pulse is present.”), (B) any logic circuit with two or more inputs and one output (used earlier in this chapter) or (C) one of the electrodes of an FET (as described in the analog portion of this chapter). To *toggle* means a signal changes state, from 1 to 0 or vice versa. A *clock* signal is one that toggles at a regular rate.

Clock control is the most common method, so it has some additional terms, illustrated by **Fig 5.66**. The *clock period* is the time between successive transitions in the same direction; the *clock frequency* is the reciprocal of the period. A *pulse* or *clock tick* is the first edge in a clock period, or sometimes the period itself or the first half of the period. The *duty cycle* is the percentage of time that the clock signal is at its asserted level. A common application of the use of clock pulses is to limit the input to a logic circuit such that the circuit is only enabled on one clock phase; that is the inputs occur before the clock changes to a logic 1. The outputs are sampled only after this point; perhaps when the clock next changes back to a logic 0.

The reaction of a synchronous circuit to its control signal is *static* or *dynamic*. Static, *gated* or *level-triggered* control allows the circuit to change state whenever the control signal is at its active or asserted level. Dynamic, or *edge-triggered*, control allows the circuit to change state only when the control signal *changes* from unasserted to asserted. By convention, a control signal is active high if state changes occur when the signal is high or at the rising edge and active low in the opposite case. Thus, for positive logic, the convention is enable = 1 or enable goes from 0 to 1. This transition from 0 to 1 is called

Fig 5.66 — Clock signal terms. The duty cycle would be t_H / t_{PERIOD} for an active high signal and t_L / t_{PERIOD} for an active low signal.

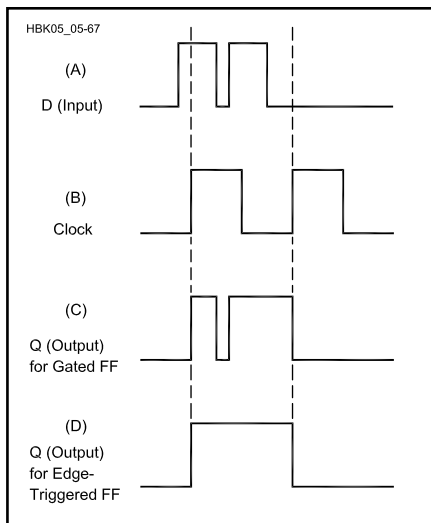

Fig 5.67 — Level-triggered vs edge-triggered for a D flip-flop: (A) input D, (B) clock input, (C) output Q for level-triggered: circuit responds whenever clock is 1. (D) output Q for edge-triggered: circuit responds only at rising edge of clock. Notice that the short negative pulse on the input D is not reproduced by the edge-triggered flip-flop.

positive edge-triggered and is indicated by a small triangle inside the circuit box. A circuit responding to the opposite transition, from 1 to 0, is called *negative edge-triggered*, indicated by a bubble with the triangle. Whether a circuit is level-triggered or edge-triggered can affect its output, as shown by **Fig 5.67**. Input D includes a very brief pulse, called a *glitch*, which may be caused by noise. The differing results at the output illustrate how noise can cause errors.

CIRCUIT DESIGN — FLIP-FLOPS

Flip-flops are the basic building blocks of sequential circuits. A *flip-flop* is a device with two stable states: the *set* state (1) or the *reset* state (0). (The reset state is also called the *cleared* state.) The flip-flop can be placed in one or the other of the two

states by applying the appropriate input. (Since a common use of flip-flops is to store one bit of information, some use the term *latch* interchangeably with flip-flop. A set of latches, or flip-flops holding an n-bit number is called a register.) While gates have special symbols, the schematic symbol for most components is a rectangular box with the circuit name or abbreviation, the signal names and assertion bubbles. For flip-flops, the circuit name is usually omitted since the signal names are enough to indicate a flip-flop and its type. The four basic types of flip-flops are the S-R, D, T and J-K. The most common flip-flops available to Amateurs today are the J-K and D- flip-flops; the others can be synthesized by utilizing these two varieties.

Triggering a Flip-Flop

Although the S-R (Set-reset) flip flop is no longer generally available or used, it does provide insight in basic flip-flop operations and triggering. In **Fig 5.68** the symbol for an S-R flip flop and its truth table are accompanied by a logic implementation, using NAND gates. As the truth table shows, this basic implementation requires a positive or logic 1 input on the set input to put the flip-flop in the Q or set state. Remove the input, and the flip flop stays in the Q state, which is what is expected of a flip-flop. Not until the S input receives a logic 1 input does the flip-

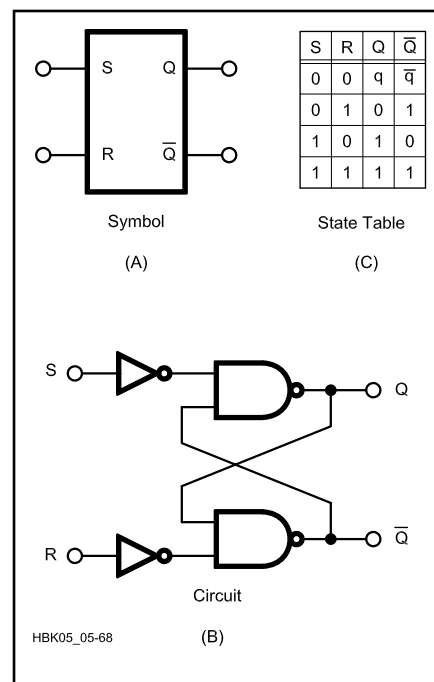

Fig 5.68 — Unlocked S-R Flip-Flop. (A) schematic symbol. (B) circuit diagram. (C) state table or truth table.

flop change state and go to the reset or $Q=0$ state.

Note that the input can be a short pulse or a level; as long as it is there for some minimum duration, the flip-flop will respond. By contrast the clocked S-R flip-flop in Fig 5.69 requires both a positive level to be present at either the S or R inputs and a positive clock pulse; the clock pulse is ANDed with the S or R input to trigger the flip-flop. In this case the flip-flop shown is implemented with a set of NOR gates.

A final triggering method is edge triggering. Here, instead of using the clock pulse as shown in the timing diagram of Fig 5.69, just the edge of the clock pulse is used. This will be discussed more in the section on J-K flip-flops. The edge-triggered flip-flop helps solve a problem with noise. Edge-triggering minimizes the time during which a circuit responds to its inputs: the chance of a glitch occurring during the nanosecond transition of a clock pulse is remote. A side benefit of edge-triggering is that only one new output is produced per clock period. Edge-triggering is denoted by a small rising-edge or falling-edge symbol in the clock column of the flip-flop's truth table. It can also appear, instead of the clock triangle, inside the schematic symbol.

Although this description uses positive

levels and positive clock pulses, other implementations of these flip-flops can be made with negative levels, negative clock pulses or combinations of positive and negative levels and pulses. This will again be illustrated in the section on J-K flip-flops.

Master/Slave Flip-Flop

One major problem with the simple flip-flop shown up to now is the question of when is there a valid output. Suppose a flip-flop receives input that causes it to change state; at the same time the output of this flip-flop is being sampled to control some other logic element. There is a real risk here that the output will be sampled just as it is changing and thus the validity of the output is questionable.

A solution to this problem is a circuit that samples and stores its inputs before changing its outputs. Such a circuit is built by placing two flip-flops in series; both flip-flops are triggered by a common clock but an inverter on the second flip-flop's clock input causes it to be asserted only when the first flip-flop is not asserted. The action for a given clock pulse is as follows: The first, or master, flip-flop can change only when the clock is high, sampling and storing the inputs. The second, or slave, flip-flop gets its input from the master and changes when the clock is low.

Hence, when the clock is 1, the input is sampled; then when the clock becomes 0, the output is generated. Note that a bubble may appear on the schematic symbol's clock input, reminding us that the output appears when the clock is asserted low. This is conventional for TTL-style J-K flip-flops, but it can be different for CMOS devices.

The master/slave method isolates output changes from input changes, eliminating the problem of series-fed circuits. It also ensures only one new output per clock period, since the slave flip-flop responds to only the single sampled input. A problem can still occur, however, because the master flip-flop can change more than once while it is asserted; thus, there is the potential for the master to sample at the wrong time. There is also the potential that either flip-flop can be affected by noise.

A master-slave, S-R clocked input flip-flop synthesized from NAND gates, Fig 5.69B, is accompanied by its logic symbol, Fig 5.69A. From the logic symbols you can tell that the output changes on a negative-going clock edge.

G3A and G3B form the master set-reset flip-flop, and G4A and G4B the slave flip flop. The input signals S and R are controlled by the positive going edge of the clock through gates G1A and G1B. G2A and G2B control the inputs into the slave flip-flop; these inputs are the outputs of the master flip-flop. Note G5 inverts the clock; thus while the positive-going edge places new data into the master flip-flop, the other edge of the clock transfers the output of the master into the slave on the following negative clock edge.

Table 5.8 provides a summary of the two basic flip-flops currently readily available, the D flip-flop and the J-K flip-flop. The S-R (Set-Reset) used for illustration previously and the T or toggle flip-flop can be synthesized by using the J-K or D flip-flops. The T flip-flop is primarily used to count. With proper input, it changes state for each input pulse – alternating between $Q = 1$ and $Q = 0$ each time a clock pulse appears.

D Flip-Flop

In a D (data) flip-flop, the *data* input is transferred to the outputs when the flip-flop is enabled. The logic level at input D is transferred to Q when the clock is positive; the Q output retains this logic level until the next positive clock pulse (see Fig 5.70). The truth table summarizes this operation. If $D = 1$ the next clock pulse makes $Q = 1$. If $D = 0$, the next clock pulse makes $Q = 0$. A D flip-flop is useful to store one bit of information. A collection of D flip-flops forms a register.

t: If J = K, the clock toggles the flip-flop

J-K Flip-Flop

The most readily available flip-flop today is the J-K flip-flop, shown schematically in Fig 5.71A. It has five inputs, and the unit shown uses both positive active (the J and K inputs) and negative active inputs (notes the “bubbles” on the C or clock, PR or preset and CL or clear inputs). With these inputs almost any other type of flip-flop may be synthesized.

The truth table of Fig 5.71B provides an explanation. Lines 1 and 2 show the preset and clear inputs and their use. These are active low, meaning that when one (and only one) of them goes to a logic 0, the flip-flop responds, just as if it was a S-R or set-reset flip-flop. Make PR a logic 0, and leave CL a logic 1, and the flip-flop goes into the Q = 1 state (line 1). Do the reverse (line 2) – PR = 1, CL = 0 and the flip-flop goes into a Q' = 1 state. When these two inputs are used, J, K and C are marked as X or don't care, because the PR and CL inputs override them. Line 3 corresponds to the unused state of the R-S flip-flop.

Lines 4 and 5 show that if J = 1 and K = 0, the next clock transition from high to low sets Q = 1 and Q' = 0. Alternately, J = 0 and K = 1 sets Q = 0 and Q' = 1. Therefore if a signal is applied to J, and the inverted signal sent to K, the J-K flip-flop will mimic a D flip-flop, echoing its input.

The most unique feature of the J-K flip-flop is line 7. If both J and K are connected to a 1, then each clock 1 to 0 transition will flip or toggle the flop-flop. Thus the J-K flip-flop can be used as a T flip-flop, as in a ripple counter (see the following COUNTERS section.)

Summary

Only the D and J-K flip-flops are generally available as commercial integrated circuit chips. Since memory and temporary storage are so often desirable, the D flip-flop is manufactured as the simplest way to provide memory. When more functionality is needed, the J-K flip-flop is available. The J-K flip-flop (using its PR and CL inputs) can substitute for an S-R flip-flop and a T flip-flop can be created from either the D or J-K flip-flop.

GROUPS OF FLIP-FLOPS

Counters

Groups of flip-flops can be combined to make counters. Intuitively, a counter is a circuit that starts at state 0 and sequences up through states 1, 2, 3, to m, where m is the maximum number of states available. From state m, the next state will return the counter to 0. This describes the most common counter: the *n-bit binary counter*, with n outputs corresponding to $2^n = m$ states.

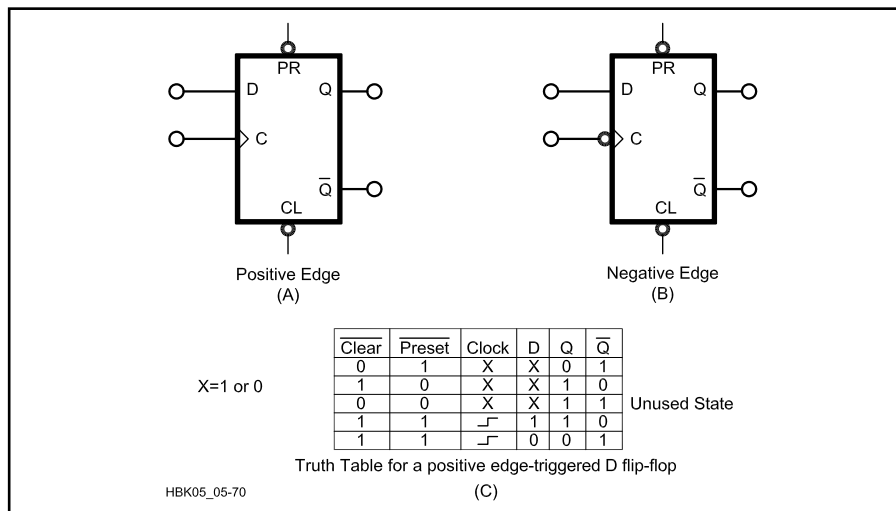

Fig 5.70 — (A & B) The D flip-flop. (C) A truth table for the positive edge-triggered D flip-flop.

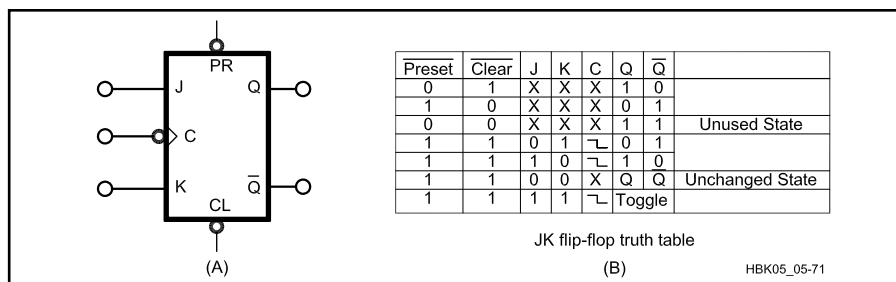

Fig 5.71 — (A) JK flip-flop. (B) JK flip-flop truth table.

Such a counter can be made from n flip-flops, as shown in Fig 5.72. This figure shows implementations for each of the types of synchronicity. Both circuits pass the data count from stage to stage. In the asynchronous counter, Fig 5.72A, the clock is also passed from stage to stage and the circuit is called *ripple* or *ripple-carry*.

The J-K flip-flop truth table shows that with PR (Preset) and CL (Clear) both positive, and therefore not effecting the operation, the flip-flop will toggle if J and K are tied to a logic 1. In Fig 5.72A the first stage has its J and K inputs permanently tied to a logic 1, and each succeeding stage has its J and K inputs tied to Q of the preceding stage. This provides a direct ripple counter implementation.

Design of a synchronous counter is bit more involved. It consists of determining, for a particular count, the conditions that will make the next stage change at the same clock edge when all the stages are changing.

To illustrate this, notice the binary counting table of Fig 5.72. The right-hand column represents the lowest stage of the counter. It alternates between 1 and 0 on every line. Thus, for the first stage the J and K inputs are tied to logic 1. This provides the alternation required by the counting table.

The middle column or second stage of the counter changes state right after the lower stage is a one (lines C, E and G). Thus if the Q output of the lowest stage is tied to the J and K inputs of the second stage, each time the output of the lowest stage is a 1 the second stage toggles on the next clock pulse.

Finally, the third column (third stage) toggles when both the first stage and the second stage are both 1s (line D). Thus by ANDing the Q outputs of the first two stages, and then connecting them to the J and K inputs of the third stage, the third stage will toggle whenever the first two stages are 1s.

There are formal methods for determining the wiring of synchronous counters. The illustration above is one manual method that may be used to design a counter of this type. The advantage of the synchronous counter is that at any instant, except during clock pulse transition, all counter stage outputs *are correct* and delay due to propagation through the flip flops is not a problem.

In the synchronous counter, Fig 5.72B, each stage is controlled by a common clock signal.

There are numerous variations on this first example of a counter. Most counters have the ability to *clear* the count to 0. Some counters can also *preset* to a desired

Fig 5.72 — Three-bit binary counter using J-K flip-flops: (A) asynchronous or ripple, (B) synchronous.

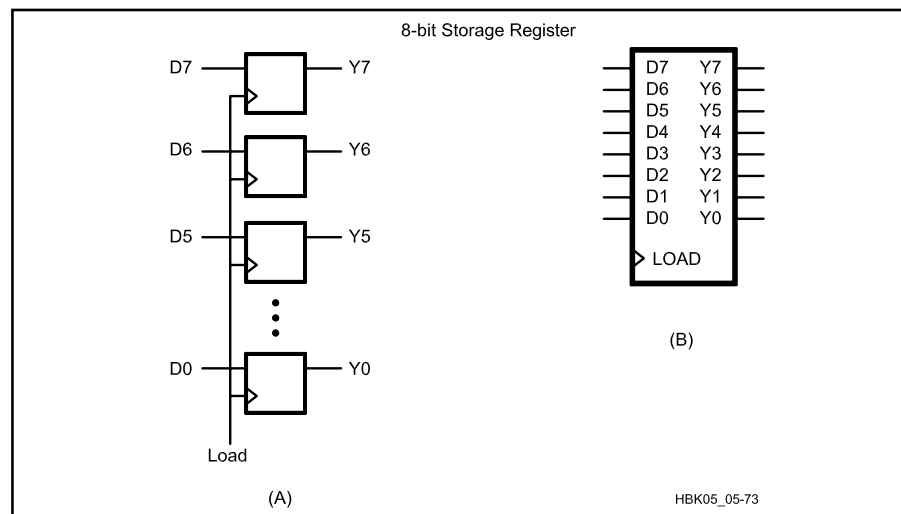

Fig 5.73 — An eight-bit storage register: (A) circuit and (B) schematic symbol.

count. The clear and preset control inputs are often asynchronous — they change the output state without being clocked. Counters may either count up (increment) or down (decrement). *Up/down* counters can be controlled to count in either direction. Counters can have sequences other than the standard numbers, for example a BCD counter.

Counters are also not restricted to changing state on every clock cycle. An n -bit counter that changes state only after m clock pulses is called a *divider* or *divide-by- m* counter. There are still $2^n = m$ states; however, the output after p clock pulses is now p / m . Combining different divide-by- m counters can result in almost any desired count. For example, a base 12

counter can be made from a divide-by-2 and a divide-by-6 counter; a base 10 (decade) counter consists of a divide-by-2 and a BCD divide-by-5 counter.

The outputs of these counters are binary. To produce output in decimal form, the output of a counter would be provided to a binary-to-decimal decoder chip and/or an LED display.

Registers

Groups of flip-flops can be combined to make registers, usually implemented with D flip-flops. A *register* stores n bits of information, delivering that information in response to a clock pulse. Registers usually have asynchronous *set* to 1 and *clear* to 0 capabilities.

Storage Register

A storage register simply stores temporary information, for example, incoming information or intermediate results. The size is related to the basic size of information handled by a computer: 8 flip-flops for an 8-bit or *byte register* or 16 bits for a *word register*. Fig 5.73 shows a typical circuit and schematic symbols for an 8-bit storage register. In (C), although the bits are passed on 8 separate lines (from 8 flip-flops), a slash and number, “/8,” is used to simplify the symbol. Storage registers are important to computer architecture; this topic is discussed in depth later in the chapter.

Shift Register

Shift registers also store information and provide it in response to a clock signal, but they handle their information differently: When a clock pulse occurs, instead of each flip-flop passing its result to the output, the flip-flops pass their data to each other, up and down the row. For example, in up mode, each flip-flop receives the output of the preceding flip-flop. A data bit starting in flip-flop D0 in a left shifter would move to D1, then D2 and so on until it is shifted out of the register. If a 0 was input to the least significant bit, D0, on each clock pulse then, when the last data bit has been shifted out, the register contains all 0s.

Shift registers can be left shifters, right shifters or controlled to shift in either direction. The most general form, a *universal shift register*, has two control inputs for four states: Hold, Shift right, Shift left and Load. Most also have asynchronous inputs for preset, clear and parallel load. The primary use of shift registers is to convert parallel information to serial or vice versa. This is useful in interfacing between devices, and is discussed in detail in the Interfacing section.

Additional uses for a shift register are to (1) delay or synchronize data, (2) multiply or divide a number by a factor 2^n or (3) provide random data. Data can be delayed simply by taking advantage of the Hold feature of the register control inputs. Multiplication and division with shift registers is best explained by example: Suppose a 4-bit shift register currently has the value $1000 = 8$. A right shift results in the new parallel output $0100 = 4 = 8 / 2$. A second right shift results in $0010 = 2 = (8 / 2) / 2$. Together the 2 right shifts performed a division by 2^2 . In general, shifting right n times is equivalent to dividing by 2^n . Similarly, shifting left multiplies by 2^n . This can be useful to compiler writers to make a computer program run faster. Random data is provided via a ring

counter. A *ring counter* is a shift register with its output fed back to its input. At each clock pulse, the register is shifted up or down and some of the flip-flops feed back to other flip-flops, generating a random binary number. Shift registers with several feedback paths can be used as a *pseudorandom number generator*, where the sequence of bits output by the generator meets one or more mathematical criteria for randomness.

MULTIVIBRATORS

Multivibrators are a general type of circuit with three varieties: bistable, monostable and astable. The only truly digital multivibrator is bistable, having two stable states. The flip-flop is a *bistable multivibrator*: both of its two states are stable; it can be triggered from one stable state to the other by an external signal. The other two varieties of multivibrators are partly analog circuits and partly digital. While their output is one or more pulses, the internal operation is strictly analog.

Monostable Multivibrator

A *monostable* or *one-shot* multivibrator has one energy-storing element in its feedback paths, resulting in one stable and one quasi-stable state. It can be switched, or *triggered*, to its quasi-stable state; then returns to the stable state after a time delay. Thus, when triggered, the one-shot multivibrator puts out a pulse of some duration, T .

A very common integrated circuit used for non-precision generation of a signal

pulse is the 555 timer IC. Fig 5.74 shows a 555 connected as a one-shot multivibrator. The one-shot is activated by a negative-going pulse between the trigger input and ground. The trigger pulse causes the output (Q) to go positive and capacitor C to charge through resistor R. When the voltage across C reaches two-thirds of V_{CC} , the capacitor is quickly discharged to ground and the output returns to 0. The output remains at logic 1 for a time determined by $T = 1.1 RC$, where R is the resistance in ohms and C is the capacitance in farads.

A very common, but again, non-precision application of this circuit is the generation a delayed pulse. If there is a requirement to generate a 50-microsecond pulse, but delayed from a trigger by 20 ms, two 555s might be used. The first 555, configured as an astable multivibrator, generates the 20-ms pulse, and the trailing edge of the 20-ms pulse is used to trigger a second 555 that in turn generates the 10 microsecond pulse.

Astable Multivibrator

An *astable* or *free-running* multivibrator has two energy-storing elements in its feedback paths, resulting in two quasi-stable states. It continuously switches between these two states without external excitation. Thus, the astable multivibrator puts out a sequence of pulses. By properly selecting circuit components, these pulses can be of a desired frequency and width.

Fig 5.75 shows a 555 timer IC connected as an astable multivibrator. The

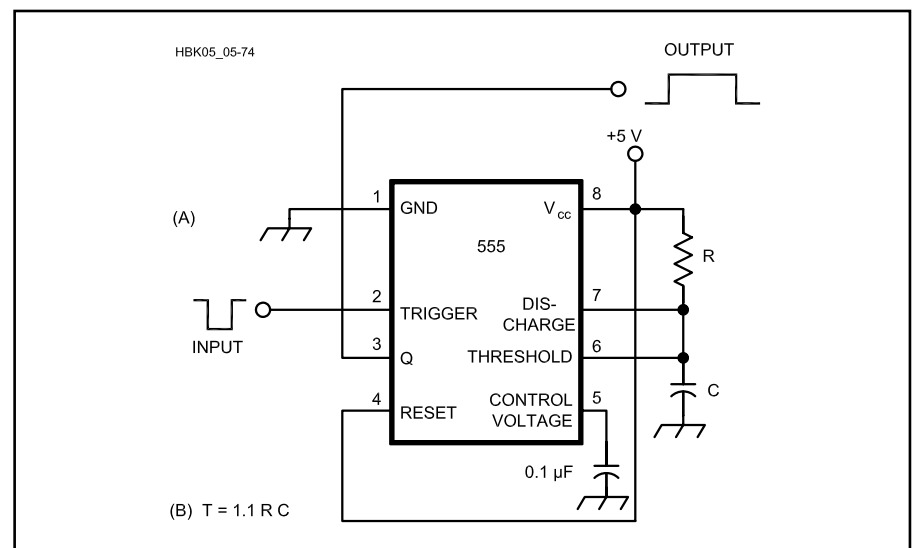

Fig 5.74 — (A) A 555 timer connected as a monostable multivibrator. (B) The equation to calculate values for R in ohms and C in farads, where T is the pulse duration in seconds.

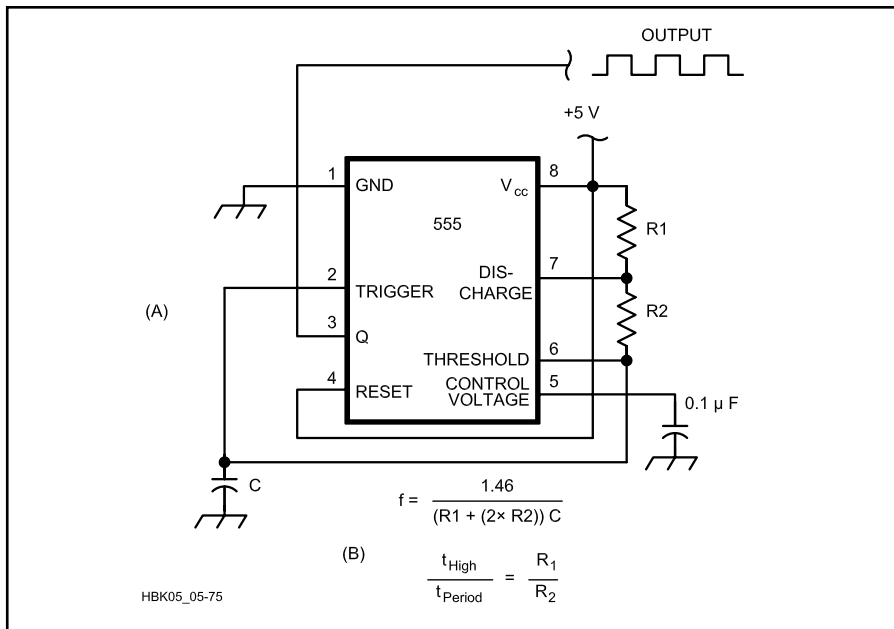

Fig 5.75 — (A) A 555 timer connected as an astable multivibrator. (B) The equations to calculate values for R1, R2 in ohms and C in farads, where f is the clock frequency in Hertz.

capacitor C charges to two-thirds V_{CC} through R1 and R2 and discharges to one-third V_{CC} through R2. The ratio R1 : R2 sets the asserted high duty cycle of the pulse: t_{HIGH} / t_{PERIOD} . The output frequency is determined by:

$$f = \frac{1.46}{(R1 + 2 R2)C}$$

where:

R1 and R2 are in ohms,
C is in farads and
f is in hertz.

It may be difficult to produce a 50% duty cycle due to manufacturing tolerance for the resistors R1 and R2. One way to ensure a 50% duty cycle is to run the astable multivibrator at 2f and then divide

by 2 with a toggle flip-flop.

Astable multivibrators, and the 555 integrated circuit in particular, are very often used to generate clock pulses. Although this is a very inexpensive and minimum hardware approach, the penalty is stability with temperature. Since the frequency and the pulse dimensions are set by resistors and capacitors, drift with temperature and to some extent aging of components will result in changes with time. However, this is no different than the problem faced by designers of L-C controlled VFOs.

SUMMARY

Digital logic plays an increasingly important role in Amateur Radio. Most of this logic is binary and can be described and designed using Boolean algebra. Using the NOT, AND and OR gates of combinational logic, designers can build sequential logic circuits that have memory and feedback. The simplest sequential logic circuit is called a flip-flop. By using control inputs, a flip-flop can latch a data value, retaining one bit of information and acting as memory. Combinations of flip-flops can form useful circuits such as counters, storage registers and shift registers. While this section discussed discrete logic, synthesized with available integrated circuits, most new commercial designs begin with a gate/flip-flop design and then use automated tools to build the entire system or major parts of it with programmable logic devices (PLDs) or equivalent custom integrated circuits.

Digital Integrated Circuits

Integrated circuits (ICs) are the cornerstone of digital logic devices. Modern technology has enabled electronics to become miniature in size and less expensive. Today's complex digital equipment would be impossible with vacuum tubes or even with discrete transistors.

An IC is a miniature electronic module of components and conductors manufactured as a single unit. All you see is a ceramic or black plastic package and the silver-colored pins sticking out. Inside the package is a piece of material, usually silicon, created (fabricated) in such a way that it conducts an electric current to perform logic functions, such as a gate, flip-flop or decoder.

As each generation of ICs surpassed the previous one, they became classified according to the number of gates on a single

chip. These classifications are roughly defined as:

- Small-scale integration (SSI):
10 or fewer gates on a chip.
- Medium-scale integration (MSI):
10-100 gates.
- Large-scale integration (LSI):
100-1000 gates.
- Very-large-scale integration (VLSI):
1000 or more gates.

This chapter will primarily deal with SSI ICs, the basic digital building blocks. Microprocessors, memory chips and programmable logic devices are discussed later in the Computer Hardware section of this chapter.

The previous section discussed the design of a digital circuit. To build that circuit, the designer must choose between IC chips available in various logic families.

Each family and subfamily has its own desirable characteristics. This section reviews the primary IC logic families of interest to radio amateurs. The designer may also be challenged to interface between different logic families or between a logic device and a peripheral device. The former is discussed at the end of this section; the latter with Computer Hardware, later in the chapter.

COMPARING LOGIC FAMILIES

When selecting devices for a circuit, a designer is faced with choosing between many families and subfamilies of logic ICs. The determination of which logic subfamily is right for a specific application is based upon several desirable characteristics: logic speed, power consumption, fan-out, noise immunity and cost. From a practical

view-point, the primary integrated circuit families available from most suppliers today are the TTL and CMOS ICs. Within these families, there are tradeoffs that can be made with respect to individual circuit capabilities, especially in the areas of speed and power consumption. Except under the most demanding circumstances, normal commercial grade temperature rating will do for amateur service. However, at a premium price and with perhaps some problems in availability, military temperature grade equivalent circuits can be selected.

Fan-out

A gate output can supply only a limited amount of current. Therefore, a single output can only drive a limited number of inputs. The measure of driving ability is called fan-out, expressed as the number of inputs (of the same subfamily) that can be driven by a single output. If a logic family that is otherwise desirable does not have sufficient fan-out, consider using noninverting buffers to increase fan-out, as shown by Fig 5.76.

Noise Immunity

The noise margin was illustrated in Fig 5.53. The choice of voltage levels for the binary states determines the noise margin. If the gap is too small, a spurious signal can too easily produce the wrong state. Too large a gap, however, produces longer, slower transitions and thus decreased switching speeds.

Circuit impedance also plays a part in noise immunity, particularly if the noise is from external sources such as radio transmitters. At low impedances, more energy is needed to change a given voltage level than at higher impedances.

BIPOLAR LOGIC FAMILIES

Two broad categories of digital logic ICs are *bipolar* and *metal-oxide semiconductor* (MOS). Numerous manufacturing techniques have been developed to fabri-

cate each type. Each surviving, commercially available family has its particular advantages and disadvantages and has found its own special niche in the market.

Bipolar semiconductor ICs usually employ NPN junction transistors. (Bipolar ICs can be manufactured using PNP transistors, but NPN transistors make faster circuits.) While early bipolar logic was faster and had higher power consumption than MOS logic, these distinctions have blurred as manufacturing technology has developed. There are several families of bipolar logic devices, and within some of these families there are subfamilies. The most-used digital logic family is Transistor-Transistor Logic (TTL). Another bipolar logic family, Emitter Coupled Logic (ECL), has exceptionally high speed but high power consumption.

Transistor-Transistor Logic (TTL)

The TTL family has seen widespread acceptance because it is fast and has good noise immunity. It is by far the most commonly used logic family. TTL levels were shown earlier in Fig 5.53: An input voltage between 0.0-0.4 V will represent LOW and an input voltage between 2.4-5.0 V will represent HIGH.

TTL Subfamilies

The original standard TTL is infrequently used today. In the standard TTL circuit, the transistors saturate, reducing the operating speed. TTL variations cure this by clamping the transistors with Schottky diodes to prevent saturation, or by using a dopant in the chip fabrication to reduce transistor recovery time. Schottky-clamped TTL is the faster of these two manufacturing processes.

TTL IC identification numbers begin with either 54 or 74. The 54 prefix denotes a military temperature range of -55 to 125°C, while 74 indicates a commercial temperature range of 0 to 70°C. The next letters, in the middle of the TTL device number, indicate the TTL subfamily. Following the subfamily designation is a 2, 3 or 4-digit device-identification number. For example, a 7400 is a standard TTL NAND gate and a 74LS00 is a low-power Schottky NAND gate. (The NAND gate is the workhorse TTL chip. Recall, from Fig 5.68, the alternative implementation of the S-R flip-flop.) The following TTL subfamilies are available:

	74xx	standard TTL
H	74Hxx	High-speed
L	74Lxx	Low-power
S	74Sxx	Schottky
LS	74LSxx	Low-power Schottky
AS	74ASxx	Advanced Schottky
ALS	74ALSxx	Advanced Low-power Schottky

Each subfamily is a compromise between speed and power consumption. Because the speed-power product is approximately constant, less power consumption results in less speed and vice versa. For the amateur, an additional consideration to the speed-versus-power trade-off is the cost trade-off. The advanced Schottky devices offer both increased speed and reduced power consumption but at a higher cost.

In addition to the above power/speed/cost trade-offs, each TTL subfamily has particular characteristics that can make it suitable or unsuitable for a specific design. Table 5.9 shows some of these parameters. The actual parameter values may vary slightly from manufacturer to manu-

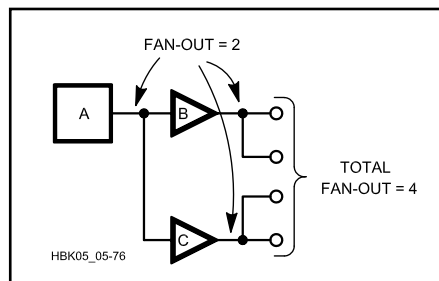

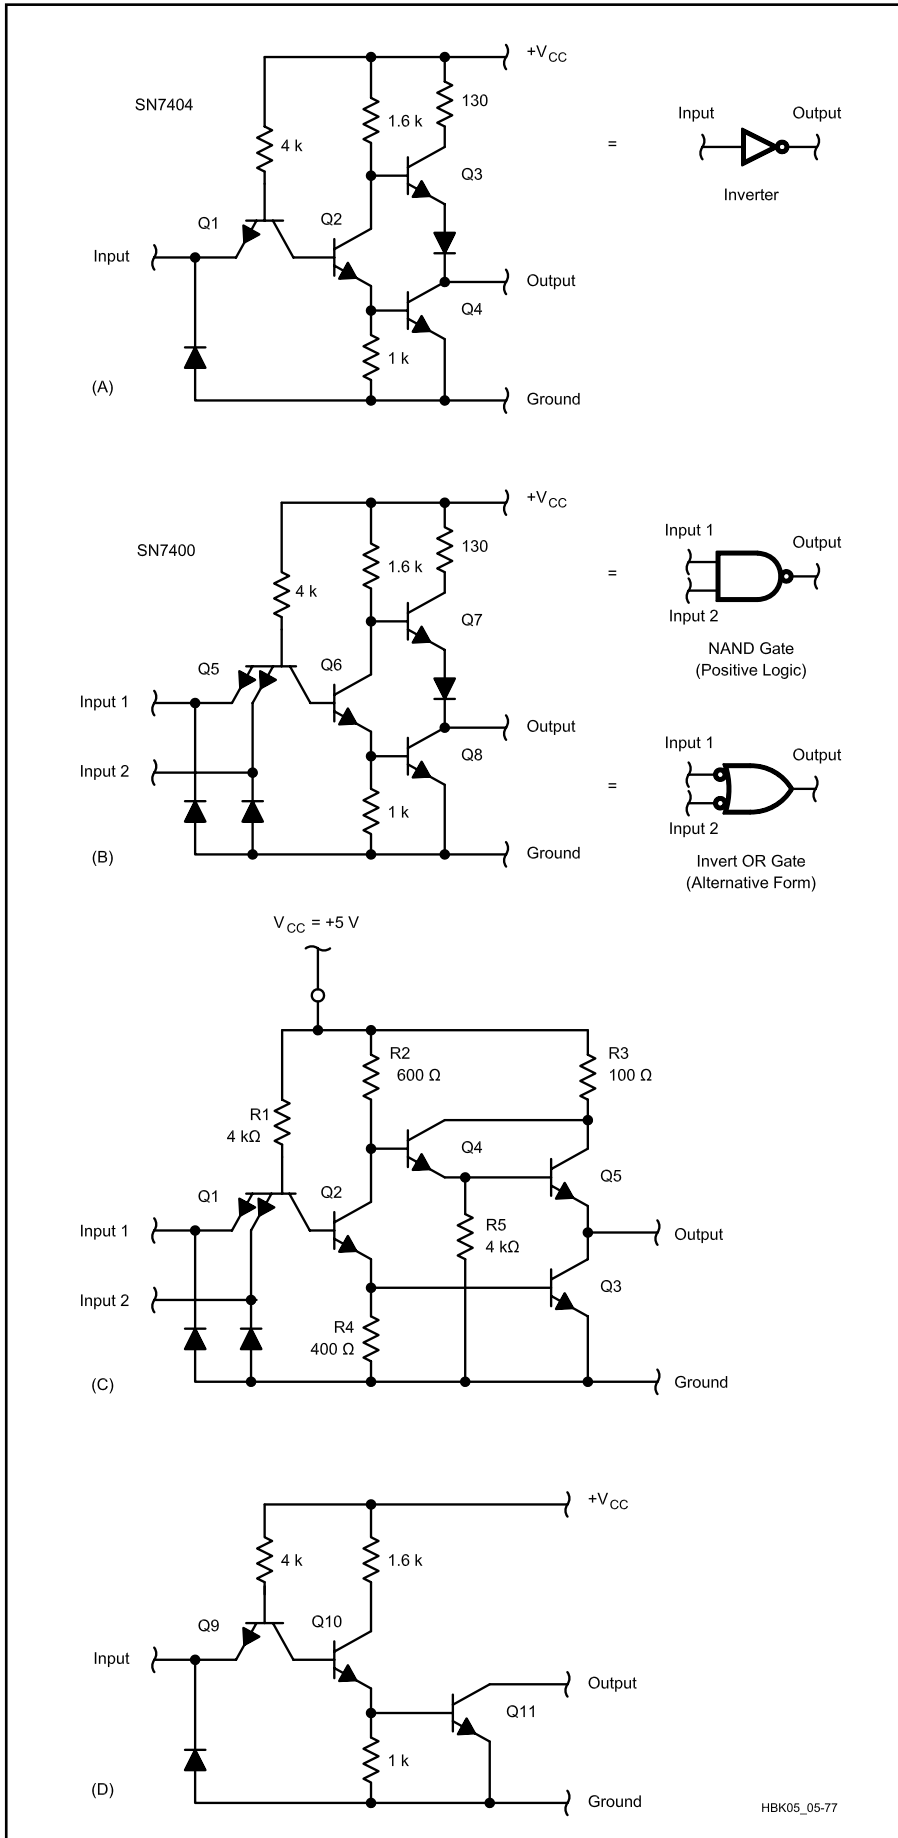

Fig 5.76 — Nonverting buffers used to increase fan-out: Gate A (fan-out = 2) is connected to two buffers, B and C, each with a fan-out of 2. Result is a total fan-out of 4.

Table 5.9

TTL and CMOS Subfamily Performance Characteristics

TTL Family	Propagation Delay (ns)	Per Gate Power Consumption (mW)			Speed Power Product (pico-joules)		
Standard	9	10			90		
L	33	1			33		
H	6	22			132		
S	3	20			60		
LS	9	2			18

facturer, so always consult the manufacturers' data books for complete information.

TTL Circuits

Fig 5.77A shows the schematic representation of a TTL hex inverter. A 7404 chip contains four of these inverters. When the input is low, Q1 is ON, conducting current from base to emitter through the input lead and into ground. Thus, a low TTL input device must be prepared to sink current from the input. Since Q1 is saturated, Q2 is OFF because there is not enough voltage at its base. Similarly, Q4 is also OFF. With Q2 and Q4 OFF, Q3 will be ON and pull the output high, about one volt below V_{CC}. When the input is high, an unusual situation occurs: Q1 is operating in the inverse mode, with current flowing from base to collector. This current causes Q2 to be ON, which causes Q4 to be ON. With Q2 and Q4 ON, there is not enough current left for Q3, so Q3 is OFF. Q4 is pulling the output low.

By replacing Q1 with a multiple-emitter transistor, as is done with the two-input Q5 in Fig 5.77B, the inverter circuit becomes a NAND gate. Commercially available TTL NAND gates have as many as 13 inputs, the limiting factor being the number of input pins on the standard 16-pin chip. The operation of this multiple-input NAND circuit is the same as described for the inverter, the difference being that any one of the emitter inputs being low will conduct current through the emitter, leading to the conditions described above to produce a high at the output. Similarly, all inputs must be high to produce the low output.

In the TTL circuit of Fig 5.77A, transistors Q3 and Q4 are arranged in a *totem-pole* configuration. This configuration gives the output circuit a low source impedance, allowing the gate to source (supply) or sink substantial output current. The 130-Ω resistor between the collector of Q3 and +V_{CC} limits the current through Q3.

When a TTL gate changes state, the amount of current that it draws changes rapidly. These changes in current, called switching transients, appear on the power supply line and can cause false triggering

Fig 5.77 — Example TTL circuits and their equivalent logic symbols: (A) an inverter and (B) a NAND gate, both with totem-pole outputs. (C) A NAND gate with a Darlington output. (D) A NAND gate with an open-collector output. (Indicated resistor values are typical. Identification of transistors is for text reference only. These are not discrete components but parts of the silicon die.)

HBK05_05-77

of other devices. For this reason, the power bus should be adequately decoupled. For proper decoupling, connect a 0.01 to 0.1 μF capacitor from V_{CC} to ground near each device to minimize the transient currents caused by device switching and magnetic coupling. These capacitors must be low-inductance, high-frequency RF capacitors (disk-ceramic capacitors are preferred). In addition, a large-value (50 to 100 μF) capacitor should be connected from V_{CC} to ground somewhere on the board to accommodate the continually changing I_{CC} requirements of the total V_{CC} bus line. These are generally low-inductance tantalum capacitors rather than rolled-foil Mylar or aluminum-electrolytic capacitors.

Darlington and Open-Collector Outputs

Fig 5.77C and D show variations from the totem-pole configuration. They are the Darlington transistor pair and the open-collector configuration respectively.

The Darlington pair configuration replaces the single transistor Q4 with two transistors, Q4 and Q5. The effect is to provide more current-sourcing capability in the high state. This has two benefits: (1) the rise time is decreased and (2) the fan-out is increased.

Transistor(s) on the output in both the totem-pole and Darlington configurations provide active pull-up. Omitting the transistor(s) and providing an external resistor for passive pull-up gives the open-collector configuration. This configuration, unfortunately, results in slower rise time, since a relatively large external resistor must be used. The technique has some very useful applications, however: driving other devices, performing wired logic, busing and interfacing between logic devices.

Devices that need other than a 5-V supply can be driven with the open-collector output by substituting the device for the external resistor. Example devices include light-emitting diodes (LEDs), relays and solenoids. Inductive devices like relay coils and solenoids need a “flyback” protection diode across the coil. You must pay attention to the current ratings of open-collector outputs in such applications. You may need a switching transistor to drive some relays or other high-current loads.

Open-collector outputs can perform wired logic, rather than gated IC logic, by wire-ANDing the outputs. This can save the designer an AND gate, potentially simplifying the design. Wire-ANDed outputs are several open-collector outputs connected to a single external pull-up resistor. The overall output, then, will only be

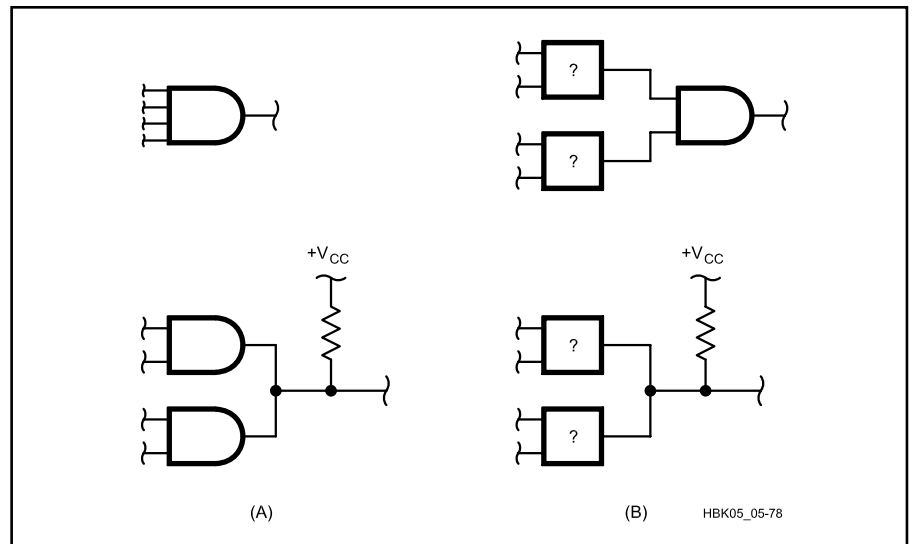

Fig 5.78 — The outputs of two open-collector-output AND gates are shorted together (wire ANDed) to produce an output the same as would be obtained from a 4-input AND gate.

high when all pull-down transistors are OFF (all connected outputs are high), effectively performing an AND of the connected outputs. If any of the connected outputs are low, the output after the external resistor will be low. Fig 5.78 illustrates the wire-ANDing of open-collector outputs.

The wire-ANDed concept can be applied to several devices sharing a common bus. At any time, all but one device has a high-impedance (off) output. The remaining device, enabled with control circuitry, drives the bus output.

Open-collector outputs are also useful for interfacing TTL gates to gates from other logic families. TTL outputs have a minimum high level of 2.4 V and a maximum low level of 0.4 V. When driving non-TTL circuits, a pull-up resistor (typically 2.2 k Ω) connected to the positive supply can raise the high level to 5 V. If a higher output voltage is needed, a pull-up resistor on an open-collector output can be connected to a positive supply greater than 5 V, so long as the chip output voltage and current maximums are not exceeded.

Three-State Outputs

While open-collector outputs can perform bus sharing, a more popular method is three-state output, or tristate, devices. The three states are low, high and high impedance, also called Hi-Z or *floating*. An output in the high-impedance state behaves as if it is disconnected from the circuit, except for possibly a small leakage current. Three-state devices have an additional disable input. When enable is

low, the device provides high and low outputs just as it would normally; when enable is high, the device goes into its high-impedance state.

A bus is a common set of wires, usually used for data transfer. A three-state bus has several three-state outputs wired together. With control circuitry, all devices on the bus but one have outputs in the high-impedance state. The remaining device is enabled, driving the bus with high and low outputs. Care should be taken to ensure only one of the output devices can be enabled at any time, since simultaneously connected high and low outputs may result in an incorrect logic voltage. (The condition when more than one driver is enabled at the same time is called *bus contention*.) Also, the large current drain from V_{CC} to ground through the high driver to the low driver can potentially damage the circuit or produce noise pulses that can affect overall system behavior.

Unused TTL Inputs

A design may result in the need for an n -input gate when only an $n + m$ input gate is available. In this case, the recommended solution for extraneous inputs is to give the extra inputs a constant value that won't affect the output. A low input is easily provided by connecting the input to ground. A high input can be provided with either an inverter whose input is ground or with a pull-up resistor. The pull-up resistor is preferred rather than a direct connection to power because the resistor limits the current, thus protecting the circuit from transient voltages. Usually, a 1-k Ω to 5-k Ω resistor is used; a single

1-k Ω resistor can handle up to 10 inputs.

It's important to properly handle all inputs. Design analysis would show that an unconnected, or floating TTL input is usually high but can easily be changed low by only a small amount of capacitively-coupled noise.

METAL-OXIDE SEMICONDUCTOR (MOS) LOGIC FAMILIES

While bipolar devices use junction transistors, MOS devices use field effect transistors (FETs). MOS is characterized by simple device structure, small size (high density) and ease of fabrication. MOS circuits use the NOR gate as the workhorse chip rather than the NAND. MOS families are used extensively in digital watches, calculators and VLSI circuits such as microprocessors and memories.

P-Channel MOS (PMOS)

The first MOS devices to be fabricated were PMOS, conducting electrical current by the flow of positive charges (holes). PMOS power consumption is much lower than that of bipolar logic, but its operating speed is also lower. The only extensive use of PMOS is in calculators and watches, where low speed is acceptable and low power consumption and low cost are desirable.

N-Channel MOS (NMOS)

With improved fabrication technology, NMOS became feasible and provided improved performance and TTL compatibility. The speed of NMOS is at least twice that of PMOS, since electrons rather than holes carry the current. NMOS also has greater gain than PMOS and supports greater packaging density through the use of smaller transistors.

Complementary MOS (CMOS)

CMOS combines both P-channel and N-channel devices on the same substrate to achieve high noise immunity and low power consumption: less than 1 mW per gate and negligible power during standby. This accounts for the widespread use of CMOS in battery-operated equipment. The high impedance of CMOS gates makes them susceptible to electromagnetic interference, however, particularly if long traces are involved. Consider a trace $\frac{1}{4}$ -wavelength long between input and output. The output is a low-impedance point, hence the trace is effectively grounded at this point. You can get high RF potentials $\frac{1}{4}$ -wavelength away, which disturbs circuit operation.

A notable feature of CMOS devices is that the logic levels swing to within a few millivolts of the supply voltages. The in-

put-switching threshold is approximately one half the supply voltage ($V_{DD} - V_{SS}$). This characteristic contributes to high noise immunity on the input signal or power supply lines. CMOS input-current drive requirements are minuscule, so the fan-out is great, at least in low-speed systems. For high-speed systems, the input capacitance increases the dynamic power dissipation and limits the fan-out.

CMOS Subfamilies

There are a number of CMOS subfamilies available. Like TTL, the original CMOS has largely been replaced by later subfamilies using improved technologies. The original family, called the 4000-series, has numbers beginning with 40 or 45 followed by two or three numbers to indicate the specific device. 4000B is second generation CMOS. When introduced, this family offered low power consumption but was fairly slow and not easy to interface with TTL.

Later CMOS subfamilies provided improved performance and TTL compatibility. For simplicity, the later subfamilies were given numbers similar to the TTL numbering system, with the same leading numbers, 54 or 74, followed by 1 to 3 letters indicating the subfamily and as many as 5 numbers indicating the specific device. The subfamily letters usually include a "C" to distinguish them as CMOS.

The following CMOS device families are available:

4000	4071B	standard CMOS
C	74Cxx	CMOS versions of TTL

Devices in the 74C subfamily are pin and functional equivalents of many of the most popular parts in the 7400 TTL family. It may be possible to replace all TTL ICs in a particular circuit with 74C-series CMOS, but this family should not be mixed with TTL in a circuit without care-

ful design considerations. Devices in the C series are typically 50% faster than the 4000 series.

HC 74HCxx High-speed CMOS

Devices in the 74HC subfamily have speed and drive capabilities similar to Low-power Schottky (LS) TTL but with better noise immunity and greatly reduced power consumption. High-speed refers to faster than the previous CMOS family, the 4000-series.

HCT 74HCTxx High-Speed CMOS, TTL compatible

Devices in this subfamily were designed to interface TTL to CMOS systems. The HCT inputs recognize TTL levels, while the outputs are CMOS compatible.

AC 74ACxxxxx Advanced CMOS

Devices in this family have reduced propagation delays, increased drive capabilities and can operate at higher speeds than standard CMOS. They are comparable to Advanced Low-power Schottky (ALS) TTL devices.

ACT 74ACTxxxxx Advanced CMOS, TTL compatible

This subfamily combines the improved performance of the AC series with TTL-compatible inputs.

As with TTL, each CMOS subfamily has characteristics that make it suitable or unsuitable for a particular design. You should consult the manufacturer's data books for complete information on each subfamily being considered.

CMOS Circuits

A simplified diagram of a CMOS logic inverter is shown in **Fig 5.79**. When the

Fig 5.79 — Internal structure of a CMOS inverter.

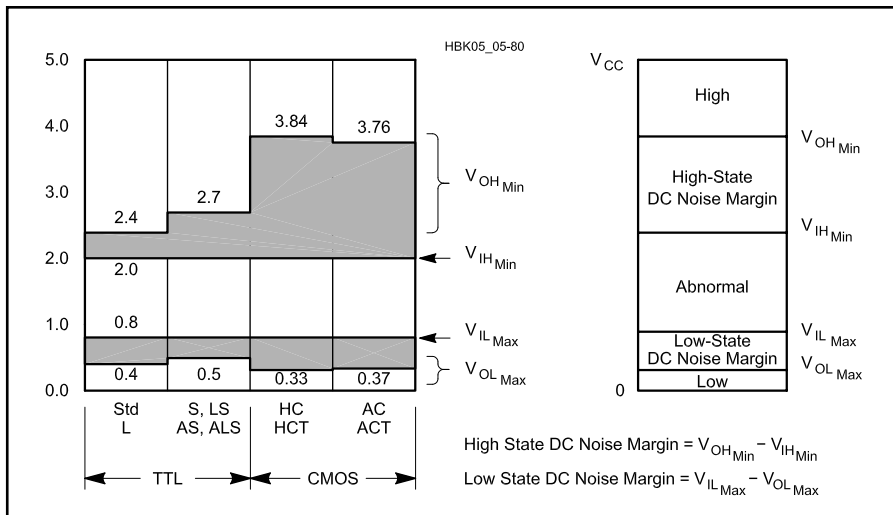

Fig 5.80 — Differences in logic levels for some TTL and CMOS families.

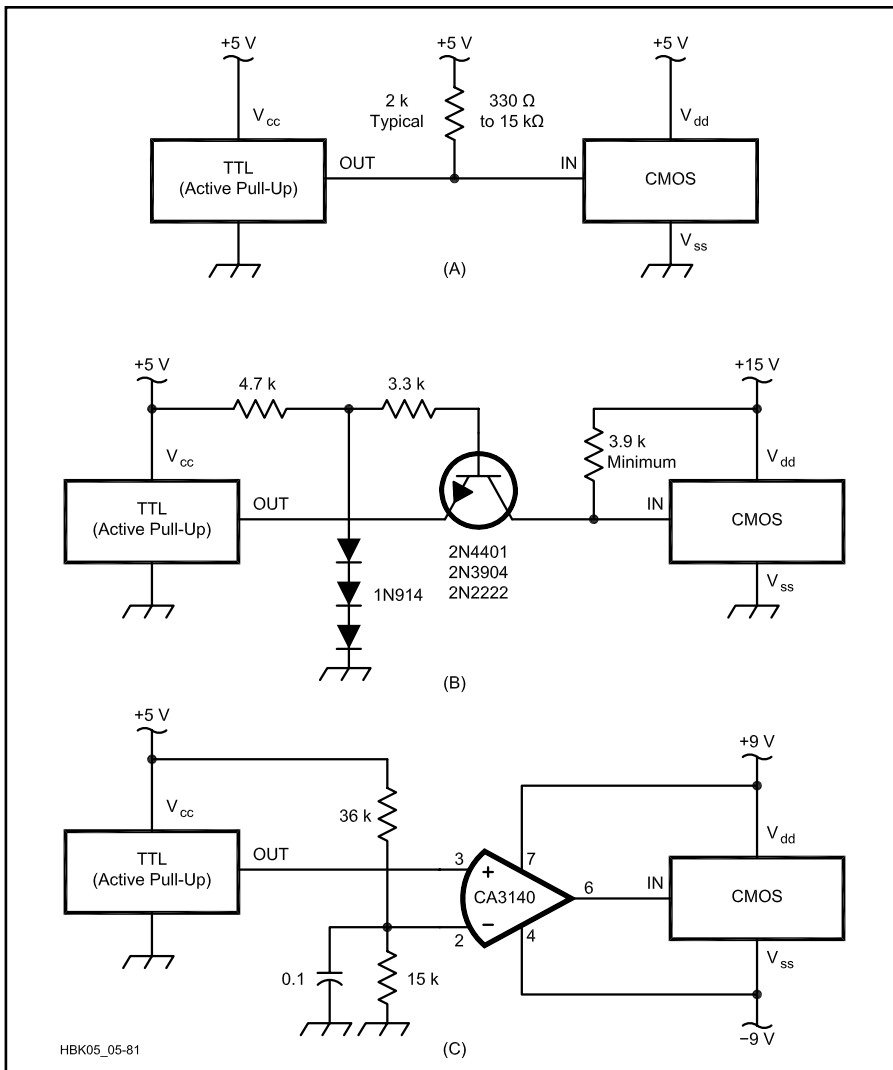

Fig 5.81 — TTL to CMOS interface circuits: (A) pull-up resistor, (B) common-base level shifter and (C) op amp configured as a comparator.

input is low, the resistance of Q2 is low so a high current flows from V_{CC} . Since Q1's resistance is high, the high current flows to the output. When the input is high, the opposite occurs: Q2's resistance is low, Q1's is high and the output is low. The diodes are to protect the circuit against static charges.

Special Considerations

Some of the diodes in the input- and output-protection circuits are an inherent part of the manufacturing process. Even with the protection circuits, however, CMOS ICs are susceptible to damage from static charges. To protect against damage from static, the pins should not be inserted in Styrofoam as is sometimes done with other components. Instead, a spongy conductive material is available for this purpose. Before removing a CMOS IC from its protective material, make certain that your body is grounded. Touching nearly any large metal object before handling the ICs is probably adequate to drain any static charge off your body. Some people prefer to touch a grounded metal object or to use a conductive bracelet connected to the ground terminal of a three-wire ac outlet through a 10-M Ω resistor. Since wall outlets aren't always wired properly, you should measure the voltage between the ground terminal and any metal objects you might touch. Connecting yourself to ground through a 1-M Ω to 10-M Ω resistor will limit any current that might flow through your body.

All CMOS inputs should be tied to an input signal. A positive supply voltage or ground is suitable if a constant input is desired. Undetermined CMOS inputs, even on unused gates, may cause gate outputs to oscillate. Oscillating gates draw high current, overheat and self destruct.

The low power consumption of CMOS ICs made them attractive for satellite applications, but standard CMOS devices proved to be sensitive to low levels of radiation — cosmic rays, gamma rays and X rays. Later, radiation-hardened CMOS ICs, able to tolerate 10^6 rads, made them suitable for space applications. (A rad is a unit of measurement for absorbed doses of ionizing radiation, equivalent to 10^{-2} joules per kilogram.)

SUMMARY

There are many types of logic ICs, each with its own advantages and disadvantages. Regardless of the application, consult up-to-date literature when designing logic circuits. IC databooks and application notes are usually available from IC manufacturers and distributors. Also, just about all of this information is available

on the Internet. By using a search engine and entering a few key word specifications, you will locate application notes, tutorials and a host of other information.

INTERFACING LOGIC FAMILIES

Each semiconductor logic family has its own advantages in particular applications. When a design mixes ICs from different logic families, the designer must account for the differing voltage and current requirements each logic family recognizes. The designer must ensure the appropriate interface exists between the point at which one logic family ends and another begins. A knowledge of the specific input/output (I/O) characteristics of each device is necessary, and a knowledge of the general internal structure is desirable to ensure reliable digital interfaces. Typical internal structures have been illustrated for each common logic family. **Fig 5.80** illustrates the logic level changes for different TTL and CMOS families. Databooks should be consulted for manufacturer's specifications.

Often more than one conversion scheme is possible, depending on whether the designer wishes to optimize power consumption or speed. Usually one quality must be traded off for the other. The following section discusses some specific logic conversions. Where an electrical connection between two logic systems isn't possible, an optoisolator can sometimes be used.

TTL Driving CMOS

TTL and low-power TTL can drive 74C series CMOS directly over the commercial temperature range without an external pull-up resistor. However, they cannot drive 4000-series CMOS directly, and for HC-series devices, a pull-up resistor is recommended. The pull-up resistor, connected between the output of the TTL gate and V_{CC} as shown in **Fig 5.81A**, ensures proper operation and enough noise margin by making the high output equal to V_{DD} . Since the low output voltage will also be affected, the resistor value must be chosen with both desired high and low voltage ranges in mind. Resistor values in the range 1.5 k Ω to 4.7 k Ω should be suitable for all TTL families under worst conditions. A larger resistance reduces the maximum possible speed of the CMOS gate; a lower resistance generates a more favorable RC product but at the expense of increased power dissipation.

HCT-series and ACT-series CMOS devices were specifically designed to interface non-CMOS devices to a CMOS system. An HCT device acts as a simple buffer between the non-CMOS (usually TTL) and CMOS device and may be com-

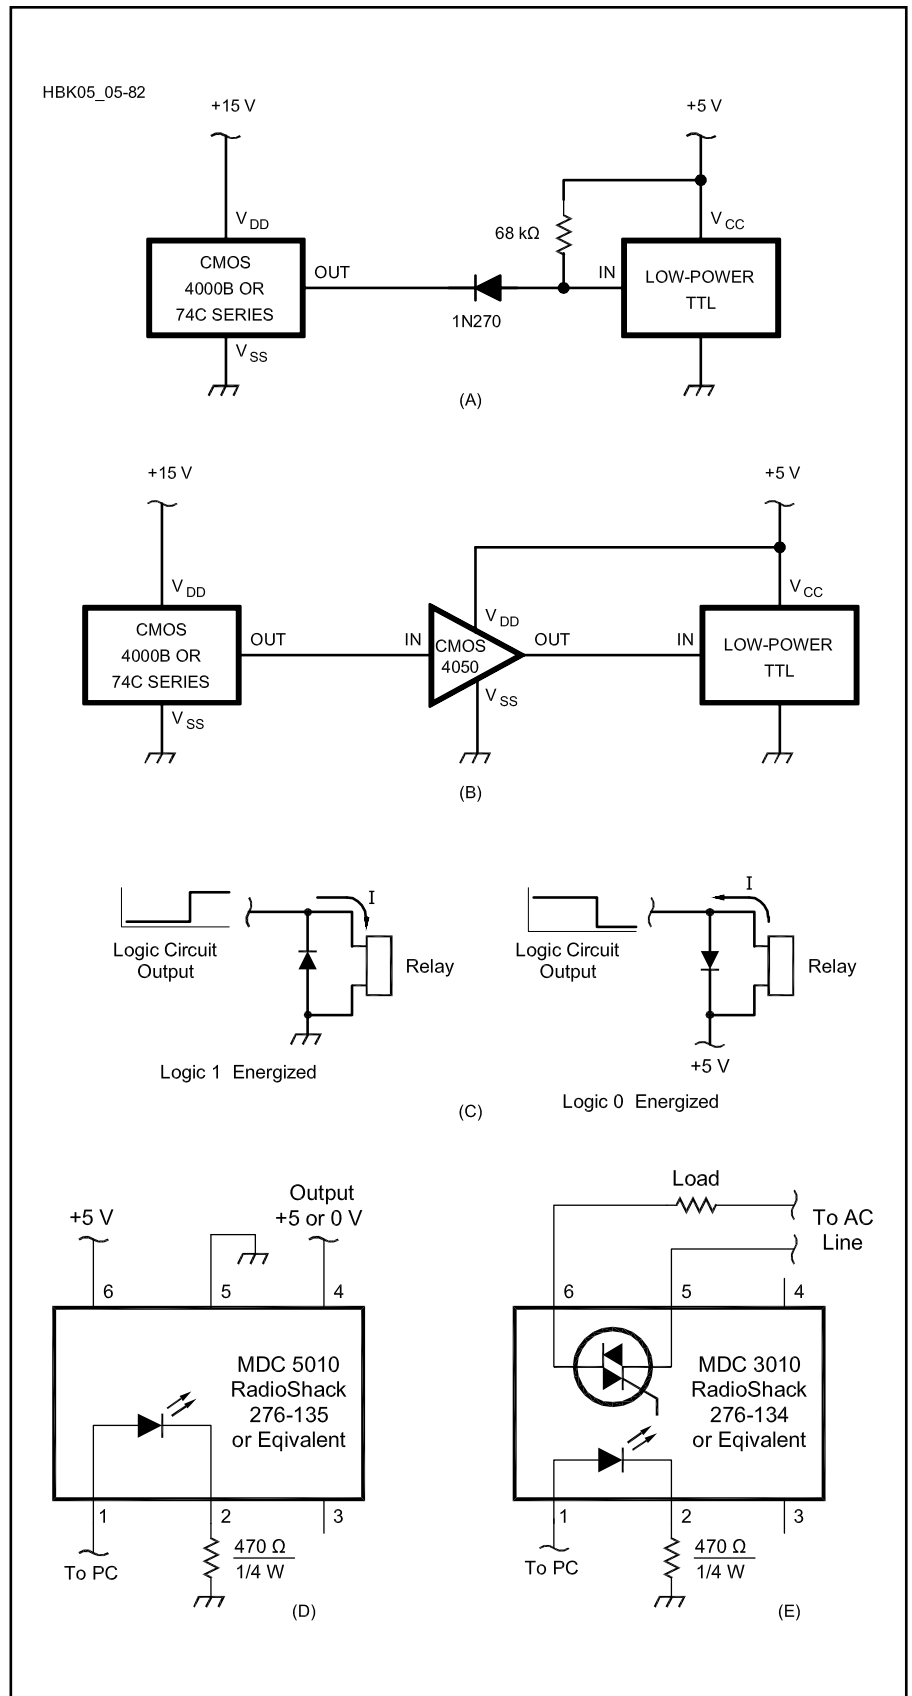

Fig 5.82 — CMOS to TTL interface circuits: (A) blocking diode chosen when different supply voltages are used. The diode is not necessary if both devices operate with a +5 V supply. (B) CMOS noninverting buffer IC. (C) Relay interface for total isolation. (D) An electro-optical coupler can be used in place of a relay. (E) An electro-optical coupler can also drive a triac-based unit for switching ac.

bined with a logic function if a suitable HCT device is available.

When the CMOS device is operating from a power supply other than +5 V, the TTL interface is more complex. One fairly simple technique uses a TTL open-collector output connected to the CMOS input, with a pull-up resistor from the CMOS input to the CMOS power supply. Another method, shown in Fig 5.81B, is a common-base level shifter. The level shifter translates a TTL output signal to a +15 V CMOS signal while preserving the full noise immunity of both gates. An excellent converter from TTL to CMOS using dual power supplies is to configure an operational amplifier as a comparator, as shown in Fig 5.81C. An FET op amp is shown because its output voltage can usually swing closer to the rails (+ and – supply voltages) than a bipolar device.

CMOS Driving TTL

Certain CMOS devices can drive TTL loads directly. The output voltages of CMOS are compatible with the input requirements of TTL, but the input-current requirement of TTL limits the number of TTL loads that a CMOS device can drive from a single output (the fan-out).

Interfacing CMOS to TTL is a bit more complicated when the CMOS is operating at a voltage other than +5 V. One technique is shown in Fig 5.82A. The diode blocks the high voltage from the CMOS gate when it is in the high output state. A germanium diode is used because its lower forward-voltage drop provides higher noise immunity for the TTL device in the low state. The 68-k Ω resistor pulls the input high when the diode is back biased.

There are two CMOS devices specifically

designed to interface CMOS to TTL when TTL is using a lower supply voltage. The CD4050 is a noninverting buffer that allows its input high voltage to exceed the supply voltage. This capability allows the CD4050 to be connected directly between the CMOS and TTL devices, as shown in Fig 5.82B. The CD4049 is an inverting buffer that has the same capabilities as the CD4050.

Real-World Interfacing

Quite often logic circuits must either drive or be driven from non-logic sources. A very common requirement is sensing the presence or absence of a high (as compared to +5 volts) voltage or perhaps turning on or off a 120-VAC motor, such as an antenna rotor. A similar problem occurs when two different units in the shack must be interfaced since induced AC voltages or ground loops can cause problems with the desired signals.

A slow speed but safe way to interface such circuits is to use a relay. This provides absolute isolation between the logic circuits and the load. Fig 5.82C shows the correct way to provide this connection. The relay coil is selected to draw less than the available current from the driving logic circuit. The diode, most often a 1N914 or equivalent switching diode, prevents the inductive load from back-biasing the logic circuit and possibly destroying it.

Electro-optical couplers can also be used for this circuit interfacing. Fig 5.82D uses one to interface two sets of logic circuits, and Fig 5.82E interfaces with the AC line.

MSI, LSI VLSI Circuits and Controllers

In addition to using the basic logic ele-

ments discussed in the previous sections, there are many integrated circuits available for Amateur Radio applications that include the equivalent of dozens, hundreds or perhaps even thousands of gates. Often, it is no harder to use one of these units than it is to use a few gates and flip-flops.

The analog ((D/A) and digital-to-analog ((D/A) converters discussed in the section following (on the parallel port) are examples. Hybrid (containing both analog and digital functions) integrated circuits provide other opportunities for builders. As additional examples, the LM3914 is a LED driver that takes an analog signal in and turns on one or more LEDs, depending on the analog voltage. A self-contained signal generator, the MAX038, can accept either switch closures or digital control signals and generates selectable sin, square or triangle waves with variable frequency.

At the other end of the spectrum are microcontrollers, which can be considered *PCs on a chip*. These include a reduced version of an arithmetic-logic unit, as described in the next section as well as interfacing and some data and program storage. However, these units require a special purpose programmer to load and store the programs, and programming them can become quite involved.

A larger, but perhaps friendlier microcontroller is the various versions (and clones) of the *BASIC Stamp* (*BASIC Stamp* is a registered trademark of Parallax, Inc.) Several varieties are available, with varying capabilities. They are programmed in a version of the *BASIC* language using a PC, and, then, the program is downloaded from the PC into the *BASIC Stamp*.

Computer Hardware

So far, this chapter segment has discussed digital logic, the implementation of that logic with integrated circuits, interfacing IC logic families and the use of memory to store information used by the ICs. The synthesis of all this technology is the microcomputer — combining a microprocessor IC, memory, peripheral devices, and user interface into the modern personal computer. A computer has both physical components (hardware) and a collection of programs (software) to tell it what to do. This section (by Bob Wolbert, K6XX with additional material by Paul Danzer, N1II) will focus on the physical

components of the computer: its internal physical components, their interaction, and peripheral I/O devices that communicate with other systems and the operator.

Material relating to computers in general, and PCs in particular, tends to become obsolete very quickly. For that reason, a quick look at the ever-growing PC-related section at your local bookstore will show very few books on the shelf older than perhaps 12 to 18 months. While the basic technology of electronics as applied to PCs does not change, the standard, performance and configurations change monthly, weekly and perhaps even daily.

Thus, this section will provide only an overview of PC hardware and technology.

A WORD ABOUT AVAILABILITY

While many of an application's programs such as RTTY, SSTV, PSK AMTOR (and several dozen others) work best with fast, new PC hardware, many Amateur applications using the hardware as a controller do not require very much capability. Since many used computers are available at prices ranging from nothing (just haul it away) to perhaps \$100, these units are worth considering for single, special applications. Want a modulation

monitor or a recording voltmeter? How about basing the design on an old PC? Application of the material in this chapter to interfacing with an old PC can provide a host of ham-shack capabilities.

WHAT IS A COMPUTER?

The strictest definition of the term “computer” includes special purpose digital systems optimized for a particular task. For example, a modern synthesized transceiver, with its memory, I/O, serial control, DSP, etc. meets the definition of a computing device. Many of the concepts discussed in this section apply equally well to your HF rig as well as to your PC; however, our definition of a computer will be restricted to a general purpose machine whose task is quickly and easily changed by loading or changing software. If its task cannot be readily modified — to compute a spreadsheet or compose e-mail, for example — we will exclude that system from our discussion. The personal computer (PC) will be emphasized due to its ubiquitous nature.

The three major divisions of a PC are its hardware, its software, and its firmware. See Fig 5.83. The hardware includes the *central processing unit* (CPU) and input/output (I/O) devices. Software refers to the programs that are loaded into the computer to configure it for the task at hand. Firmware, also called microcode or BIOS (Basic Input/Output System), is a hybrid of both hardware and software that is used to perform specific tasks. The microcode is the basis of the microprocessor’s command set that tells it how to fetch data and add numbers. For example, the BIOS is firmware generally used to start-up (boot) the system.

COMPUTER ARCHITECTURE

Unlike many present textbooks, where computer architecture is narrowly defined as only including those attributes of the

Fig 5.83 — Hardware, software and firmware comprise a computer.

system that interest programmers, our discussion deals with the structural organization and hardware design of the digital computer system. All modern computer systems consist of three basic sections: the CPU, memory, and peripherals for interfacing with the operator and the real world. The architecture of a computer is the arrangement of these two specific internal subsystems, the CPU and the bus. The CPU (central processing unit), called a *microprocessor* in personal computers, is an IC consisting of three major parts: a control unit, an arithmetic logic unit (ALU), and temporary storage registers. The *bus* is a set of wires carrying address, data and control information, which interconnects all of the subsystems. Virtually all computers are designed based on the basic “Von Neumann” architecture shown in Fig 5.84.

The microprocessor, memory chips and other circuitry are all part of the system’s hardware, the physical components of a system. The computer case, the nuts and bolts and physical parts are other parts of the hardware. A computer also includes software, a collection of programs or sequence of instructions to perform a specified task. The design of computers is so complex, however, that it is nearly impossible to design an original architecture without any bugs. Thus many designers use microprocessors that include *microcode* or microinstructions, which are instructions in the control unit of a microprocessor. This hybrid between hardware and software is called firmware. Firmware also includes software stored in ROM or EPROM rather than being stored

on magnetic disk or tape.

Computer designers make decisions on hardware, software and firmware based on cost versus performance. Today’s computer market includes a wide range of systems, from high-performance super-computers costing millions of dollars, to the personal microcomputer, with prices in the high hundreds to a few thousands new and ranging from free on up for older used models.

THE CENTRAL PROCESSING UNIT

The central processing unit is usually a single microprocessor chip, although its subsystems can be on more than one chip. The CPU at least includes a control unit, timing circuitry, an arithmetic logic unit (ALU) and registers for temporary storage. Modern microprocessors have tens of millions of transistors and are designed in modules.

Control Unit

The control unit directs the operation of the computer, managing the interaction between subunits. It takes instructions from the memory and executes them, performing tasks such as accessing data in memory, calling on the ALU or performing I/O. Control is one of the most difficult parts to design; thus it is the most likely source of bugs in designing an original architecture.

Microprocessors consist of both hard-wired control and micro-programmed control. In both cases, the designer determines a sequence of states through which the computer cycles, each with inputs to examine and outputs to activate other CPU sub-

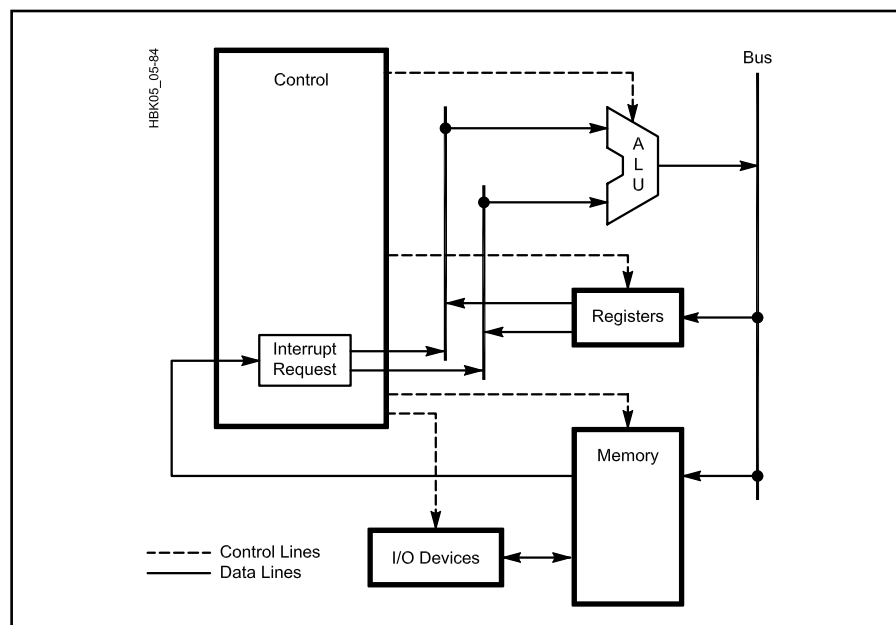

Fig 5.84 — Example of a basic computer architecture.

systems (including activating itself, indicating which state to do next). For example, the sequence usually starts with “Fetch the next instruction from memory,” with control outputs to activate memory for a read, a program counter to send the address to be fetched and an instruction register to receive the memory contents. Hardwired control is completely via circuitry, usually with a programmed logic array. Microprogrammed control uses a microprocessor with a modifiable control memory, containing microcode or micro-instructions. An advantage of microprogrammed control is flexibility; the code can be changed without changing the hardware, making it easier to correct design errors.

Timing

Usually, an oscillator controlled by a quartz crystal generates the microcomputer’s clock signal. The output of this clock goes to the microprocessor and to other ICs. The clock synchronizes the microcomputer subunits. For example, each of the microinstructions is designed to take only one clock cycle to execute, so any components triggered by a microinstruction’s control outputs should finish their actions by the end of the clock cycle. The exception to this is memory, which may take multiple clock cycles to finish, so the control unit repeats in its same state until memory says it’s done. Since the clock rate effectively controls the rate at which instructions are executed, the clock frequency is one way to measure the speed of a computer. Clock frequency, however, cannot be the only criteria considered because the actions performed during a clock cycle vary for different designs, particularly processors with superscalar or pipelined designs capable of computing multiple items simultaneously.

Arithmetic Logic Unit

The *arithmetic logic unit* (ALU) performs logical operations such as AND, OR and SHIFT and two number arithmetic operations such as addition, subtraction, multiplication and division. The ALU depends on the control unit to tell it which operation to perform and also to trigger other devices (memory, registers and I/O) to supply its input data and to send out its results to the appropriate place.

The ALU often only performs simple operations. Complex operations, such as multiplication, division and operations involving decimal numbers, are performed by dedicated hardware, called floating-point processors, or *coprocessors*.

Registers

Microprocessor chips have some inter-

nal memory locations that are used by the control unit and ALU. Because they are inside the microprocessor IC, these registers can be accessed more quickly than main memory locations. Special purpose registers or *dedicated registers* are purely internal, have predefined uses and cannot be directly accessed by programs. *General-purpose registers* hold data and addresses in use by programs and can be directly accessed, although usually only by assembly level programs.

The dedicated registers include the instruction register, program counter, effective address register and status register. The first step to execute an instruction is to fetch it from memory and put it in the *instruction register* (IR). The *program counter* (PC) is then incremented to contain the address of the next instruction to be fetched. An instruction may change the program counter as a result of a conditional branch (if-then), loop, subroutine call or other nonlinear execution. If data from memory is needed by an instruction, the address of the data is calculated and fetched with the *effective address register* (EAR). The *status register* (SR) keeps track of various conditions in the computer. For example, it tells the control unit when the keyboard has been typed on so the control unit knows to get input. It also notices if something goes wrong during an instruction execution, for example an attempted divide by 0, and tells the control unit to halt the program or fix the error. Certain bits in the status register are known as the *condition codes*, flags set by each instruction. These flags tell information about the result of the latest instruction, such as if the result was negative, positive or zero and if an arithmetic overflow or a carry error occurred. The flags can then be used by a conditional branch to decide if that branch should be chosen.

MEMORY

Computers and other digital circuits rely on stored information, either data to be acted upon or instructions to direct circuit actions. This information is stored in memory devices, in binary form. Comput-

ers use four main types of memory, as shown in Fig 5.85.

Accessing a Memory Item

Memory devices consist of a large number of memory cells each capable of remembering one bit of binary information. The information in memory is stored in digital form with collections of bits, called words, representing numbers and symbols. The most common symbol set is the American National Standard Code for Information Interchange (ASCII). Words in memory, just like the letters in this sentence, are stored one after the other. They are accessed by their location or address. The number of bits in each word, equal to the number of memory cells per memory location, is constant within a memory device but can vary for different devices. Common memory devices have word sizes of 8, 16 and 32 bits.

Addresses and Chip Size

An *address* is the identifier, or name, given to a particular location in memory. Since this address is expressed as a binary number, the number of unique addresses available in a particular memory chip is determined by the number of bits to express the address. For example, a memory chip with 8 bit addresses has $2^8 = 256$ memory locations. These locations are accessed as the addresses 00000000 through 11111111, 0 through 255 decimal or 00 through FF hex. (For ease of notation, programmers and circuit designers use hexadecimal (base 16) notation to avoid long strings of 1s and 0s.) The memory chip size can be expressed as $M \times N$, where M is the number of unique addresses, or memory locations and N is the word size, or number of bits per memory location. Memory chips come in a variety of sizes and can be arranged, together with control circuitry and decoders, to meet a designer’s needs.

Memory chips, no matter how large or small, have several things in common. Each chip has address, data and control lines. A memory chip must have enough

Fig 5.85 — Computer memory types.

address lines to uniquely address each of its words and as many data lines as there are bits per word. Memory size is usually specified in kilobytes (kbyte). This is usually abbreviated as K. Notice this is not quite the same as the metric prefix kilo, because it represents 1024, rather than 1000. When checking memory size on a PC, using various programs and tools, it is very common to see slightly different numbers as a result of these checks and tools. These differences are usually due to some processes giving results in increments of 1024 and some is actual increments of 1000.

Memory Types

The concepts described above are applied to several types of random-access, semiconductor memory. Semiconductor memories are categorized by the ease and speed with which they can be accessed and their ability to “remember” in the absence of power.

SAM versus RAM

One way to categorize memory is by which memory cells can be accessed at a given instant. *Sequential-access memory* (SAM) must be accessed by stepping past each memory location until the desired location is reached. Magnetic tapes implement SAM. To reach information in the middle of the tape, the tape head must pass over all of the information on the beginning of the tape. Two special types of SAM are the queue and the push-down stack. In a *queue*, also called a first-in, first-out (FIFO) memory, locations must be read in the order that they were written. The queue is a first-come, first-served device, like a line at a ticket window. The push-down stack is also called last-in, first-out (LIFO) memory. In LIFO memory, the location written most recently is the next location read. LIFO can be visualized as a stack, always adding to and removing from the top of the stack. *Random-access memory* (RAM) allows any memory cell to be accessed at any instant, with no time wasted stepping past the beginning parts of the data. Random-access memory is like a bookcase; any book can be pulled out at any time.

It is usually faster to access a desired word in RAM than in SAM. Also, all words in RAM have the same access time, while each word in a SAM has a different access time based on its position. Generally, the semiconductor memory devices internal to computers are random-access memories. Magnetic devices, such as tapes and disks, have at least some sequential access characteristics. We will leave tapes and disks for a later section and con-

centrate here on random-access, solid-state memories.

Random Access Memory

Most RAM chips are *volatile*, meaning that stored information is lost if power is removed. RAM is either static or dynamic. *Dynamic RAM* (DRAM) stores a bit of information as the presence or absence of charge. This charge, since it is stored in a capacitor, slowly leaks away and must be refreshed periodically. Memory refresh typically occurs every few milliseconds and is usually performed by a dynamic RAM controller chip. *Static RAM* (SRAM) stores a bit of information in a flip-flop. Since the bit will retain its value until either power is removed or another bit replaces it, refresh is not necessary.

Both types of RAM have their advantages and disadvantages. The advantage of DRAM is increased density and ease of manufacture, making them significantly less expensive. SRAMs, however, have much faster access times. Most general purpose computers use DRAMs, since large memory size and low cost are the major objectives. Where the amount of memory required doesn't justify the use of DRAM, and the faster access time is important, SRAMs are common, for example, in embedded systems (telephones, toasters), battery powered devices, and for cache memories. Cost, power consumption and access time, provided in manufacturers' data sheets, are factors to consider in selecting the best RAM for a given application.

New acronyms for various new memory types appear to be invented daily. The only solution to this problem is to do an internet-based search on an unfamiliar acronym; any result brought up by the search engine over 6-months old is almost certain to be obsolete!

Read-Only Memory

Read-only memory (ROM) is nonvolatile; its contents are not lost when power is removed from the memory. Despite its name, all ROMs can be written or programmed at least once. The earliest ROM designs were “written” by clipping a diode between the memory bit and power supply wherever a 0 was desired. Modern MOS ROMs use a transistor instead of a diode. Mask ROMs are programmed by having ones and zeros etched into their semiconductors at manufacturing time, according to a pattern of connections and non-connections provided in a mask. Since the programming of a mask ROM must be done by the manufacturer, adding expense and time delays, this type of ROM is primarily used only in high

volume applications.

For low-volume applications, the programmable ROM (PROM) is the most effective choice since the data can be written after manufacture. A PROM is manufactured with all its diodes or transistors connected. A PROM programmer device then burns away undesired connections. This type of PROM can be written only once.

Two types of PROMs that can be erased and reprogrammed are EPROMs and EEPROMs. The transistors in UV erasable PROMs (EPROMs) have a floating gate surrounded by an insulating material. When programming with a bit value, a high voltage creates a negative charge on the floating gate. Exposure to ultraviolet light erases the negative charge. Similarly, electrically erasable PROMs (EEPROMs) erase their floating-gate values by applying a voltage of the opposite polarity.

Besides being nonvolatile, PROMs are also distinguished from RAMs by their read and write times. RAM read and write times are nearly equal, in the nanosecond range. Naturally, since PROMs are only written to infrequently, they can have slow write times (in the millisecond range). Their read times, however, are near those of RAM. Two factors make it hard to write to PROMs: (1) PROMs must be erased before they can be reprogrammed and (2) PROMs often require a programming voltage higher than their operating voltage.

ROMs are practical only for storing data or programs that do not change frequently and must survive when power is removed from the memory. The BIOS program that starts a computer when it is first switched on or the memory that holds the call sign in a repeater IDer are prime candidates for ROM.

Nonvolatile RAM

For some situations, the ideal memory would be as nonvolatile as ROM but as easy to write to as RAM. The primary example is data that must not be allowed to perish despite a power failure. Low-power RAMs can be used in such applications if they are supplied with NiCd or lithium cells for backup power. A more elegant and durable solution is nonvolatile RAM (NVRAM), which includes both RAM and ROM. The standard volatile RAM, called shadow RAM, is backed up by nonvolatile EEPROM. When the RECALL control is asserted, such as when power is first applied, the contents of the ROM are copied into the RAM. During normal operation, the system reads and writes to the RAM. When the STORE control is triggered, such as by a power failure or before turning off the system, the entire contents of the RAM are copied into the ROM for nonvolatile storage. In

the event of primary power failure, to successfully save the RAM data, some power must be maintained until the memory store is complete, generally about 20 ms.

Cache versus Main Memory

Memory is in high demand for many applications. To balance the trade-off of speed versus cost, most computers use a larger, slower, but cheaper main memory in conjunction with a smaller, faster, but more expensive cache memory. As you run a computer program, it accesses memory frequently. When it needs an item, a piece of data or the next part of the program to execute, it first looks in the cache. If the item is not found in the cache, it is copied to the cache from the main memory. As you run a computer program, it often repeats certain parts of the program and repeatedly uses pieces of data. Since this information has been copied to the high-speed cache, your computer game or other application can run faster. Information used less often or not being used at all (programs not currently being run) can stay in the slower main memory.

A “cache” is a place to store treasure; the treasure, the information you are using frequently, can be accessed quickly because it is in the high-speed cache. The use of cache versus main memory is managed by a computer’s CPU so it is transparent to the user. The improvement in program execution time is similar to accessing a floppy disk versus the computer’s internal memory.

I/O TRANSFERS

No computer will perform useful work without some means of communicating with the real world. Its input and output system allow the computer to react to and affect the outside world. The ability to interact with their environment is a primary reason why computers are so useful and cost-effective. Often, I/O is provided by a user, and a great deal of effort goes towards making computers user-friendly. Alongside the drive for user-friendly computers is the drive for automation. Data are acquired and operations are performed automatically, such as the packet bulletin board automatically forwarding a message.

BUS STRUCTURE: LOCAL BUSESSES

Tying the blocks together is the data bus, the main information corridor inside the computer. The bus carries signals to and from various components, such as the CPU, the keyboard, mass storage, and communications ports. The first IBM PC

and compatibles used the 62-pin, 8-bit, 8-MHz ISA bus, which was revised to the AT-bus, a 98-pin, 16-bit wide 8-MHz bus. Other pre-PCI bus architectures include Apple’s NuBus, the Extended Industry Standard Architecture (EISA), and the VESA Local Bus.

The slow ISA bus was a bottleneck to system performance, so a separate bus was implemented between the microprocessor and main memory. This bus was called a *local bus*, as it was local to the CPU and memory only. Eventually, graphics and hard disk drive speeds increased to the point where they could ride on the local bus as well, without impacting memory access performance. Present computer systems are built around the Peripheral Components Interface (PCI-X) bus, a 64-bit wide system running at 133 MHz or higher.

The need to remain compatible with older PC architectures and conventions has hampered bus development and changes. As a result, instead of the invention of a host of new bus structures, most new PCs now include external bus attachments, such as USB. This permits attachment of more and faster devices than the older bus structures would allow.

PERIPHERALS

Peripherals work with the CPU and memory to provide additional capabilities. One of the most common examples is communication with a user via input devices and output devices. Peripherals may be divided into three groups: bidirectional (input/output) devices, input devices, and output devices. Bidirectional devices allow data storage and communications with the outside world. Input devices provide the computer both data to work on and programs to tell it what to do. Output devices present the results of computer operations to the user or another system and may even control an external system. Both input and output combine to provide user-friendly interaction. Most of these devices have adapted to certain standards and use readily available connectors and cables, enabling easy incorporation into a system. Knowledge of how external memory devices work is more useful and will be discussed in more detail.

Bidirectional Input/Output Devices

Mass storage and communications devices provide data input as well as output. Perhaps the most important peripheral in the computer system is the mass storage unit, such as the *disk drive*. Another important I/O unit is the *modem* (a contraction of MODulator/DEModulator), which allows easy communication between com-

puters across standard telephone lines. A third is the *local area network* (LAN) card, which provides high speed communications between nearby computers.

Hard Disk Drives

An electromechanical hybrid, the hard disk drive provides the largest capacity at the lowest cost per byte of any random-access storage media. Hard drives are an essential part of present computer systems. Their key features include:

- Low cost per byte of storage.
- Large capacity available.
- Random access to data.
- Non-volatile magnetic storage.

Hard drives consist of three main units, the *head/disk assembly* (HDA), the *read/write channel*, and the *controller*. The HDA comprises the mechanical portion of the assembly, with one or more aluminum disks mounted on a spindle, which is rotated by a brushless dc motor, generally between 3600 and 7200 rpm. Read/write heads are mounted on an actuator arm that sweeps across the disk surfaces. The read/write amplifier is affixed to the actuator by a flexible cable to provide the lowest possible noise pickup. Read/write heads do not touch the disk surface; instead, air flowing over the rapidly spinning disk causes them to fly slightly above the disk. “Slightly” is no exaggeration — typical flying heights of drives made in the year 2000 are approximately two millionths of an inch (about 500 nanometers). Due to these extremely tight tolerances, the entire HDA is enclosed in a sealed aluminum casting that prevents contamination. As shown in **Fig 5.86**, debris such as a hair or a dust particle tower over the flying heads.

The drive controller performs data caching and communication with the host bus. Common hard drive busses include the EIDE (Extended Integrated Device Electronics), the (similar) ATA (AT-Attachment), and SCSI (small computer systems interface). External hard drives, interfacing with USB ports, are now both readily available and provide portability from PC to PC. In fact, some newer PCs now will boot from an external drive. Instead of carrying a PC from location to location, just unplug these thumb-sized drives and plug them back in at the new location.

Data is stored on both surfaces of each disk in concentric arcs called sectors, as shown in **Fig 5.87**. All sectors on one surface a given distance from the disk edge constitute a track. A cylinder is the collection of all similar tracks on all surfaces of the drive. When a new drive is installed, most newer PCs and their BIOS will rec-

Fig 5.86 — Hard disk drive head flying height compared to common debris size.

ognize the new drive and set the BIOS directly for the new drive.

Occasionally, when installing a hard drive in an older PC, the motherboard must be informed of the number of disk heads and sectors available. Often, the number entered is not the actual number of physical heads and sectors, as intelligent controllers map data requests to the proper physical location without burdening the CPU with the fine details.

Important hard disk drive parameters include bus type (for compatibility with your system), storage capacity, average and worst-case seek time, and size of onboard cache. Seek times are dominated by mechanical considerations, such as the time the read head arms require to settle from track to track or from one edge to the other, and by the rotational speed of the disk. Better overall performance is expected with larger on-board cache memory. The best drives have high capacity, fast seek times, and large caches.

Floppy Disk Drive

The most common storage peripheral in the PC is the 3.5-in., 1.44 MB floppy disk drive. The floppy drive operates similarly to its higher speed/higher capacity brother, but its media is removable and it does not offer much on-board intelligence. Floppy disks enclose the magnetic-media platter in a protective casing, as shown in **Fig 5.88**, so the disk can be carried around. The floppy disk can be inserted into a disk drive and the read/write head automatically extended. When the recording is complete, the read/write head is automatically retracted before the disk is ejected from the drive.

Most standard PCs contain a cable to connect a single floppy. This cable may be replaced with one that allows connection of two floppies. Some PCs have a cable that permits the connection of two floppies. The first drive, drive A, attaches to the *end* of the standard “twisted” control cable; if only one drive is used, leave the middle connector free. The twist in the cable causes the floppy controller to recognize the end drive as **drive A**; while the second drive — if you connect one — registers as **drive B**, and is before the twist.

Fig 5.88 — Standard 3.5-in. floppy disk.

Other Magnetic Disk Drives

Disk drives featuring moderate storage capacity and performance with removable media are available, such as the Iomega Zip and Jazz, and the Imation SuperDrive. These drives use the same basic techniques as the hard drives, but with somewhat looser mechanical tolerances that allow an unsealed disk chamber and more flexible media. These drives are available with EIDE, SCSI, parallel port, USBs, and PC-Card interfaces for internal or external use. Previously very widely used for both back-up and transferring data from PC to PC, these proprietary drives are now competing with very inexpensive hard drives and USB connected hard drives. Adding a second hard drive and cloning the first hard drive (Drive C:) to the second is a popular back-up technique. Using a USB-connected hard drive for data transfer also is very convenient and popular.

Optical Storage

The audio compact disc evolved into the CD-ROM offering over 600 MB of storage on a very low-cost, single-sided platter. Initially a read-only media, writable and re-writable discs are used as removable mass storage. While media cost is low, the low performance and restricted number of write sessions, even on the re-writable discs, prevent these technologies from competing with the magnetic hard drive except in archival or other applications where removability is important. Another transplant from the consumer entertainment industry, the DVD is another important optical storage format. Similar in appearance to CD-ROM discs, DVDs offer up to 8.5GB of storage capability per disc.

Both the CD-ROM and the DVD use a laser and an optical system to detect the surface deformities that represent data. Unlike the hard disk and floppy drives, which employ concentric tracks, the optical drives use a spiral pattern that works out from the center. Also, more elaborate data handling is necessary since the raw data error rate is significantly higher than that from magnetic drives.

All drives and disks eventually fail, and the data on the disk can be lost. Therefore, it is prudent to make backup copies of your disks, stored in a clean, dry, cool place.

Tape

Tape is one of the more inexpensive options for auxiliary memory. Tape access time is slow, since the data must be accessed sequentially, so tape is primarily used for backup copies of a system's hard drive. Tape is available in cassette form (common sizes are comparable to the cas-

ettes for a portable tape player and VCR tapes) and on digital-audio tape (DAT). A single 4-mm-wide DAT cartridge, which fits in the palm of your hand, can hold over 2 gigabytes (GB) of data (1 GB = 1000 MB). Tape units are rarely used now in home PCs, but they are often seen at hamfests as obsolescent equipment.

Modems

Nearly all computers assembled today include a modem for connecting to the Internet via standard telephone lines. Besides connecting to an ISP or online service, this peripheral may call another modem-equipped PC or send standard facsimiles. The so-called 56-k modem uses V.90 protocol with its sophisticated DSP techniques providing echo cancellation and dynamic line equalization. This protocol uses the telephone line to gain every possible bit per second of data transfer rate. While the data rate never reaches 56 kbps, if the modem is less than four miles from the telephone central office, expect speeds of 40 kbps to 53 kbps. Achieving the 56 kbps rate would necessitate increasing transmission power above the -9 dBm limit and could cause excessive crosstalk between lines. The V.90 specification has an unusual characteristic in that the bit rate is non-symmetrical. The modem originating a call is limited to approximately 33 kbps while the answering modem runs up to 53 kbps. This compromise was made because most modem traffic is between a user and an ISP, where the user downloads much more data from the World Wide Web than he uploads.

Modems are available in three configurations, internal, external, and PC-Card. Internal modems plug directly into the computer motherboard, external devices attach to a serial port, and PC-Card (often called PCMCIA) modems plug into a PC-Card slot. The internal version is the least expensive and most common. PC-Card modems are popular with notebook computers due to their small size. External modems offer the advantage of providing immediate visual feedback of all data transfer activity. Additionally, external modems provide another level of surge protection to the computer system; if a destructive surge travels through the phone line it *might* be stopped outside the PC cabinet by the external modem.

Input Devices

The keyboard is probably the most familiar input device. A keyboard simply makes and breaks electrical contacts. The open or closed contacts are usually sensed by a microprocessor built into the circuit board under the keys. This microprocessor

decodes the key closures and sends the appropriate ASCII code to the main computer unit. Keyboards will generate the entire 128-character ASCII set and often, with CONTROL and ALT (Alternate) keys, the 256-character extended ASCII set.

The mouse is a close second in familiarity to the keyboard. This pointing device controls the position of a cursor on the screen, and switches on the mouse make and break connections (clicking) to select and activate items (icons) on the screen. Touchpads, trackballs, and pen input on a sensitive screen are variations of the mouse and may offer a more natural, human-friendly interface to the computer. Voice recognition systems promise even easier data entry.

Digital cameras and streaming video cameras allow quick transfer of images into the computer realm.

Image scanners digitize photographs and older printed pages, allowing reuse of material without laboriously recreating the work. Scanners are available in four major configurations: handheld, sheet feed, flatbed, and drum. The handheld scanner is low cost and very portable. The sheet feed scanner is also small and is easier to use, since pages are better aligned. Flatbed scanners are an economical and a moderately high resolution means of entering data from book or other bound sources. Drum scanners provide the best resolution and color reproduction, but their high cost relegates them to professional graphics shops.

Output Devices

The most familiar output device is the computer screen, or monitor. The next most common output device is the printer, to produce paper hardcopy. Sound cards provide high-fidelity-stereo audio.

Monitors and most printers share a common display technique: images, such as characters and graphics, are formed by tiny dots, called *pixels* (picture elements). On screens, these are dots of light turned on and off. In printers, they are dots of ink or electrostatic toner imposed onto the paper. For color displays, pixels in red, green and blue (RGB) are spaced closely together and appear as colors to the human eye.

Video Displays

Video monitors are usually specialized high-resolution cathode-ray tube (CRT) displays, except in notebook computers, which use screens fabricated with liquid-crystal displays (LCDs). Most monitors employ *raster scanning* techniques to turn on the screen pixels, similar to that used by standard broadcast television receiv-

Fig 5.89 — An example of daisy-chained transmit level controls. Note that the controls are in series, and the resultant output is affected by each of the prior control settings.

ers. The electron beam paints the screen one row of pixels at a time, from left to right and top to bottom. Then, a vertical retrace brings the beam back to the top of the screen to begin again. Raster scanning signals every pixel on or off for each screen pass.

Printers

Printers suitable for hamshack use generally fall into two categories, inkjet and laser. The inkjet printer uses a controlled spray of liquid ink to produce images. Photographic-quality full-color prints are possible when the proper paper and ink is employed.

Laser printers produce exceptionally crisp text and graphics in black or a few colors at relatively high speed and low cost per page. While color laser printers do not (yet) produce the lifelike quality images of inkjets, they are not as fussy about the quality of the paper used, and its powdered *toner*, or “ink,” does not dry up when stored in the printer over time as does the inkjet pigment. The use of dry paper is important, especially with many inkjet printers.

Today’s state of the art in manufacturing and construction has made possible a host of very inexpensive inkjet printers, both black and white and color. There are several disadvantages to many of these units. First, and most noticeable, is the cost of replacement cartridges, especially color cartridges. It is not uncommon to pay under \$100 for one of these printers and discover that two or three sets of cartridges, easily used up in a single year, cost the same as the printer. Some manufacturers have configured their printers so that when the ink goes below a certain level, the printer stops and no further operation is possible. Thus even if you wish to print in black and white, an exhausted color cartridge might prevent you from doing so. Finally, some printers are configured with a *smart chip* that prevents you from manually refilling a cartridge. The refilled cartridge may be full; the chip tells the printer it is empty.

Sound Cards

Your PC will produce and record full

CD-quality audio when a suitable sound card and speaker system is deployed. Microphone and auxiliary inputs and line level outputs on the sound card let the PC serve as a contest voice keyer. When the proper software is used, it can also serve as a RTTY, CW, Pactor, PSK31, etc, terminal.

PCs running various versions of the Windows operating system do have a major annoyance in their use of soundcards. **Figure 5.89** shows a typical installation, where a PC with a sound card is the source of transmitted data. There may be as many as three level or gain controls on the PC software, perhaps one in the interfacing unit and effectively one to three in the transmitter. While all controls in the interface units and the transmitter tend to remain set, unless manually changed, that is not always true for the controls in the PC software. Some of these level set controls may revert back to a nominal value after re-booting the PC, and often several tries will be needed to set a system so that the constantly reverting levels do not have to be touched. For further information on this problem, see *QST*, Oct 2003, page 33, *The Ins and Outs of a Sound Card*.

COMMUNICATIONS: INTERNAL AND EXTERNAL INTERFACING

Designing an interface, or simply using an existing interface, to connect two devices involves a number of issues. For example, digital interfacing can be categorized as parallel or serial, internal or external and asynchronous or synchronous. Additional issues are the data rate, error detection methods and the signaling format or standards. The format can be especially important since many standards and conventions have developed that should be taken into consideration. This section focuses on some basic concepts of digital communications for interfacing between devices.

Parallel Versus Serial Signaling

To communicate a word to you across the room, you could hold up flash cards displaying the letters of the word. If you

hold up four flash cards, each with a letter on it, all at once, then you are transmitting in parallel. If instead, you hold up each of the flashcards only one at a time, then you are transmitting in serial. *Parallel* means all the bits in a group are handled exactly at the same time. *Serial* means each of the bits is sent in turn over a single channel or wire, according to an agreed sequence. **Fig 5.90** gives a graphic illustration of parallel and serial signaling.

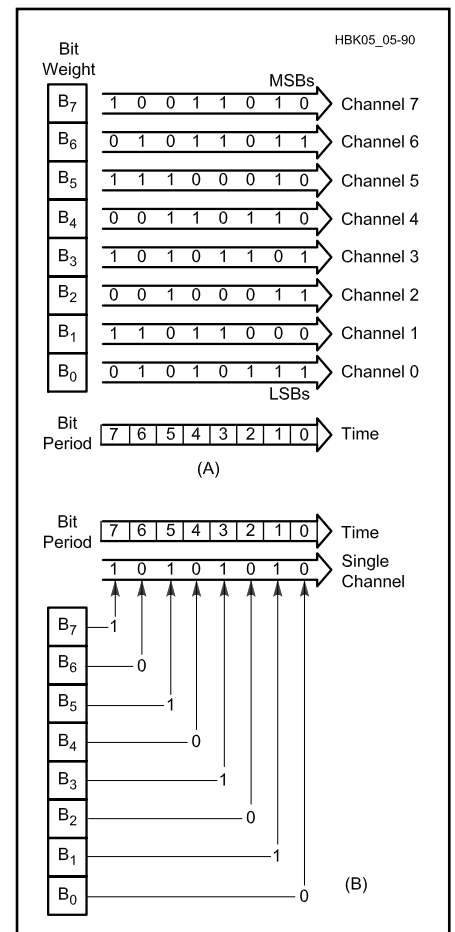

Fig 5.90 — Parallel (A) and serial (B) signaling. Parallel signaling in this example uses 8 channels and is capable of transferring 8 bits per bit period. Serial transfer only uses 1 channel and can send only 1 bit per bit period.

Interfacing To The Parallel Port

While there is a choice of ports on the PC for Amateur use and direct interfacing, the parallel port is probably the simplest. With eight data wires, several control wires and bidirectional capability, it offers a convenient way to get information in and out of a PC. The examples in the next two sections use an older software language, BASIC or GWBASIC to get information in and out. Newer languages can be used, however several varieties of BASIC are available on the internet at no cost, and the learning curve for someone who has never used a programming language is very short — usually a matter of a few minutes. The two examples that follow interface single chip analog to digital and digital to analog converters to the parallel port of a PC.

Single-Chip Dual-Channel A/D

In this analog world, often there is need to measure an analog voltage and convert it to a digital value for further processing in a PC. This single chip converter and accompanying software performs this task for two analog voltages.

Circuit Description

The circuit consists of a single-chip A/D converter, U2, and a DB-25 male plug (Fig A). Pins 2 and 3 are identical voltage inputs, with a range from 0 to slightly less than the supply voltage V_{CC} (+5 V). R1, R2, C3 and C4 provide some input isolation and RF bypass. There are four signal leads on U2. DO is the converted data from the A/D out to the computer; DI and CS are control signals from the computer, and CLK is a computer-generated clock signal sent to pin 7 of U2.

The +5-V supply is required. It may be obtained from a +12-V source and regulator U1. Current drain is usually less than 20 mA, so any 5-V regulator may be used for U1. The power supply ground, the circuit ground and the computer ground are all tied together. If you already have a source of regulated 5 V, U1 is not needed.

In this form the circuit will give you two identical dc voltmeters.

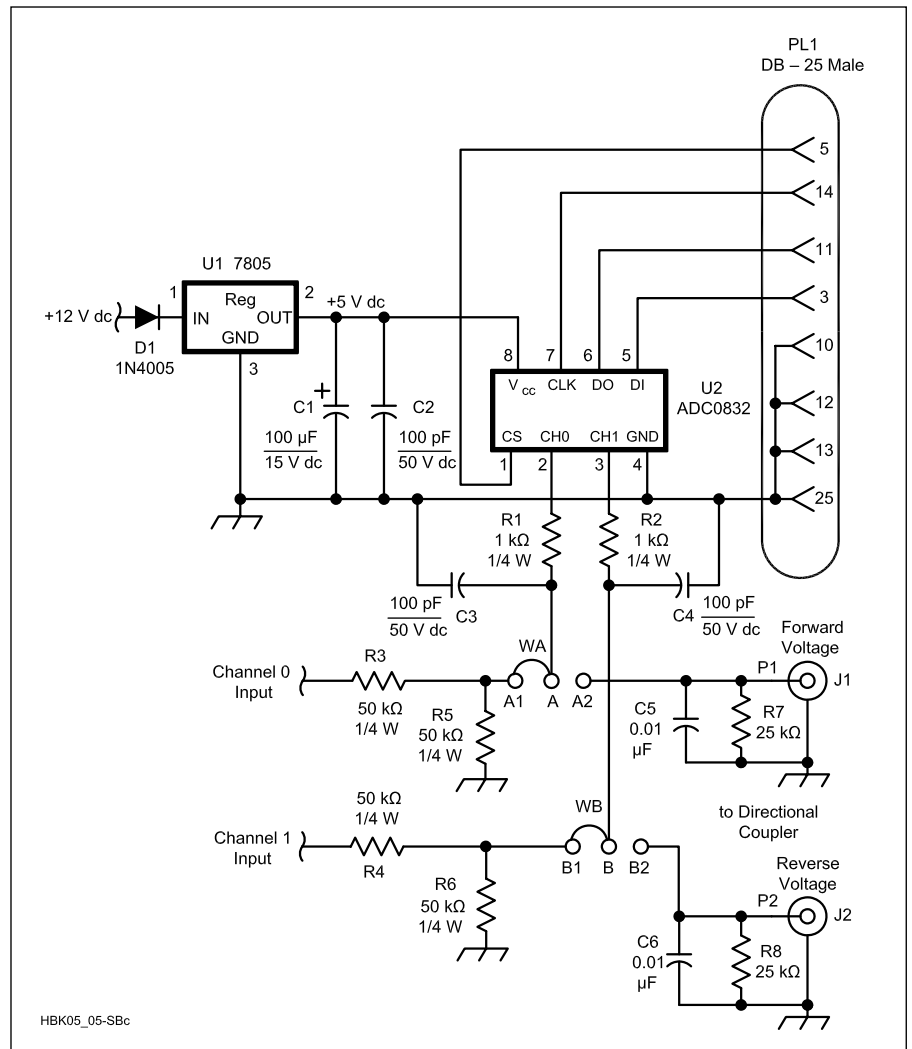

Fig A — Only two chips are used to provide a dual-channel voltmeter. PL1 is connected through a standard 25-pin cable to your computer printer port. U2 requires an 8-pin IC socket. All resistors are 1/4 W. You can use the A/D as an SWR display by connecting it to a sensor such as the one shown in Chapter 19 of this *Handbook* (Tandem Match Wattmeter project). A few more resistors are all that are needed to change the voltmeter scale. The 50-kΩ resistors from 2:1 voltage dividers, extending the voltmeter scale on both channels to almost 10 V dc.

To extend their range, connect voltage dividers to the input points A and B. A typical 2:1 divider, using 50-kΩ resistors, is shown in the figure. Resistor accuracy is not important, since the circuit is calibrated in the accompanying software.

Software

The software, *A2D.BAS*, includes a voltmeter function and an SWR function. It is written in *GWBASIC* and saved as an

ASCII file. Therefore, you can read it on any word processor, but if you modify it, make sure you re-save it as an ASCII file. It can be imported into *QBasic* and most other Basic dialects.

The program was written to be understandable rather than to be highly efficient. Each line of basic code has a comment or explanation. It can be modified for most PCs. The printer port used is LPT1, which is at a hex address of 378h. If you wish to use LPT2

(printer port 2), try changing the address to 278h. To find the addresses of your printer ports, run *FINDLPT.BAS*.

A2D.BAS was written to run on computers as slow as 4.7-MHz PC/XTs. If you get erratic results with a much faster computer, set line 1020(CD=1) to a higher value to increase the width of the computer-generated clock pulses.

The software is set up to act as an SWR meter. Connecting points A and B to the forward and reverse voltage points on any conventional SWR bridge will result in the program calculating the value of SWR.

Initially the software reads the value of voltage at point A into the computer, followed by the voltage at point B. It then prints these two values on the screen, and computes their sum and difference to derive the SWR. If you use the project as a voltmeter, simply ignore the SWR reading on the screen or suppress it by deleting lines 2150, 2160 and 2170. If the two voltages are very close to each other (within 1 mV), the program declares a bad reading for SWR.

Calibration

Lines 120 and 130 in the program independently set the calibration for the two voltage inputs. To calibrate a channel, apply a known voltage to input point A. Read the value on the PC screen. Now multiply the constant in line 120 by the correct value and divide the result by the value you previously saw on the screen. Enter this constant on line 120. Repeat the procedure for input point B and line 130.

D to A CONVERTERS — CONTROLLING ANALOG DEVICES

The complement to A/D converters is D/A (digital-to-analog) converters. Once there is a digital value in your PC, a D/A will provide an analog voltage proportional to the digital value. Normally the actual value is scaled. As an example, an 8-bit converter allows a maximum count of 255. If the converter is set up with a +5 Vdc reference voltage, a maximum value digital value of 255 would result in a D/A output value of 5-V. Lower digital inputs

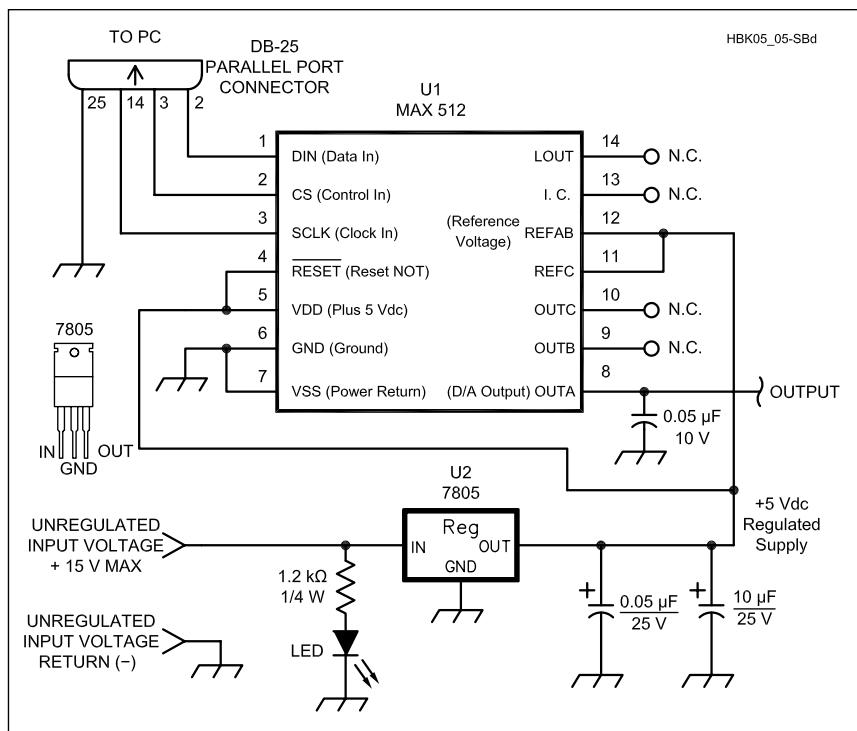

Fig B — Only three wires and a ground lead are needed to connect the converter to your PC.

would give proportionally lower voltages.

Circuit Description

This project is the complement of the parallel port A/D converter described earlier. It takes a digital number from the computer, and converts it to a voltage from 0 to 5 V dc. Only one chip, the MAX 512, is required. It operates from a 5-V supply and is connected to the computer by a standard DB-25 parallel port connector. The chip may be ordered from Digi-Key, Allied Electronics and other ham suppliers as MAX512CPD-ND. The voltage regulator in **Fig B** provides the 5-volt source required to power the chip.

Software

The software needed to run the chip, *D2A.BAS*, can be downloaded from Internet sites. It is about 60-lines long, fully commented and written in *GWBASIC*, so it may be readily modified. The parallel port address is defined on line 105 as `PORTO=&H378`. Your computer may use a different address. To find the correct

address, run *FINDLPT.BAS*.

The program takes the value AIN from the keyboard (line 230), converts it to a number between 0 and 255, and then sends it out as a serial word to the DIA chip. If you would like to use the project with another program, use your other program to set AIN to the value you want to generate, and then run this program as a subroutine.

At the end of the program is the clock pulse subroutine. In the event your computer is too fast for the converter chip, you can stretch the clock pulses by changing CD in line 5010 to a value greater than the default value of 1.

Applications

This circuit provides the capability of setting a voltage under computer control. It can be calibrated to match the power supply and the actual chip used. Tests with several chips showed an error of 25 mV or less over the range of 0 to 5 V dc output.

— Paul Danzer, N111

Both parallel and serial signaling are appropriate for certain circumstances. Parallel signaling is faster, since all bits are transmitted simultaneously, but each bit needs its own conductor, which can be expensive. Parallel signaling is more likely to be used for internal communications. For spanning longer distances, such as to an external device, serial signaling is more appropriate. Each bit is sent in turn, so communication is slower, but it is also less expensive, since fewer channels are needed between the devices.

Most amateur digital communications use serial transmission to minimize cost and complexity. The number of channels needed for signaling also depends on the operational mode. One channel is required per bit for simplex (one-way, from sender to receiver only) and for half-duplex (two-way communication, but only one person can talk at a time), but two channels per bit are needed for full-duplex (simultaneous communications in both directions).

Parallel I/O Interfacing

Fig 5.91 shows an example of a parallel input/output chip. Typically, they have eight data lines and one or more handshaking lines. *Handshaking* involves a number of functions to coordinate the data transfer. For example, the READY line indicates that data are available on all 8 data lines. If only the READY line is used, however, the receiver may not be able to keep up with the data. Thus, the STROBE line is added so the receiver can determine when the transmitter is ready for the next character.

On standard PCs, a parallel port is available using a 25-pin DB-25 connector. This port was originally intended for use with a printer. Several versions of the parallel port exist, and late-model PCs feature a high speed, bidirectional parallel port that, in addition to high-speed printing, may also interface with mass storage devices, scanners, and other I/O devices. The most common parallel ports are:

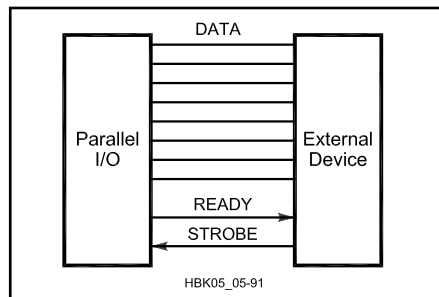

Fig 5.91 — Parallel interface with READY and STROBE handshaking lines.

- Printer Mode — The most basic, output mode only port.
- Standard & Bidirectional (SPP) — The low-speed bidirectional port
- Enhanced Parallel Port (EPP) — Uses local hardware handshaking and strobing to accomplish 500 kB/s to 2 MB/s transfer rates.
- Extended Capabilities Port (ECP) — Similar to EPP, except negotiates a reverse channel with the external peripheral and requires that peripheral controls handshaking. It is optimized for the Windows operating system and uses DMA channels, a FIFO buffer, and real time data compression of up to 64:1.

Most PCs offer a choice of port protocol in the BIOS setup. Unless you have a reason to do otherwise, select the “ECP and EPP 1.9 Mode” for maximum flexibility and performance.

Serial I/O Interfacing

Serial input/output interfacing is more complex than parallel, since the data must be transmitted based on an agreed sequence. For example, transmitting the 8 bits (b7, b6, . . . b0) of a word includes specifying whether the least significant bit, b0, or the most significant bit, b7, is sent first. Fortunately, a number of standards have been developed to define the agreed sequence, or encoding scheme. Use only IEEE specified cable to ensure availability of the correct number of conductors.

Data Rate

There are a number of limitations on how fast data can be transferred: (1) The sending equipment has an upper limit on how fast it can produce a continuous stream of data. (2) The receiving equipment has an upper limit on how fast it can accept and process data. (3) The signaling channel itself has a speed limit, often based on how fast data can be sent without errors. (4) Finally, standards and the need for compatibility with other equipment may have a strong influence on the data rate.

Two ways to express data transmission rates are *baud* and *bits per second (bps)*. These two terms are not interchangeable: Baud describes the signaling, or symbol, rate — a measure of how fast individual signal elements *could* be transmitted through a communications system. Specifically, the baud is defined as the reciprocal of the shortest element (in seconds) in the data-encoding scheme. For example, in a system where the shortest element is 1-ms long, the maximum signaling rate would be 1000 elements per

second. (Note that, since baud is measured in elements per second, the term “baud rate” is incorrect since baud is already a measure of speed, or rate.) Continuous transmission is not required, because signaling speed is based only on the shortest signaling element.

Signaling rate in baud says nothing about actual information transfer rate. The maximum information transfer rate is defined as the number of equivalent binary digits transferred per second; this is measured in bits per second.

When binary data encoding is employed, each signaling element represents one bit. Complications arise when more sophisticated data encoding schemes are used. In a quadrature-phase-shift keying (QPSK) system, a phase transition of 90° represents a level shift. There are four possible states in a QPSK system; thus, two binary digits are required to represent the four possible states. If 1000 elements per second are transmitted in a quadri-phase system where each element is represented by two bits, then the actual information rate is 2000 bps.

This scheme can be extended. It is possible to transmit three bits at a time using eight different phase angles (bps = 3 × baud). In addition, each angle can have more than one amplitude. A 9600 bps modem uses 12 phase angles, 4 of which have two amplitude values. This yields 16 distinct states, each represented by four binary digits. Using this technique, the information transfer rate is four times the signaling speed. This is what makes it possible to transfer data over a phone line at a rate that produces an unacceptable bandwidth using simpler binary encoding. This also makes it possible to transfer data at 2400 bps on 10 m, where FCC regulations allow only 1200-baud signals.

When are transmission speed in bauds and information rate in bps equal? Three conditions must be met: (1) binary encoding must be used, (2) all elements used to encode characters must be equal in width and (3) synchronous transmission at a constant rate must be employed. In all other cases, the two terms are not equivalent.

Within a given piece of equipment, it is desirable to use the highest possible data rate. When external devices are interfaced, it is normal practice to select the highest standard signaling rate at which both the sending and receiving equipment can operate.

Error Detection

Since data transfers are subject to errors, data transmission should include some method of detecting and correcting errors. Numerous techniques are avail-

able, each used depending on the specific circumstances, such as what types of errors are likely to be encountered. Some error detection techniques are discussed in the Modes and Modulation Sources chapter. One of the simplest and most common techniques, parity check, is discussed here.

Parity Check

Parity check provides adequate error detection for some data transfers. This method transmits a parity bit along with the data bits. In systems using odd parity, the parity bit is selected such that the number of 1 bits in the transmitted character (data bits plus parity bit) is odd. In even parity systems, the parity bit is chosen to give the character an even number of ones. For example, if the data 1101001 is to be transmitted, there are 4 (an even number) ones in the data. Thus, the parity bit should be set to 1 for odd parity (to give a total of 5 ones) or should be 0 for even parity (to maintain the even number, 4). When a character is received, the receiver checks parity by counting the ones in the character. If the parity is correct, the data is assumed to be correct. If the parity is wrong, an error has been detected.

Parity checking only detects a small fraction of possible errors. This can be intuitively understood by noting that a randomly chosen word has a 50% chance of having even parity and a 50% chance of having odd parity. Fortunately, on relatively error-free channels, single-bit errors are the most common and parity checking will always detect a single bit in error. However, an even number of errors will go undetected, whereas an odd number of errors will be detected. Parity checking is a simple error detection strategy. Because it is easy to implement, it is frequently used. Other more complex techniques are used in commercial data transmission services.

Standard Interface Busses

Signaling Levels

Inside equipment and for short runs of wire between equipment, the normal practice is to use neutral keying; that is, simply to key a voltage such as +5 V on and off. In neutral keying, the off condition is considered to be 0 V. Over longer runs of wire, the line is viewed as a transmission line, with distributed inductance and capacitance. It takes longer to make the transition from 0 to 1 or vice versa because of the additional inductance and capacitance. This decreases the maximum speed at which data can be transferred on the wire and may also cause the 1s and 0s to be

different lengths, called bias distortion. Also, longer lines are more likely to pick up noise, which can make it difficult for the receiver to decide exactly when the transition takes place. Because of these problems, bipolar keying is used on longer lines. Bipolar keying uses one polarity (for example +) for a logical 1 and the other (– in this example) for a 0. This means that the decision threshold at the receiver is 0 V. Any positive voltage is taken as a 1 and any negative voltage as a 0.

EIA-RS-232

The most common serial bus protocol, EIA-RS-232, addresses this issue (however, a Mark “1” is a negative voltage and a Space “0” is positive). Generally called RS-232, this protocol defines connectors and voltages between data terminal equipment (DTE) such as a PC, and data communications equipment (DCE), such as a modem or TNC. The connector is the DB-25, or the presently more popular DB-9 version. Signaling voltages are defined between +3 V and +25 V for logic “0” and between –3 V and –25 V for logic “1.” Although the top data rate addressed in the specification is only 20 kbps, speeds of up to 115 kbps are commonly used. Communications distances of hundreds of meters are possible at reasonable data rates.

Since neutral keying is usually used inside equipment and bipolar keying for lines leaving equipment, signals must be converted between bipolar and neutral. Discrete level shifters or op amp circuits may perform this task, or low cost specialized IC line drivers and receivers are available.

RS-422

RS-422 is a serial protocol similar to RS-232, but employing fully differential data lines. Differential data offers the important advantage that common grounds between remote units are not necessary, and an important cause of ground loops (and their associated problems) is eliminated. Available on many Apple Macintosh computers, RS-422 systems may connect to standard RS-232 modems and TNCs by building a cable that makes the following translations:

<i>RS-422 DTE</i>	<i>RS-232 DCE</i>
RXD–	RXD
TXD–	TXD
RXD+	GND
TXD+	No Connection
GPI	CD

IrDA (Infrared Data Access)

Another high-speed serial protocol is the IrDA, which is a simple, short range wireless system using infrared LEDs and detectors. Data rates up to 3 MB/sec are

possible between compatible units.

Universal Serial Bus (USB)

USB is a computer standard for an intelligent serial data transfer protocol. In addition to its higher speed than RS-232, USB offers reasonable power availability to its loads, or *functions*. Under certain circumstances, up to 127 hubs and functions may connect to a single computer. USBs requires that each function have on-board intelligence and that it negotiate with the host for power and bandwidth allocation, and has the major advantage of *hot-pluggability* — the PC need not reboot when new functions are added. The USB connectors use four-conductor cable, with two bidirectional, differential data lines, power, and ground. Approximately 5 V at 100 mA is allowed per function, with up to 500 mA available if the host system has the capability. This means that relatively sophisticated devices, such as modems, small video cameras, or hand-held scanners may operate from the bus without additional power supplies. Preventing power back-flowing up from function to host is accomplished by configuring the connector shapes such that the host has a rectangular connector while that of functions are nearly square.

There are currently two USB standards. USB 1.1, somewhat obsolete but common in PCs just a few years old, is capable of 12 megabits per second (12 Mbps). USB 2.0 is the later standard and is rated up to 480 Mbps. Most USB 2.0 ports will allow the use of older USB 1.1 devices—that is they are backwards compatible. However maximum cable lengths and available power to devices may be affected.

IEEE-1394 (FireWire)

A very high speed serial protocol, IEEE-1394 (christened “FireWire” by its creator, Apple Computer), is capable of up to 400 Mbps of sustained transfer. It is ideal for high bandwidth systems, such as live video, external hard drives, or high-speed DVD player/recorders. Up to 63 devices may daisy-chain together at once via a standard six-wire cable. Unlike USB, 1394 is peer-to-peer, meaning any device may initiate a data transfer — the PC does not have to initiate a data transfer. Similar to USB, IEEE-1394 is hot-pluggable and provides power on the cable, but the voltage may vary from 7 V to almost 40 V, and may be sourced by any device. Allowable current drain per device may reach 1 A.

PC-Card (PCMCIA)

The PC-Card Standard is a collection of specifications for miniature plug-in peripherals. The most common is colloquial-

ally referred to as PCMCIA cards — 68-pin devices the size of thick credit cards that contain a modem, LAN, GPS receiver, USB port, FireWire port, high resolution video, an extra serial or parallel port, or memory storage expansion. The standard PC-Card allows up to 5 V at 1 A peak current, or 3.3 V at 1 A, depending upon configuration. Other voltages may be used if available from the host. Other portions of the specification define memory storage-only cards in even smaller footprints.

Small Computer System Interface (SCSI)

SCSI interfaces provide for up to 320 MB/s transmission rates with up to 15 devices. Used mostly with disk drives, the “skuzzy” bus also supports a very wide variety of high-speed peripherals. A wide variety of bus widths, speeds, and connectors exist. With the widespread use of USB, SCSI is no longer generally used except where large numbers of storage disks are needed — primarily in commercial installations.

10Base2, 10BaseT, 10Base4, 100BaseT

Common office/home networks use 10BaseN protocol. 10Base2 is generally recommended for Amateur Radio installations, since it uses shielded cable (RG-58, renamed “thin coax” in this application). Additionally, no separate hub is needed as the connected computers work on a peer-to-peer basis. A drawback of 10Base2 is its maximum data rate is limited to 10 Mbps. Also, shorter runs may occasionally require a simple extension in length of approximately 30-50 feet for proper operation. The other protocols use one or more hubs, RJ-45 connectors, and unshielded Category 5 cable. 100BaseT systems are rated to 100 Mbps.

Explanation of the *MBaseN* and *Category N* terminology can be found in many available networking books. Newer home networks are wireless; often, they are more trouble-free from high power Amateur Radio installations because the unshielded cable used for wired networks tends to pick up RF readily. Unfortunately, high power VHF and UHF installations may pose problems with wireless networks.

POWER SYSTEMS AND ATX

When the initial personal computers were designed, the most common logic family was TTL and CMOS that interfaced with TTL levels at 5 V. Disk drive and fan motors preferred +12 V. RS-232 demanded a higher voltage bipolar supply, so -12 V was added to complement the

12 V already used. The analog portion of the early modems required -5 V. Thus, the initial “silver box” PC supply provided +5 V at high current, +12 V at moderate current, and -5 V and -12 V at low current. Advances in semiconductor technology allowed shrinking transistor geometries. The smaller transistors were faster, but they had lower breakdown voltages, thus a new logic voltage of 3.3 V was introduced. Initially, computer manufacturers responded by placing IC regulators on the motherboard to power the 3.3-V circuits, but eventually the current demanded by these circuits exceeded that of the traditional +5V components and a new physical standard, called ATX, was introduced.

The ATX standard defines a layout physically different from older “AT-type” computers. The computer case, motherboard mounting holes, expansion slot location, and the power supply and its connector are all changed. ATX computers are recommended for the hamshack due to their better RFI control, resulting from careful mechanical design of connectors and consideration of card slot case penetration. ATX power supplies produce +3.3 V, +5 V, +12 V, -5 V and -12 V. They also provide an output voltage, even when the power supply is otherwise off, allowing *sleep mode* operation. Sleep mode retains the computer RAM contents and configuration so a reboot is not necessary each time the computer is used, and is especially critical to extending battery life in notebook PCs.

As semiconductor technology continued improving, the 3.3 V source became too high for the fine-geometry microprocessors, and an even lower voltage was required. At present, there is no standard for the next lower voltage, but devices are available that need anywhere between 1 V to 2.8 V for the microprocessor core (densest portion). Motherboard manufacturers have addressed this issue by again using on-board voltage regulators to drop an existing ATX standard voltage to the value needed by the CPU. Since there is no standard — in fact, the exact voltage preferred by a given processor family decreases as the manufacturing process evolves — motherboards provide means of selecting the matching voltage. Sometimes this process is automatic, as the on-board power supply communicates with the microprocessor before initializing and rises to the proper voltage, but other times, jumpers must be manually positioned *before* initial power is applied. Using a higher than recommended supply voltage causes excessive operating temperature and stresses the gates of the CMOS tran-

sistors, leading to reduced reliability and early (sometimes immediate) circuit death.

Power supplies removed from older computers are readily available, and there is a great temptation to reuse them for other amateur applications. Unfortunately, there is very little control on the manufacturers of these units, and quite often the expected 5-VDC, 10-amp output is poorly regulated except at currents such as one or two amperes. Many of the newer units do not have an on-off switch, but depend on connecting one lead to ground for some period to turn the supply on and off. Even when off, a portion of the supply is on to provide control voltages. Many computer handbooks and texts contain tables of the connections to the various PC power supplies, complete with wire colors. However, there is no way to tell if compliance with the color codes has been followed. Hence, use of these supplies should be limited to those voltage sources that can be measured on a particular supply.

Powering Small Circuits

Small amounts of power can be ‘stolen’ from the serial port to power devices interfacing with a PC. The signals on the serial port, in accordance with the various versions of RS-232, generally range from +15 VDC to -15 VDC. By selecting several control signals and knowing that one of these signals will be at the positive voltage level, the power source in **Fig 5.92** can be used. The amount of current available will vary depending on the specific interface chip and chip supplier for the particular PC.

By reversing the diodes and filter capacitor a negative supply can be built. The regulator should be chosen for the negative or positive supply, as needed. Most PCs will not have any difficulty supplying 10 ma, or slightly more.

Fig 5.92 — Small amounts of power can be ‘stolen’ from the serial port with this circuit. See the Component Data and References chapter for the 7805 pin connections.

Power Quality

As operating voltages drop, power quality — the measure of voltage accuracy and transient response to changing load currents — becomes simultaneously more critical and more difficult. A 500-mV spike represents a 10% error in a 5-V supply, but the same 500-mV spike applied to a 2-V processor represents an overvoltage of 25%, grossly exceeding the maximum rated supply voltage for that controller. Further, if the spike is of the opposite polarity, it seriously reduces the noise mar-

gin of the logic-high levels, possibly corrupting data.

Providing clean power becomes more difficult when the effects of sleep mode are considered. Microprocessors reduce their power consumption when idle by slowing down internal clocks and other techniques, but when called back to duty, their response occurs in nanoseconds. The result is a huge change in supply current, from nearly zero to maximum current flow in those few nanoseconds. Large voltage spikes may result from this fast rise-time current step working against the induc-

tance of the PC board power supply traces. Careful power supply design, especially during layout, and judicious use of low ESR, and low-inductance bypass capacitors mitigate the transients and keep the system reliable.

STANDARD COMPUTER CONNECTIONS

See the **Component Data and References** chapter for details on computer connector pinouts. You'll also find details on cables, such as a null modem cable.

Chapter 6

Real-World Component Characteristics

When is an inductor not an inductor? When it's a capacitor! This statement may seem odd, but it suggests the main message of this chapter. In the earlier chapter about **Electrical Fundamentals**, the basic components of electronic circuits were introduced. You saw that each has its own unique function to perform. For example, a capacitor stores energy in an electric field, a diode rectifies current and a battery provides voltage. All of these unique and different functions are necessary in order to build large circuits that perform useful tasks. The first part of this chapter, up to Low-Frequency Transistor Models, was written by Leonard Kay, K1NU.

As you may know from experience, these component pictures are *ideal*. That is, they are perfect mathematical pictures. An ideal component (or *element*) by definition behaves exactly like the mathematical equations that describe it, and *only* in that fashion. For example, an ideal capacitor passes a current that is equal to the capacitance C times the rate of change of the voltage across it. Period, end of sentence.

We call any other exhibited behavior either *nonideal*, *nonlinear* or *parasitic*. Nonideal behavior is a general term that covers any deviation from the theoretical picture. Ideal circuit elements are often linear: The graphs of their current versus voltage characteristics are straight lines when plotted on a suitable (Cartesian, rectangular) set of axes. We therefore call deviation from this behavior nonlinear: For example, as current through a resistor exceeds its power rating, the resistor heats up and its resistance changes. As a result, a graph of current versus voltage is no longer a straight line.

When a component begins to exhibit

properties of a different component, as when a capacitor allows a dc current to pass through it, we call this behavior *parasitic*. Nonlinear and parasitic behavior are both examples of nonideal behavior.

Much to the bane of experimenters and design engineers, ideal components exist only in electronics textbooks and computer programs. Real components, the ones we use, only approximate ideal components (albeit very closely in most cases).

Real diodes store minuscule energy in electric fields (junction capacitance) and magnetic fields (lead inductance); *real* capacitors conduct some dc (modeled by a parallel resistance), and real battery voltage is not *perfectly* constant (it may even decrease nonlinearly during discharge).

Knowing to what extent and under what conditions real components cease to behave like their ideal counterparts, and what can be done to account for these behaviors, is the subject of component or circuit *modeling*. In this chapter, we will explore how and why the real components behave differently from ideal components, how we can account for those differences when analyzing circuits, how to select components to minimize, or exploit, nonideal behaviors and give a brief introduction to computer-aided circuit modeling.

Much of this chapter may seem intuitive. For example, you probably know that #20 hookup wire works just fine for wiring many experimental circuits. When testing a circuit after construction, you probably don't even think about the voltage drops across those pieces of wire (you inherently assume that they have zero resistance). But, connect that same #20 wire directly across a car battery—

with no *other* series resistance—and suddenly, the resistance of the wire *does* matter, and it changes—as the wire heats, melts and breaks—from a very small value to infinity!

LUMPED VS DISTRIBUTED ELEMENTS

Most electronic circuits that we use everyday are inherently and mathematically considered to be composed of *lumped elements*. That is, we assume each component acts at a single point in space, and the wires that connect these lumped elements are assumed to be *perfect conductors* (with zero resistance and insignificant length). This concept is illustrated in **Fig 6.1**. These assumptions are perfectly reasonable for many applications, but they have limits. Lumped element models break down when:

- Circuit impedance is so low that the small, but non-zero, resistance in the wires is important. (A significant portion of the circuit power may be lost to heat in the conductors.)
- Operating frequency (f_0) is high enough that the length of the connecting wires is a significant fraction (>0.1) of the wavelength. (Radiation from the conductors may be significant.)
- Transmission lines are used as conductors. (Their characteristic impedance is usually significant, and impedances connected to them are transformed as a function of the line length. See the **Transmission Lines** chapter for more information.)

Effects such as these are called *distributed*, and we talk of *distributed* elements or effects to contrast them to lumped elements.

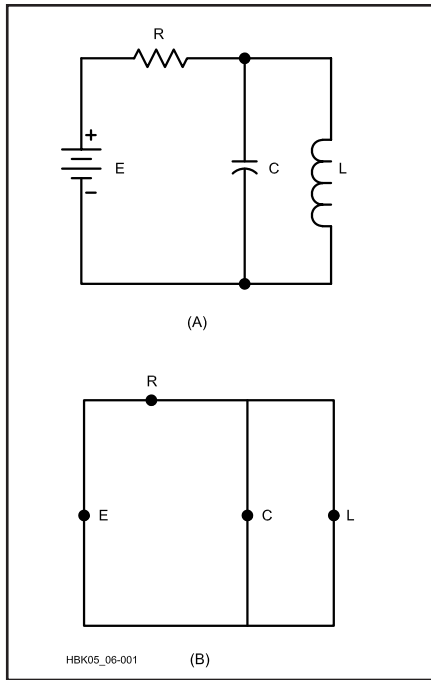

Fig 6.1—The lumped element concept. Ideally, the circuit at A is assumed to be as shown at B, where the components are isolated points connected by perfect conductors. Many components exhibit nonideal behavior when these assumptions no longer hold.

To illustrate the differences between lumped and distributed elements, consider the two resistors in **Fig 6.2**, which are both 12-inches long. The resistor at A is a uniform rod of carbon—a battery anode, for example. The second “resistor” B is made of two 6-inch pieces of silver rod (or other highly conductive material), with a small resistor soldered between them. Now imagine connecting the two probes of an ohmmeter to each of the two resistors, as in the figure. Starting with the probes at the far ends, as we slide the probes toward the center, the carbon rod will display a constantly decreasing resistance on the ohmmeter. This represents a *distributed* resistance. On the other hand, the ohmmeter connected to the other 12-inch “resistor” will display a constant resistance as long as one probe remains on each side of the small resistance. (Oh yes, as long as we neglect the resistance of the silver rods!) This represents a *lumped* resistance connected by perfect conductors.

Lumped elements also have the very desirable property that they introduce no phase shift resulting from propagation delay through the element. (Although combinations of lumped elements can produce phase shifts by virtue of their R, L and C properties.) Consider a lumped ele-

Fig 6.2—A, distributed and B, lumped resistances. See text for discussion.

ment that is carrying a sinusoidal current, as in **Fig 6.3A**. Since the element has negligible length, there is no phase difference in the current between the two sides of the element—*no matter how high the frequency*—precisely *because* the element length is negligible. If the physical length of the element were long, say 0.25λ as shown in **Fig 6.3B**, the current phase would *not* be the same from end to end. In this instance, the current is delayed 90 electrical degrees. The amount of phase difference depends on the circuit’s electrical length.

Because the relationship between the physical size of a circuit and the wavelength of an ac current present in the circuit will vary as the frequency of the ac signal varies, the ideas of lumped and distributed effects actually occupy two ends of a spectrum. At HF (30 MHz and below), where $\lambda \geq 10$ m, the lumped element concept is almost always valid. In the UHF

Fig 6.3—The effects of distributed resistance on the phase of a sinusoidal current. There is no phase delay between ends of a lumped element.

region and above, where $\lambda \geq 10$ m and physical component size can represent a significant fraction of a wavelength, everything shows distributed effects to one degree or another. From roughly 30 to 300 MHz, problems are usually examined on a case-by-case basis.

Of course, if we could make resistors, capacitors, inductors and so on, very small, we could treat them as lumped elements at much higher frequencies.

Thanks to the advances constantly being made in microelectronic circuit fabrication, this is in fact possible. Commercial monolithic microwave integrated circuits (MMICs) in the early 1990s often use lumped elements that are valid up to 50 GHz. Since this frequency represents a wavelength of roughly 5 mm, this implies a component size of less than 0.5 mm.

LOW-FREQUENCY COMPONENT MODELS

Every circuit element behaves non-ideally in some respect and under some conditions. It helps to know the most common types of nonideal behavior so we can design and build circuits that will perform as intended under expected ranges of operating conditions. In the sections below, we will discuss the basic components in order of increasing common nonideal behavior. Please note that much of this section applies only through HF; the peculiarities of VHF frequencies and above are discussed later in the chapter.

First, remember that some of the common limitations associated with real components are manufacturing concerns: tolerance and standard values. Tolerance is the measure of how much the actual value of a component may differ from its labeled value; it is usually expressed in percent. By convention, a “*higher*” (actually *closer*) tolerance component indicates

a *lower* (lesser) percentage deviation and will usually cost more. For example, a 1-k Ω resistor with a 5% tolerance has an actual resistance of anywhere from 950 to 1050 Ω . When designing circuits be careful to include the effects of tolerance. More specific examples will be discussed below.

Keep standard values in mind because not every conceivable component value is available. For instance, if circuit calculations yield a 4,932- Ω resistor for a demanding application, there may be trouble. The nearest commonly available values are 4700 Ω and 5600 Ω , and they'll be rated at 5% tolerance!

These two constraints prevent us from building circuits that do precisely what we wish. In fact, the measured performance of any circuit is the summation of the tolerances and temperature characteristics of all the components in both the circuit under test and the test equipment itself. As a result, most circuits are designed to operate within tolerances such as "up to a certain power" or "within this frequency range." Some circuits have one or more adjustable components that can compensate for variations in others. These limitations are then further complicated by other problems.

RESISTORS

Resistors are made in several different ways: carbon composition, carbon film, metal film, and wire wound. Carbon composition resistors are simply small cylinders of carbon mixed with various binding agents. Carbon is technically a semiconductor and can be *doped* with various impurities to produce any desired resistance. Most common everyday $\frac{1}{2}$ - and $\frac{1}{4}$ -W resistors are of this sort. They are moderately stable from 0 to 60 $^{\circ}\text{C}$ (their resistance increases above and below this temperature range). They are not inductive, but they are relatively noisy, and have relatively wide tolerances.

The other resistors exploit the fact that resistance is proportional to the length of the resistor and inversely proportional to its cross-sectional area:

Wire-wound resistors are made from wire, which is cut to the proper length and wound on a coil form (usually ceramic). They are capable of handling high power; their values are very stable, and they are manufactured to close tolerances.

Metal-film resistors are made by depositing a thin film of aluminum, tungsten or other metal on an insulating substrate. Their resistances are controlled by careful adjustments of the width, length and depth of the film. As a result, they have very close tolerances. They are used exten-

sively in surface-mount technology. As might be expected, their power handling capability is somewhat limited. They also produce very little electrical noise.

Carbon film resistors use a film of doped carbon instead of metal. They are not quite as stable as other film resistors and have wider tolerances than metal-film resistors, but they are still as good as (or better than) composition resistors.

Resistors behave much like their ideal through AF; lead inductance becomes a problem only at higher frequencies. The major departure from ideal behavior is their temperature coefficient (TC). The resistivity of most materials changes with temperature, and typical TC values for resistor materials are given in **Table 6.1**. TC values are usually expressed in parts-per-million (PPM) for each degree (centigrade) change from some nominal temperature, usually room temperature (77 $^{\circ}\text{F}/27^{\circ}\text{C}$). A positive TC indicates an increase in resistance with increasing temperature while a negative TC indicates a decreasing resistance. For example, if a 1000- Ω resistor with a TC of +300 PPM/ $^{\circ}\text{C}$ is heated to 50 $^{\circ}\text{C}$, the *change* in resistance is $300(50 - 27) = 6900$ PPM, yielding a new resistance of

$$1000 \left(1 + \frac{6900}{1000000} \right) = 1006.9 \Omega$$

Carbon-film resistors are unique among the major resistor families because they alone have a negative temperature coefficient. They are often used to "offset" the thermal effects of the other components (see Thermal Considerations, below).

If the temperature increase is small (less than 30-40 $^{\circ}\text{C}$), the resistance change with temperature is nondestructive—the resistor will return to normal when the temperature returns to its nominal value. Resistors that get too hot to touch, however, may be permanently damaged even if they appear normal. For this reason, be conservative when specifying power ratings for resistors. It's common to specify

a resistor rated at 200% to 400% of the expected dissipation.

Wire-wound resistors are essentially inductors used as resistors. Their use is therefore limited to dc or low-frequency ac applications where their reactance is negligible. Remember that this inductance will also affect switching transient waveforms, even at dc, because the component will act as an RL circuit.

As a rough example, consider a 1- Ω , 5-W wire-wound resistor that is formed from #24 wire on a 0.5-inch diameter form. What is the approximate associated inductance? First, we calculate the length of wire using the wire tables:

$$L = \frac{R}{\Omega/\text{ft for \#24 wire}}$$

$$= \frac{1}{25.7 \Omega/1000 \text{ ft}} = 39 \text{ ft}$$

This yields a total of $(39 \times 12 \text{ inches}) / (0.5 \pi \text{ inch/turn}) \approx 298$ turns, which further yields a coil length (for #24 wire close-wound at 46.9 turns per inch) of 6.3 inches, assuming a single-layer winding. Then, from the inductance formula for air coils in the **Electrical Fundamentals** chapter, calculate

$$L = \frac{(0.5)^2 \times 298^2}{18 \times 0.5 + 40 \times 6.3} = 85 \mu\text{H}$$

Real wire-wound resistors have multiple windings layered over each other to minimize both size and parasitic inductance (by winding each layer in opposite directions, much of the inductance is canceled). If we assume a five-layer winding, the length is reduced to 1.8 inches and the inductance to approximately 17 μH . If we want the inductive reactance to stay below 10% of the resistor value, then this resistor cannot be used above $f = 0.1 / (2\pi \times 17 \mu\text{H}) = 937$ Hz, or roughly 1 kHz.

Another exception to the rule that resistors are, in general, fairly ideal has to do with skin effect at RF. This will be discussed later in the chapter. **Fig 6.4** shows some more accurate circuit models for resistors at low frequencies. For a treatment of pure resistance theory, look at the **Electrical Fundamentals** chapter.

VOLTAGE AND CURRENT SOURCES

An ideal voltage source maintains a constant voltage across its terminals no matter how much current is drawn. Consequently, it is capable of providing infinite power, for an infinite period of time. Similarly, an ideal current source provides a

Table 6.1

Temperature Coefficients for Various Resistor Compositions

1 PPM = 1 part per million = 0.0001%

Type	TC (PPM/ $^{\circ}\text{C}$)
Wire wound	$\pm(30 - 50)$
Metal Film	$\pm(100 - 200)$
Carbon Film	+350 to -800
Carbon composition	± 800

Fig 6.4—Circuit models for resistors. A is the ideal element. At B is the simple temperature-varying model for noninductive resistors. The wire-wound model with associated inductance is shown at C. For UHF or microwave designs, the model at C could be used with L representing lead inductance.

constant current through its terminals no matter what voltage appears across it. It, too, can deliver an infinite amount of power for an infinite time.

Internal Resistance

As you may have learned through experience, *real* voltage and current sources—batteries and power supplies—do not meet these expectations. All real power sources have a finite *internal resistance* associated with them that limits the maximum power they can deliver.

We can model a real dc voltage source as a Thevenin-equivalent circuit of an *ideal* source in series with a resistance R_{th} that is equal to the source's internal resistance. Similarly, we can model a real dc current source as a Norton-equivalent circuit: an ideal current source in *parallel* with R_{th} . These two circuits shown in **Fig 6.5** are interchangeable through the relation

$$V_{\text{OC}} = I_{\text{SC}} \times R_{\text{th}} \quad (1)$$

Using these more realistic models, the maximum current that a real voltage source can deliver is seen to be I_{sc} and the maximum voltage is V_{oc} .

We can model sinusoidal voltage or current sources in much the same way, keeping in mind that the internal *impedance*, Z_{th} , for such a source may not be purely resistive, but may have a reactive component that varies with frequency.

Battery Capacity and Discharge Curves

Batteries have a finite energy capacity as well as an internal resistance. Because of the physical size of most batteries, a convenient unit for measuring capacity is the *milliampere hour* (mAh) or, for larger

Fig 6.5—Norton and Thevenin equivalent circuits for real voltage and current sources.

units, the *ampere hour* (Ah). Note that these are units of charge (coulombs per second \times seconds) and thus they measure the total net charge that the battery holds on its plates when full.

A capacity of 1 mAh indicates that a battery, when fully charged, holds sufficient electrochemical energy to supply a steady current of 1 mA for 1 hour. If a battery discharges at a constant rate, you could estimate the useful time of a battery charge by the simple formula

$$\text{Time (hr)} = \frac{\text{capacity (mAh)}}{\text{current (mA)}} \quad (2)$$

In practice, however, the usable capacity of a rechargeable battery depends on the discharge *rate*, decreasing slightly as the current increases. For example, a 500 mAh nickel-cadmium (NiCd) battery may supply a current of 50 mA for almost 10 hours while maintaining a current of 500 mA for only 45 minutes.

The finite capacity of a battery does not *in itself* change the circuit model for a real source as shown in Fig 6.5. However, the chemistry of electrolytic cells, from which batteries are made, does introduce a minor, but significant, change. The voltage of a discharging battery does not stay constant, but slowly drops as time goes on. **Fig 6.6** illustrates the *discharge curve*

Fig 6.6—Discharge curve (terminal voltage vs percent capacity remaining) for a typical NiCd rechargeable battery. Note the dramatic voltage drop near the end.

for a typical NiCd rechargeable battery. For a given battery design, such curves are fairly reproducible and often used by battery-charging circuits to sense when a battery is fully charged or discharged.

CAPACITORS

The ideal capacitor is a pair of infinitely large parallel metal plates separated by an insulating or *dielectric* layer, ideally a vacuum (see **Fig 6.7**). For a discussion of pure capacitance see the **Electrical Fundamentals** chapter. For this case, the capacitance is given by

$$C = \frac{A \epsilon_r \epsilon_0}{d} \quad (3)$$

where

C = capacitance, in farads

A = area of plates, cm

d = spacing of the plates, cm

ϵ_r = dielectric constant of the insulating material

ϵ_0 = permittivity of free space, 8.85×10^{-14} F/cm.

If the plates are not infinite, the actual capacitance is somewhat higher due to *end effect*. This is the same phenomenon that causes a dipole to resonate at a lower frequency if you place large insulators (which add capacitance) on the ends.

If we built such a capacitor, we would find that (neglecting the effects of quantum mechanics) it would be a perfect open circuit at dc, and it could be operated at whatever voltage we desire without breakdown.

Leakage Conductance and Breakdown

If we use anything other than a vacuum for the insulating layer, even air, we introduce two problems. Because there are

Fig 6.7—The ideal parallel-plate capacitor.

atoms between the plates, the capacitor will now be able to conduct a dc current. The magnitude of this *leakage current* will depend on the insulator quality, and the current is usually very small. Leakage current can be modeled by a resistance R_L in parallel with the capacitance (in the ideal case, this resistance is infinite).

In addition, when a high enough voltage is applied to the capacitor, the atoms of the dielectric will ionize due to the extremely high electric field and cause a large dc current to flow. This is *dielectric breakdown*, and it is destructive to the capacitor if the dielectric is ruined. To avoid dielectric breakdown, a capacitor has a *working voltage* rating, which represents the maximum voltage that can be permitted to develop across it.

Dielectrics

The leakage conductance and breakdown voltage characteristics of a capacitor are strongly dependent on the composition and quality of the dielectric. Various materials are used for different reasons such as availability, cost, and desired capacitance range. In rough order of “best” to “worst” they are:

Vacuum Both fixed and variable vacuum capacitors are available. They are rated by their maximum working voltages (3 to 60 kV) and currents. Losses are specified as negligible for most applications.

Air An *air-spaced* capacitor provides the best commonly available approximation to the ideal picture. Since $\epsilon_r = 1$ for air, air-dielectric capacitors are large when compared to those of the same value using other dielectrics. Their capacitance is very stable over a wide temperature range, leakage losses are low, and therefore a high Q can be obtained. They also can withstand high voltages. For these reasons (and ease of construction) most variable capacitors in tuning circuits are air-spaced.

Plastic film Capacitors with plastic film (polystyrene, polyethylene or Mylar) dielectrics are more expensive than paper capacitors, but have much lower leakage rates (even at high temperatures) and low

TCs. Capacitance values are more stable than those of paper capacitors. In other respects, they have much the same characteristics as paper capacitors. Plastic-film variable capacitors are available.

Mica The capacitance of mica capacitors is very stable with respect to time, temperature and electrical stress. Leakage and losses are very low. Values range from 1 pF to 0.1 μ F, with tolerances from 1 to 20%. High working voltages are possible, but they must be derated severely as operating frequency increases.

Silver mica capacitors are made by depositing a thin layer of silver on the mica dielectric. This makes the value even more stable, but it presents the possibility of silver migration through the dielectric. The migration problem worsens with increased dc voltage, temperature and humidity. Avoid using silver-mica capacitors under such conditions.

Ceramic There are two kinds of ceramic capacitors. Those with a low dielectric constant are relatively large, but very stable and nearly as good as mica capacitors at HF. High dielectric constant ceramic capacitors are physically small for their capacitance, but their value is not as stable. Their dielectric properties vary with temperature, applied voltage and operating frequency. They also exhibit piezoelectric behavior. Use them only in coupling and bypass roles. Tolerances are usually +100% and -20%. Ceramic capacitors are available in a wide range of values: 10 pF to 1 μ F. Some variable units are available.

Electrolytic These capacitors have the space between their foil plates filled with a chemical paste. When voltage is applied, a chemical reaction forms a layer of insulating material on the foil.

Electrolytic capacitors are popular because they provide high capacitance values in small packages at a reasonable cost. Leakage is high, as is inductance, and they are polarized—there is a definite positive and negative plate, due to the chemical reaction that provides the dielectric. Internal inductance restricts aluminum-foil electrolytics to low-frequency applications. They are available with values from 1 to 500,000 μ F.

Tantalum electrolytic capacitors perform better than aluminum units but their cost is higher. They are smaller, lighter and more stable, with less leakage and inductance than their aluminum counterparts. Reformation problems are less frequent, but working voltages are not as high as with aluminum units.

Electrolytics should not be used if the dc potential is well below the capacitor working voltage.

Paper Paper capacitors are inexpensive; capacitances from 500 pF to 50 μ F are available. High working voltages are possible, but paper-dielectric capacitors have high leakage rates and tolerances are no better than 10 to 20%. Paper-dielectric capacitors are not polarized; however, the body of the capacitor is usually marked with a color band at one end. The band indicates the terminal that is connected to the outermost plate of the capacitor. This terminal should be connected to the side of the circuit at the lower potential as a safety precaution.

Loss Angle

For ac signals (even at low frequencies), capacitors exhibit an additional parasitic resistance that is due to the electromagnetic properties of dielectric materials. This resistance is often quantified in catalogs as *loss angle*, θ , because it represents the angle, in the complex impedance plane, between $Z_C = R + jX_C$ and X_C . This angle is usually quite small, and would be zero for an ideal capacitor.

Loss angle is normally specified as $\tan \theta$ at a certain frequency, which is simply the ratio R/X_C . The loss angle of a given capacitor is relatively constant over frequency, which means the *effective series resistance* or *ESR* $= (\tan \theta) / (2 \pi f C)$ goes down as frequency goes up. This resistance is placed in *series* with the capacitor because it came (mathematically) from the equation for Z_C above. It can always be converted into a parallel resistance if desired. To summarize, **Figs 6.8** and **6.9** show reasonable models for the capacitor that are good up to VHF.

Temperature Coefficients and Tolerances

As with resistors, capacitor values vary in production, and most capacitors have a tolerance rating either printed on them or listed on a data sheet. Capacitance varies with temperature, and this is important to consider when constructing a circuit that will carry high power levels or operate in a hot environment. Also, as just described, not all capacitors are available in all ranges of values due to inherent differences in material properties. Typical values, temperature coefficients and leakage conductances for several capacitor types are given in **Table 6.2**.

DIODES

An ideal diode acts as a rectifying switch—it is a short circuit when forward biased and an open circuit when reverse biased. Many circuit components can be completely described in terms of current-voltage (or *I-V*) characteristics, and to

Fig 6.8—A simple capacitor model for frequencies well below self-resonance.

Table 6.2

Typical Temperature Coefficients and Leakage Conductances for Various Capacitor Constructions

Type	TC @ 20°C (PPM/°C)	DC Leakage Conductance (Ω)
Ceramic Disc	±300(NP0) +150/−150(GP)	> 10 M
Mica	−20 to +100	> 100,000 M
Polyester	±500	> 10 M
Tantalum Electrolytic	±1500	> 10 MΩ
Small Al Electrolytic(≈ 100 μF)	−20,000	500 k - 1 M
Large Al Electrolytic(≈ 10 mF)	−100,000	10 k
Vacuum (glass)	+100	≈ ∞
Vacuum (ceramic)	+50	≈ ∞

Fig 6.10—Circuit models for rectifying switches (diodes). A: I-V curve of the ideal rectifier. B: I-V curve of a typical semiconductor diode. Note the different scales for + and − current. C shows a simplified diode I-V curve for dc-circuit calculations. D is an equivalent circuit for C.

discuss the diode, this approach is especially helpful. Fig 6.10A shows the I-V curve for an ideal rectifier.

In contrast, the I-V curve for a semiconductor diode junction is given by the following equation (slightly simplified).

$$I = I_s \left(e^{\frac{V}{V_t}} - 1 \right) \quad (4)$$

where

I = diode current

V = diode voltage

I_s = reverse-bias saturation current

$V_t = kT/q$, the thermal equivalent of voltage (about 25 mV at room temperature).

This curve is shown in Fig 6.10B.

The obvious differences between Fig 6.10A and B are that the semiconductor diode has a finite *turn-on* voltage—it requires a small but nonzero forward bias voltage before it begins conducting. Furthermore, once conducting, the diode voltage continues to increase very slowly with increasing current, unlike a true short circuit. Finally, when the applied voltage is negative, the current is not exactly zero

but very small (microamperes).

For bias (dc) circuit calculations, a useful model for the diode that takes these two effects into account is shown by the artificial I-V curve in Fig 6.10C. The small reverse bias current I_s is assumed to be completely negligible.

When converted into an equivalent circuit, the model in Fig 6.10C yields the picture in Fig 6.10D. The ideal voltage source

V_a represents the turn-on voltage and R_f represents the effective resistance caused by the small increase in diode voltage as the diode current increases. The turn-on voltage is material-dependent: approximately 0.3 V for germanium diodes and 0.7 for silicon. R_f is typically on the order of 10 Ω , but it can vary according to the specific component. R_f can often be completely neglected in comparison to the other resistances in the circuit. This very common simplification leaves only a pure voltage drop for the diode model.

Temperature Bias Dependence

The reverse saturation current I_s is not constant but is itself a complicated function of temperature. For silicon diodes (and transistors) near room temperature, I_s increases by a factor of 2 every 4.8 $^{\circ}\text{C}$. This means that for every 4.8 $^{\circ}\text{C}$ rise in temperature, either the diode current doubles (if the voltage across it is constant), or if the current is held constant by other resistances in the circuit, the diode voltage will *decrease* by $V_t \times \ln 2 = 18 \text{ mV}$. For germanium, the current doubles every 8 $^{\circ}\text{C}$ and for gallium arsenide (GaAs), 3.7 $^{\circ}\text{C}$. This dependence is highly reproducible and may actually be exploited to produce temperature-measuring circuits.

While the change resulting from a rise of several degrees may be tolerable in a circuit design, that from 20 or 30 degrees may not. Therefore it's a good idea with diodes, just as with other components, to specify power ratings conservatively (2 to 4 times over) to prevent self-heating.

While component derating does reduce self-heating effects, circuits must be designed for the expected operating environment. For example, mobile radios may face temperatures from -20° to $+140^{\circ}\text{F}$ (-29° to 60°C).

Junction Capacitance

Immediately surrounding a PN junction is a *depletion layer*. This is an electrically charged region consisting primarily of ionized atoms with relatively few electrons and holes (see Fig 6.11). Outside the depletion layer are the remainder of the P and N regions, which do not contribute to diode operation but behave primarily as parasitic series resistances.

We can treat the depletion layer as a tiny capacitor consisting of two parallel plates. As the reverse bias applied to a diode changes, the width of the depletion layer, and therefore the capacitance, also changes. There is an additional *diffusion capacitance* that appears under forward bias due to electron and hole storage in the bulk regions, but we will not discuss

this here because diodes are usually reverse biased when their capacitance is exploited. The diode junction capacitance under a reverse bias of V volts is given by

$$C_j = C_{j0} / \sqrt{V_{\text{on}} - V} \quad (5)$$

where C_{j0} = measured capacitance with zero applied voltage.

Note that the quantity under the radical is a large *positive* quantity for reverse bias.

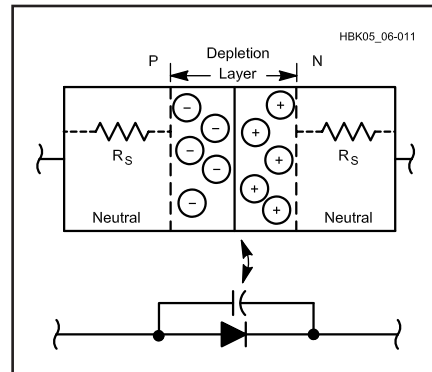

Fig 6.11—A more detailed picture of the PN junction, showing depletion layer, bulk regions and junction capacitance.

Fig 6.12—A simple resistor-diode circuit used to illustrate dynamic resistance. The ac input voltage “sees” a diode resistance whose value is the slope of the line at the Q-point, shown in B.

As seen from the equation, for large reverse biases C_j is inversely proportional to the square root of the voltage.

Junction capacitances are small, on the order of pF. They become important, however, for diode circuits at RF, as they can affect the resonant frequency. In fact, *varactors* are diodes used for just this purpose.

Reverse Breakdown and Zener Diodes

If a sufficiently large reverse bias is applied to a real diode, the internal electric field becomes so strong that electrons and holes are ripped from their atoms, and a large reverse current begins to flow. This is called *breakdown* or *avalanche*. Unless the current is so large that the diode fails from overheating, breakdown is not destructive and the diode will again behave normally when the bias is removed.

Once a diode breaks down, the voltage across it remains relatively constant regardless of the level of breakdown current. *Zener* diodes are diodes that are specially made to operate in this region with a very constant voltage, called the *Zener voltage*. They are used primarily as voltage regulators. When operating in this region, they can be modeled as a simple voltage source. Zener diodes are rated by their Zener voltage and power dissipation.

A Diode AC Model

Fig 6.12A shows a simple resistor-diode circuit to which is applied a dc bias voltage plus an ac signal. Assuming that the voltage drop across the diode is 0.6 V and R_f is negligible, we can calculate the bias current to be $I \approx (5 - 0.6) / 1 \text{ k}\Omega = 4.4 \text{ mA}$. This point is marked on the diodes I-V curve in Fig 6.12B. If we draw a line tangent to this point, as shown, the slope of this line represents the *dynamic* resistance R_d of the diode seen by a small ac signal, which at room temperature can be approximated by

$$R_d = \frac{25}{I} \Omega \quad (6)$$

where I is the diode current in mA. Note that this resistance changes with bias current and should not be confused with the dc forward resistance in the previous section, which has a similar value but represents a different concept. Fig 6.13 shows a low-frequency ac model for the diode, including the dynamic resistance and junction capacitance.

Switching Time

If you change the polarity of a signal applied to the ideal switch whose I-V curve appears in Fig 6.10A, the switch

turns on or off instantaneously. A real diode cannot do this, as a finite amount of time is required to move electrons and holes in or out of the diode as it changes states (effectively, the diode capacitances must be charged or discharged). As a result, diodes have a maximum useful frequency when used in switching applications. The operation of diode switching circuits can often be modeled by the picture in **Fig 6.14**. The approximate switching time (in seconds) for this circuit is given by

$$t_s = \tau_p \left(\frac{V_1}{R_1} \right) = \tau_p \frac{I_1}{I_2} \quad (7)$$

where τ_p is the minority carrier lifetime of the diode (a material constant determined during manufacture, on the order of 1 ms). I_1 and I_2 are currents that flow during the switching process. The minimum time in which a diode can switch from one state to the other and back again is therefore $2 t_s$, and thus the maximum usable switching frequency is $f_{sw} \text{ (Hz)} = 1/2 t_s$. It is usually a good idea to stay below this by a factor of two. Diode data sheets usually give typical switching times and show the circuit used to measure them.

Note that f_{sw} depends on the forward and reverse currents, determined by I_1 and I_2 (or equivalently V_1, V_2, R_1 , and R_2). Within a reasonable range, the switching time can be reduced by manipulating these currents. Of course, the maximum power that other circuit elements can handle places an upper limit on switching currents.

Schottky Diodes

Schottky diodes are made from metal-semiconductor junctions rather than PN

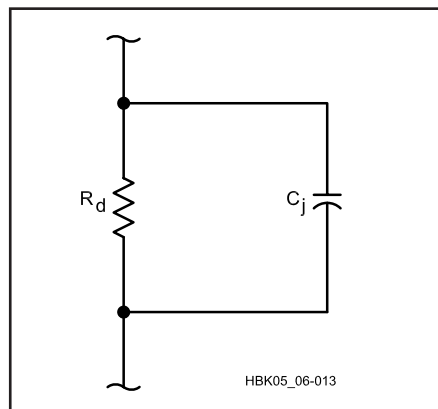

Fig 6.13—An ac model for diodes. R_d is the dynamic resistance and C_j is the junction capacitance.

junctions. They store less charge internally and as a result, have shorter switching times and junction capacitances than standard PN junction diodes.

Their turn-on voltage is also less, typically 0.3 to 0.4 V. In most other respects they behave similarly to PN diodes.

INDUCTORS

Inductors are the problem children of the component world. (Fundamental inductance is discussed in the **Electrical Fundamentals** chapter). Besides being difficult to fabricate on integrated circuits, they are perhaps the most nonideal of real-world components. While the leakage conductance of a capacitor is usually negligible, the series resistance of an inductor often is not. This is basically because an inductor is made of a long piece of relatively thin wire wound into a small coil. As an example, consider a typical air-core tuning coil from a component catalog, with $L = 33 \text{ mH}$ and a minimum Q of 30 measured at 2.5 MHz. This would indicate a series resistance of $R_s = 2 \pi f L / Q = 17 \Omega$. This R_s could significantly alter the resonant frequency of a circuit. For frequencies up to HF this is the only significant nonlinearity, and a low-frequency circuit model for the inductor is shown in **Fig 6.15**. Many of the problems associated with inductors are actually due to core materials, and not the coil itself.

Magnetic Materials

Many discrete inductors and transformers are wound on a core of iron or other magnetic material. As discussed in the **Electrical Fundamentals** chapter, the inductance value of a coil is proportional to the density of magnetic field lines that pass through it. A piece of magnetic material placed inside a coil will concentrate the field lines inside itself. This permits a

higher number of field lines to exist inside a coil of a given cross-sectional area, thus allowing a much higher inductance than what would be possible with an air core. This is especially important for transformers that operate at low frequencies (such as 60 Hz) to ensure the reactance of the windings is high.

Core Saturation

Magnetic (more precisely, ferro-magnetic) materials exhibit two kinds of non-linear behavior that are important to circuit design. The first is the phenomenon of *saturation*. A magnetic core increases the magnetic flux density of a coil because the current passing through the coil forces the atoms of the iron (or other material) to line up, just like many small compass needles, and the magnetic field that results from the atomic alignment is *much* larger than that produced by the current with no core. As coil current increases, more and more atoms line up. At some high current, all of the atoms will be aligned and the core is *saturated*. Any further increase in current can't increase the core alignment any further. Of course, added current generates its own magnetic flux, but it is very small compared to the magnetic field contributed by the aligned atoms in the magnetic core.

The important concept in terms of circuit design is that as long as the coil current remains below saturation, the inductance of the coil is essentially constant. **Fig 6.17** shows graphs of magnetic flux linkage ($N \phi$) and inductance (L) vs current (i) for a typical iron-core inductor. These quantities are related by the equation

$$N \phi = Li \quad (8)$$

where

- N = number of turns,
- ϕ = flux density
- L = inductance
- i = current.

In the lower graph, a line drawn from any point on the curve to the (0,0) point will show the effective inductance, $L = N \phi / i$,

Fig 6.14—Circuit used for computation of diode switching time.

Fig 6.15—Low- to mid-frequency inductor equivalent circuit showing series resistance R_s .

at that current. These results are plotted on the upper graph.

Note that below saturation, the inductance is constant because both $N\phi$ and i are increasing at a steady rate. Once the saturation current is reached, the inductance decreases because $N\phi$ does not increase anymore (except for the tiny additional magnetic field the current itself provides). This may render some coils useless at VHF and higher frequencies. Air-coil inductors do not suffer from saturation.

One common method of increasing the saturation current level is to cut a small air gap in the core (see Fig 6.16). This gap forces the flux lines to travel through air for a short distance. Since the saturation flux linkage of the core is unchanged, this method works by requiring a higher current to achieve saturation. The price that is paid is a reduced inductance below saturation. Curves B in Fig 6.17 show the result of an air gap added to that inductor.

Manufacturer's data sheets for magnetic cores usually specify the saturation flux density. Saturation flux density, ϕ , in gauss can be calculated for ac and dc currents from the following equations:

$$\phi_{ac} = \frac{3.49 V}{fNA} \quad (9)$$

$$\phi_{dc} = \frac{NIA_L}{10 A} \quad (10)$$

where
 V = RMS ac voltage

Fig 6.16—Typical construction of a magnetic-core inductor. The air gap greatly reduces core saturation at the expense of some inductance. The insulating laminations between the core layers help to minimize eddy currents.

f = frequency, in MHz
 N = number of turns
 A = equivalent area of the magnetic path in square inches (from the data sheet)
 I = dc current, in A
 A_L = inductance index (also from the data sheet).

Hysteresis

Consider Fig 6.18. If the current passed through a magnetic-core inductor is increased from zero (point a) to near the point of saturation (point b) and then decreased back to zero, we find that a magnetic field remains, because some of the core atoms retain their alignment. If we then increase the current in the opposite direction and again return to zero (through points c, d and e), the curve does *not* retrace itself. This is the property of *hysteresis*.

If a circuit carries a large ac current (that is, equal to or larger than saturation), the path shown in Fig 6.18 (from b to e and back again) will be retraced many times each second. Since the curve is nonlinear, this will introduce distortion in the resulting waveform. Where linear circuit operation is crucial, it is important to restrict the

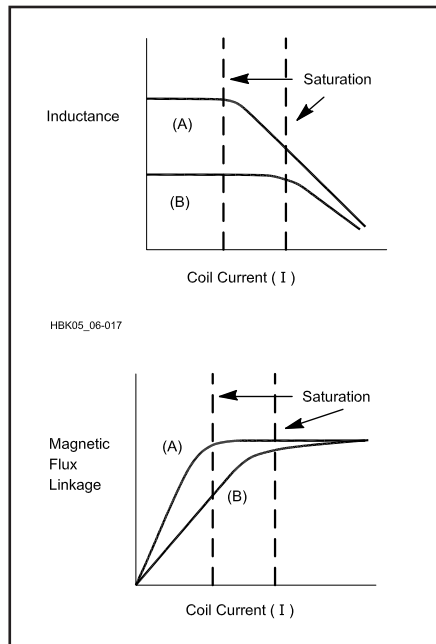

Fig 6.17—Magnetic flux linkage and inductance plotted versus coil current for (A) a typical iron-core inductor. As the flux linkage $N\phi$ in the coil saturates, the inductance begins to decrease since inductance = flux linkage / current. The curves marked B show the effect of adding an air gap to the core. The current handling capability has increased but at the expense of reduced inductance.

operation of magnetic-core inductors well below saturation.

Eddy Currents

The changing magnetic field produced by an ac current generates a “back voltage” in the core as well as the coil itself. Since magnetic core material is usually conductive, this voltage causes a current to flow in the core. This eddy current serves no useful purpose and represents power lost to heat. Eddy currents can be substantially reduced by laminating the core—slicing the core into thin sheets and placing a suitable insulating material (such as varnish) between them (see Fig 6.16).

Transformers

In an ideal transformer (described in the **Electrical Fundamentals** chapter), *all* the power supplied to its primary terminals is available at the secondary terminals. An air-core transformer provides a very good approximation to the ideal case, the major loss being the series resistances of the windings. As you might guess, there are several ways that a magnetic-core transformer can lose power. For example, useless heat can be generated through hysteresis and eddy currents; power may be lost to harmonic generation through nonlinear saturation effects.

Another source of loss in transformers (or actually, any pair of mutual inductances) is *leakage reactance*. While the main purpose of a magnetic core is to concentrate the magnetic flux entirely within itself, in a real-life device there is always some small amount of flux that does not pass through both windings. This leakage reactance can be pictured as a small amount of self-inductance appearing on

Fig 6.18—Hysteresis loop. A large current (larger than saturation current) passed through a magnetic-core coil will cause some permanent magnetization of the core. This results in a different path of flux linkage vs current to be traced as the current decreases.

each winding. **Fig 6.19** shows a fairly complete circuit model for a transformer at low to medium frequencies.

COMPONENTS AT RF

The models described in the previous section are good for dc, and ac up through AF and low RF. At HF and above (where we do much of our circuit design) several other considerations become very important, in some cases dominant, in our component models. To understand what happens to circuits at RF (a good cutoff is 30 MHz and above) we turn to a brief discussion of some electromagnetic and microwave theory concepts.

Parasitic Inductance

Maxwell's equations—the basic laws of electromagnetics that govern the propagation of electromagnetic waves and the operation of all electronic components—tell us that any wire carrying a current that changes with time (one example is a sine wave) develops a changing magnetic field around it. This changing magnetic field in turn induces an opposing voltage, or back EMF, on the wire. The back EMF is proportional to how fast the current changes (see **Fig 6.20**).

We exploit this phenomenon when we make an inductor. The reason we typically form inductors in the shape of a coil is to concentrate the magnetic field lines and thereby maximize the inductance for a given physical size. However, *all* wires carrying varying currents have these inductive properties. This includes the wires we use to connect our circuits, and even the *leads* of capacitors, resistors and so on.

The inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left[\ln \left(\frac{2b}{a} \right) - 0.75 \right] \quad (11)$$

where

L = inductance, in μH

a = wire radius, in inches
 b = wire length, in inches
 \ln = natural logarithm ($2.303 \times \log_{10}$).

Skin effect (see below) changes this formula slightly at VHF and above. As the frequency approaches infinity, the constant 0.75 in the above equation approaches 1. This effect usually presents no more than a few percent change.

As an example, let's find the inductance of a #18 wire (diam = 0.0403 inch) that is 4 inches long (a typical wire in a circuit). Then $a = 0.0201$ and $b = 4$:

$$L = 0.00508 (4) \left[\ln \left(\frac{8}{0.0201} \right) - 0.75 \right] \\ = 0.0203 [5.98 - 0.75] = 0.106 \mu\text{H}$$

It is obvious that this *parasitic* inductance is usually very small. It becomes important *only at very high frequencies*; at AF or LF, the parasitic inductive reactance is practically zero. To use this example, the reactance of a 0.106 μH inductor even at 10 MHz is only 6.6 Ω . **Fig 6.21** shows a graph of the inductance for wires of various gauges (radii) as a function of length.

Any circuit component that has wires attached to it, or is fabricated from wire, will have a parasitic inductance associated with it. We can treat this parasitic inductance in component models by adding an inductor of appropriate value in *series* with the component (since the wire lengths are in series with the element). This (among other reasons) is why minimizing lead lengths and interconnecting wires becomes very important when designing circuits for VHF and above.

Parasitic Capacitance

Maxwell's equations also tell us that if the voltage between any two points changes with time, a *displacement* current is generated between these points. See **Fig 6.22**. This displacement current re-

sults from the propagation, at the speed of light, of the electromagnetic field between the two points and is not to be confused with conduction current, which is caused by the movement of electrons. This displacement current is directly proportional to how fast the voltage is changing.

A capacitor takes advantage of this consequence of the laws of electromagnetics. When a capacitor is connected to an ac voltage source, a steady ac current can flow because taken together, conduction current and displacement current "complete the loop" from the positive source terminal, across the plates of the capacitor, and back to the negative terminal.

In general, parasitic capacitance shows up *wherever* the voltage between two points is changing with time, because the laws of electromagnetics require a displacement current to flow. Since this phenomenon represents an *additional* current path from one point in space to another, we can add this parasitic capacitance to our component models by adding a capacitor of appropriate value in *parallel* with the component. These parasitic capacitances are typically less than 1 pF, so that below VHF they can be treated as open circuits (infinite resistances) and thus neglected.

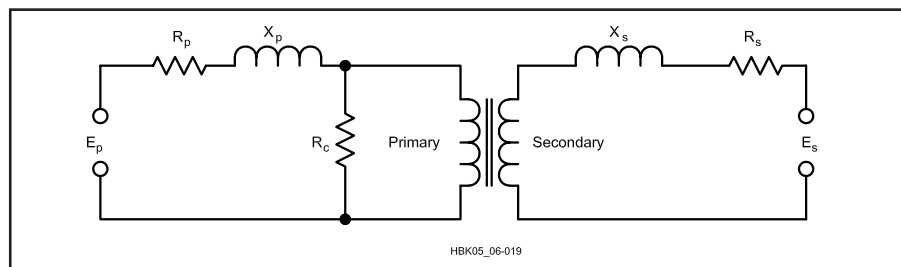

Fig 6.19—An equivalent circuit for a transformer at low to medium frequencies. R_p and R_s represent the series resistances of the windings, X_p and X_s are the leakage inductances, and R_c represents the dissipative losses in the core due to eddy currents and so on.

Fig 6.20—Inductive consequences of Maxwell's equations. At A, any wire carrying a changing current develops a voltage difference along it. This can be mathematically described as an effective inductance. B adds parasitic inductance to a generic component model.

Fig 6.21—A plot of inductance vs length for straight conductors in several wire sizes.

Consider the inductor in **Fig 6.23**. If this coil has n turns, then the ac voltage between identical points of two neighboring turns is $1/n$ times the ac voltage across the entire coil. When this voltage changes due to an ac current passing through the coil, the effect is that of many small capacitors acting in parallel with the inductance of the coil. Thus, in addition to the capacitance resulting from the leads, inductors have higher parasitic capacitance due to their physical shape.

Package Capacitance

Another source of capacitance, also in the 1-pF range and therefore important only at VHF and above, is the packaging of the component itself. For example, a power transistor packaged in a TO-220 case (see **Fig 6.24**), often has either the emitter or collector connected to the metal tab itself. This introduces an extra *inter-electrode capacitance* across the junctions.

The copper traces on a PC board also present capacitance to the circuit it holds. Double-sided PC boards have a certain capacitance per square inch. It is possible to create capacitors by leaving unetched areas of copper on both sides of the board. The capacitance is not well controlled on inexpensive low-frequency boards, how-

ever. For this reason, the copper on one side of a double-sided board should be completely removed under frequency-determining circuits such as VFOs. Board capacitance is *exploited* to make microwave transmission lines (microstrip lines). The capacitance of boards for microwave use is better controlled than that of less expensive board material.

Stray capacitance (a general term used for any “extra” capacitance that exists due to physical construction) appears in any circuit where two metal surfaces exist at different voltages. Such effects can be modeled as an extra capacitor in parallel with the given points in the circuit. A rough value can be obtained with the parallel-plate formula given above.

Thus, similar to inductance, *any* circuit component that has wires attached to it, or is fabricated from wire, or is near or attached to metal, will have a parasitic capacitance associated with it, which again, becomes important only at RF.

A GENERAL MODEL

The parasitic problems due to component leads, packaging, leakage and so on are relatively common to all components. When working at frequencies where many or all of the parasitics become important, a

Fig 6.22—Capacitive consequences of Maxwell’s equations. **A:** Any changing voltage between two points, for example along a bent wire, generates a displacement current running between them. This can be mathematically described as an effective capacitance. **B** adds parasitic capacitance to a generic component model.

complex but completely general model such as that in **Fig 6.25** can be used for just about any component, with the actual component placed in the box marked “*”. Parasitic capacitance C_p and leakage conductance G_L appear in parallel across the device, while series resistance R_s and parasitic inductance L_p appear in series with it. Package capacitance C_{pkg} appears as an additional capacitance in parallel across the whole device. This maze of effects may seem overwhelming, but remember that it is very seldom necessary to consider all parasitics. In the Computer-Aided-Design section of this chapter, we will use the power of the computer to examine the combined effects of these multiple parasitics on circuit performance.

Self-Resonance

Because of the effects just discussed, a capacitor or inductor—all by itself—exhibits the properties of a resonant RLC circuit as we increase the applied frequency. **Fig 6.26** illustrates RF models for the capacitor and inductor, which are based on the general model in **Fig 6.25**, leaving out the packaging capacitance. Note the slight difference in configuration; the pairs C_p, R_p and L_s, R_s are in series in the capacitor but in parallel in the

Fig 6.23—Coils exhibit distributed capacitance as explained in the text. The graph at B shows how distributed capacitance resonates with the inductance. Below resonance, the reactance is predominantly inductive which increases as frequency increases. However, above resonance, the reactance becomes predominantly capacitive which decreases as frequency increases.

Fig 6.24—Unexpected stray capacitance. The mounting tab of TO-220 transistors is often connected to one of the device leads. Because one lead is connected to the chassis, small capacitances from the other lead to the chassis appear as additional package capacitance at the device. Similar capacitance can appear at any device with a conductive package.

inductor. This is because in the inductor, C_p and R_p are the parasitics, while in the capacitor, L_s and R_s are the added effects.

At some sufficiently high frequency, both inductors and capacitors become *self-resonant*. Just like a tuned circuit, above that frequency the capacitor will appear inductive, and the inductor will appear capacitive.

For an example, let's calculate the approximate self-resonant frequency of a 470-pF capacitor whose leads are made from #20 wire (diam 0.032 inch), with a total length of 1 inch. From the formula above, we calculate the approximate parasitic inductance

$$L (\mu\text{H}) = 0.00508 (1) \left[\ln \left(\frac{2(1)}{(0.032/2)} \right) - 0.75 \right] = 0.021 \mu\text{H}$$

and then the self-resonant frequency is roughly

$$f = \frac{1}{2\pi\sqrt{LC}} = 50.6 \text{ MHz}$$

The purpose of making these calculations is to give you a rough feel for actual component values. They could be used as a rough design guideline, but should not be used quantitatively. Other factors such as lead orientation, shielding and so on, can alter the parasitic effects to a large extent. Large-value capacitors tend to have higher parasitic inductances (and therefore a lower self-resonant frequency) than small-value ones.

Self-resonance becomes critically important at VHF and UHF because the self-resonant frequency of many common components is at or below the frequency where the component will be used. In this case, either special techniques can be used to construct components to operate at these frequencies, by reducing the parasitic effects, or else the idea of lumped elements must be abandoned altogether in favor of microwave techniques such as striplines and waveguides.

Skin Effect

The resistance of a conductor to ac is different than its value for dc. A consequence of Maxwell's equations is that thick, near-perfect conductors (such as metals) conduct ac only to a certain depth that is proportional to the wavelength of

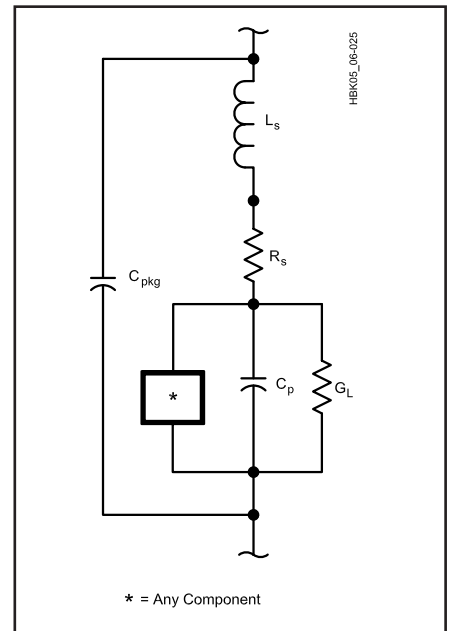

Fig 6.25—A general model for electrical components at VHF frequencies and above. The box marked "*" represents the component itself. See text for discussion.

Fig 6.26—Capacitor (A) and inductor (B) models for RF frequencies.

the signal. This decreases the effective cross-section of the conductor at high frequencies and thus increases its resistance.

This resistance increase, called *skin effect*, is insignificant at low (audio) frequencies, but beginning around 1 MHz (depending on the size of the conductor) it is so pronounced that practically all the current flows in a very thin layer near the conductor's surface. For this reason, at RF a hollow tube and a solid rod of the same diameter and made of the same metal will have the same resistance. The depth of this skin layer decreases by a factor of 10 for every 100 × increase in frequency. Consequently, the RF resistance is often much

higher than the dc resistance. Also, a thin highly conductive layer, such as silver plating, can lower resistance for UHF or microwaves, but does little to improve HF conductivity.

A rough estimate of the cutoff frequency where a nonferrous wire will begin to show skin effect can be calculated from

$$f = \frac{124}{d^2} \quad (12)$$

where

f = frequency, in MHz
 d = diam, in mils (a mil is 0.001 inch).

Above this frequency, increase the resistance of the wire by $10 \times$ for every 2 decades of frequency (roughly $3.2 \times$ for every decade). For example, say we wish to find the RF resistance of a 2-inch length of #18 copper wire at 100 MHz. From the wire tables, we see that this wire has a dc resistance of (2 in.) (6.386 Ω /1000 ft) = 1.06 milliohms. From the above formula, the cutoff frequency is found to be $124 / 40.3^2 = 76$ kHz. Since 100 MHz is roughly three decades above this (100 kHz to 100 MHz), the RF resistance will be approximately (1.06 m Ω) (10×3.2) = 34 m Ω . Again, values calculated in this manner are approximate and should be used qualitatively—that is, when you want an answer to a question such as, “Can I neglect the RF resistance of this length of connecting wire at 100 MHz?”

For additional information, see *Reference Data for Engineers*, Howard W. Sams & Co, Indianapolis, IN 46268. Chapter 6 contains a discussion and several design charts.

Effects on Q

Recall from the **AC Theory** portion of Chapter 4 that circuit Q, a useful figure of merit for tuned RLC circuits, can be defined in several ways:

$$Q = \frac{X_L \text{ or } X_C \text{ (at resonance)}}{R} \quad (13)$$

$$= \frac{\text{energy stored per cycle}}{\text{energy dissipated per cycle}}$$

Q is also related to the bandwidth of a tuned circuit’s response by

$$Q = \frac{f_0}{\text{BW}_{3\text{ dB}}} \quad (14)$$

Parasitic inductance, capacitance and resistance can significantly alter the performance and characteristics of a tuned circuit if the design frequency is anywhere

near the self-resonant frequencies of the components.

As an example, consider the resonant circuit of **Fig 6.27A**, which could represent the input tank circuit of an oscillator. Neglecting any parasitics, $f_0 = 1 / (2 \pi (LC)^{0.5}) = 10.06$ MHz. As in many real cases, assume the resistance arises entirely from the inductor series resistance. The data sheet for the inductor specified a minimum Q of 30, so assuming $Q = 30$ yields an R value of $X_L / Q = 2 \pi (10.06 \text{ MHz}) (5 \mu\text{H}) / 30 = 10.5 \Omega$.

Next, let’s include the parasitic inductance of the capacitor (**Fig 6.27B**). A reasonable assumption is that this capacitor has the same physical size as the example from the Parasitic Inductance discussion above, for which we calculated $L_s = 0.106 \mu\text{H}$. This would give the capacitor a self-resonant frequency of 434 MHz—well above our area of interest. However, the added parasitic inductance does account for an extra $0.106/5.00 = 2\%$ inductance. Since this circuit is no longer strictly series or parallel, we must convert it to an equivalent form before calculating the new f_0 .

An easier and faster way is to *simulate* the altered circuit by computer. This analysis was performed on a desktop computer using *SPICE*, a standard circuit simulation program; for more details, see the Computer-Aided Design section below. The voltage response of the circuit (given an input current of 1 mA) was calculated as a function of frequency for both cases, with and without parasitics. The results are shown in the plot in **Fig 6.27C**, where we can see that the parasitic circuit has an f_0 of 9.96 MHz (a shift of 1%) and a Q (measured from the -3 dB points) of 31.5. For comparison, the simulation of the unaltered circuit does in fact show $f_0 = 10.06$ MHz and $Q = 30$.

Inductor Coupling

Mutual inductance will also have an effect on the resonant frequency and Q of the involved circuits. For this reason, inductors in frequency-critical circuits should always be shielded, either by constructing compartments for each circuit block or through the use of “can”-mounted coils. Another helpful technique is to mount nearby coils with their axes perpendicular as in **Fig 6.28**. This will minimize coupling.

As an example, assume we build an oscillator circuit that has both input and output filters similar to the resonant circuit in **Fig 6.27A**. If we are careful to keep the two coils in these circuits uncoupled, the frequency response of either of the two circuits is that of the solid line in **Fig 6.29**, reproduced from **Fig 6.27C**.

If the two coils are coupled either through careless placement or improper shielding, the resonant frequency and Q will be affected. The dashed line in **Fig 6.29** shows the frequency response that results from a coupling coefficient of $k = 0.05$, a reasonable value for air-wound inductors mounted perpendicularly in close proximity on a circuit chassis. Note the resonant frequency shifted from 10.06 to 9.82 MHz, or 2.4%. The Q has gone up slightly from 30.0 to 30.8 as a result of the slightly higher inductive reactance at the resonant frequency.

To summarize, even small parasitics can significantly affect frequency responses of RF circuits. Either take steps to minimize or eliminate them, or use simple circuit theory to predict and anticipate changes.

Dielectric Breakdown and Arcing

Anyone who has ever watched a capacitor burn out, or heard the hiss of an arc across the inductor of an antenna tuner, while loading the 2-m vertical on 160 m, or touched a doorknob on a cold winter day has seen the effects of dielectric breakdown. When the dielectric is gaseous, especially air, we often call this *arcing*.

In the ideal world, we could take any two conductors and put as large a voltage as we want across them, no matter how close together they are. In the real world, there is a voltage limit (*dielectric strength*, measured in kV/cm and determined by the insulator between the two conductors) above which the insulator will break down.

Because they are charged particles, the electrons in the atoms of a dielectric material feel an attractive force when placed in an electric field. If the field is sufficiently strong, the force will strip the electron from the atom. This electron is available to conduct current, and furthermore, it is traveling at an extremely high velocity. It is very likely that this electron will hit another atom, and free another electron. Before long, there are many stripped electrons producing a large current. When this happens, we say the dielectric has suffered *breakdown*.

If the dielectric is liquid or gas, it can heal when the applied voltage is removed. A solid dielectric, however, cannot repair itself. A good example of this is a CMOS integrated circuit. When exposed to the very high voltages associated with static electricity, the electric field across the very thin gate oxide layer exceeds the dielectric strength of silicon dioxide, and the device is permanently damaged.

Capacitors are, by nature, perhaps the component most often associated with dielectric failure. To prevent damage, the working voltage of a capacitor—and there

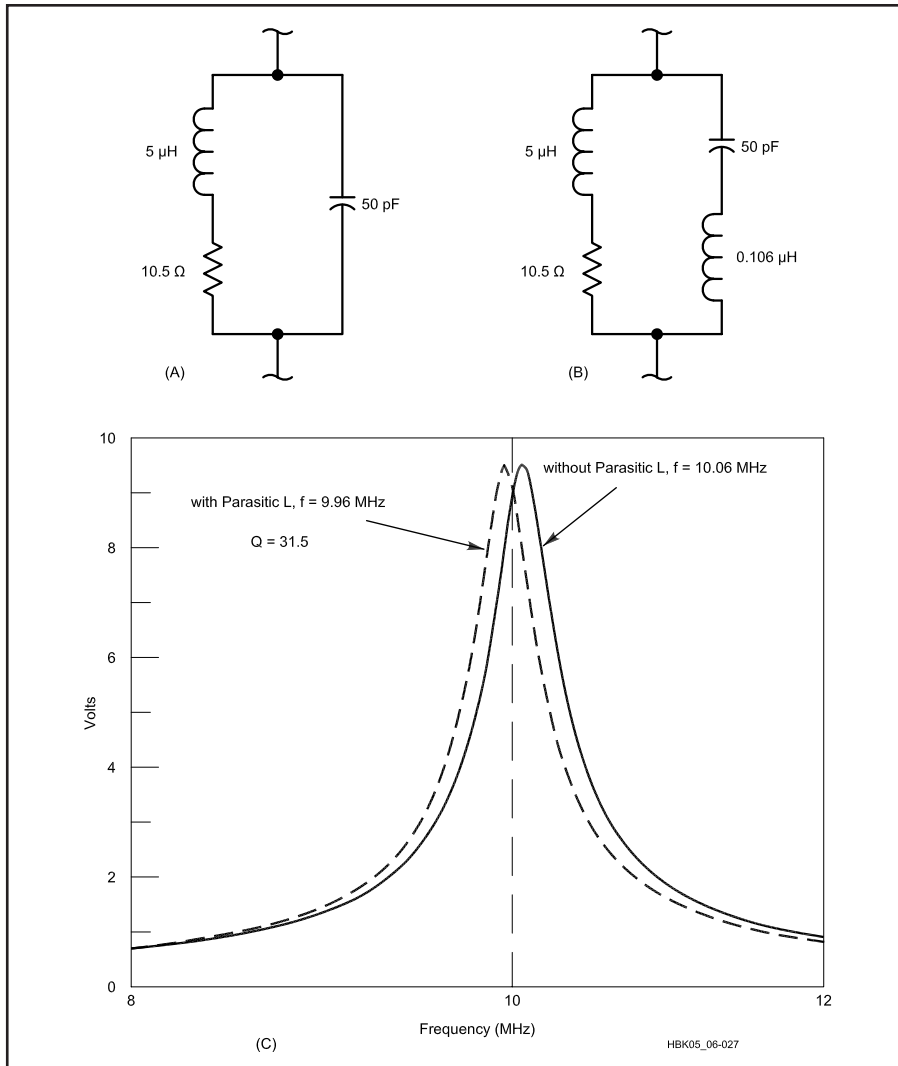

Fig 6.27—A is a tank circuit, neglecting parasitics. B same circuit including L_p on capacitor. C frequency response curves for A and B. The solid line represents the unaltered circuit (also see Fig 6.29) while the dashed line shows the effects of adding parasitic inductance.

Fig 6.28—Unshielded coils in close proximity should be mounted perpendicular to each other to minimize coupling.

are separate dc and ac ratings—should ideally be 2 or 3 times the expected maximum voltage in the circuit.

Arcing is most often seen in RF circuits where the voltages are normally high, but it is possible anywhere two components at

significantly different voltage levels are closely spaced.

The breakdown voltage of a dielectric layer depends on its composition and thickness (see **Table 6.3**). The variation with thickness is not linear; doubling the thickness does not quite double the breakdown voltage. Breakdown voltage is also a function of geometry: Because of electromagnetic considerations, the breakdown voltage between two conductors separated by a fixed distance is less if the surfaces are pointed or sharp-edged than if they are smooth or rounded. Therefore, a simple way to help prevent breakdown in many projects is to file and smooth the edges of conductors.

Radiative Losses and Coupling

Another consequence of Maxwell’s equations states that any conductor placed in an electromagnetic field will have a

current induced in it. We put this principle to good use when we make an antenna. The unwelcome side of this law of nature is the phrase “any conductor”; even conductors we don’t intend as antennas will act this way.

Fortunately, the *efficiency* of such “antennas” varies with conductor length. They will be of importance only if their length is a significant fraction of a wavelength. When we make an antenna, we usually choose a length on the order of $\lambda/2$. Therefore, when we *don’t* want an antenna, we should be sure that the conductor length is *much less* than $\lambda/2$, no more than 0.1λ . This will ensure a very low-efficiency antenna. This is why 60-Hz power lines do not lose a significant fraction of the power they carry over long distances—at 60 Hz, 0.1λ is about 300 miles!

In addition, we can use shielded cables. Such cables do allow some penetration of EM fields if the shield is not solid, but even 95% coverage is usually sufficient, especially if some sort of RF choke is used to reduce shield current.

Radiative losses and coupling can also be reduced by using twisted pairs of conductors—the fields tend to cancel. In some applications, such as audio cables, this may work better than shielding.

This argument also applies to large components, and remember that a component or long wire can *radiate* RF, as well as receive them. Critical stages such as tuned circuits should be placed in shielded compartments where possible. See the **EMI** and **Transmission Lines** chapters for more information.

REMEDIES FOR PARASITICS

The most common effect (always the most annoying) of parasitics is to influence the resonant frequency of a tuned circuit. This shift could cause an oscillator to fail, or more commonly, to cause a stable circuit to oscillate. It can also degrade filter performance (more on this later) and basically causing any number of frequency-related problems.

We can often reduce parasitic effects in discrete-component circuits by simply exploiting the models in Fig 6.26. Since parasitic inductance and loss resistance appear in series with a capacitor, we can reduce both by using several smaller capacitances in parallel, rather than of one large one.

An example is shown in the circuit block in **Fig 6.30**, which is representative of the input tank circuit used in many HF VFOs. C_{main} , C_{trim} , C1 and C3 act with L to set the oscillator frequency. Therefore, temperature effects are critical in these components. By using several capacitors in

Fig 6.29—Result of light coupling (k=0.05) between two identical circuits of Fig 6.27A on their frequency responses.

parallel, the RF current (and resultant heat) is reduced in each component. Parallel combinations are used at the feedback capacitors for the same reason.

Another example of this technique is the common capacitor bypass arrangement shown in Fig 6.31. C1 provides a bypass path at audio frequencies, but it has a low self-resonant frequency due to its large capacitance. How low? Even if we assume the 0.02-μH value shown previously in

this chapter, $f_{sc} = 355$ kHz. Adding C2 (with a smaller capacitance but much higher self-resonant frequency) in parallel provides bypass at high frequencies where C1 appears inductive.

Construction Techniques

These concepts also help explain why so many different components exist with similar values. As an example, assume you're working on a project that requires

Fig 6.30—A tank circuit of the type commonly used in VFOs. Several capacitors are used in parallel to distribute the RF current, which reduces temperature effects.

you to wind a 5 μH inductor. Looking at the coil inductance formula in the AC Theory section of Chapter 4, it comes to mind that many combinations of length and diameter could yield the desired inductance. If you happen to have both 0.5 and 1-inch coil forms, why should you select one over the other? To eliminate some other variables, let's make both coils 1 inch long, close-wound, and give them 1-inch leads on each end.

Let's calculate the number of turns required for each. On a 0.5-inch-diameter form:

$$n = \frac{\sqrt{5[(18 \times 0.5) + (40 \times 1)]}}{0.5} = 31.3 \text{ turns}$$

This means coil 1 will be made from #20 wire (29.9 turns per inch). Coil 2, on the 1-inch form, yields

$$n = \frac{\sqrt{5[(18 \times 1) + (40 \times 1)]}}{1} = 17.0 \text{ turns}$$

which requires #15 wire in order to be close-wound.

What are the series resistances associated with each? For coil 1, the total wire length is 2 inches + $(31.3 \times \pi \times 0.5) = 51$ inches, which at $10.1 \Omega / 1000$ ft gives $R_s = 0.043 \Omega$ at dc. Coil 2 has a total wire length of 2 inches + $(17.0 \times \pi \times 1) = 55$ inches, which at $3.18 \Omega / 1000$ ft gives a dc resistance of $R_s = 0.015 \Omega$, or about 1/3 that of coil 1. Furthermore, at RF, coil 1 will begin to suffer from skin effect at a frequency about 3 times lower than coil 2 because of its smaller conductor diameter. Therefore, if Q were the sole consider-

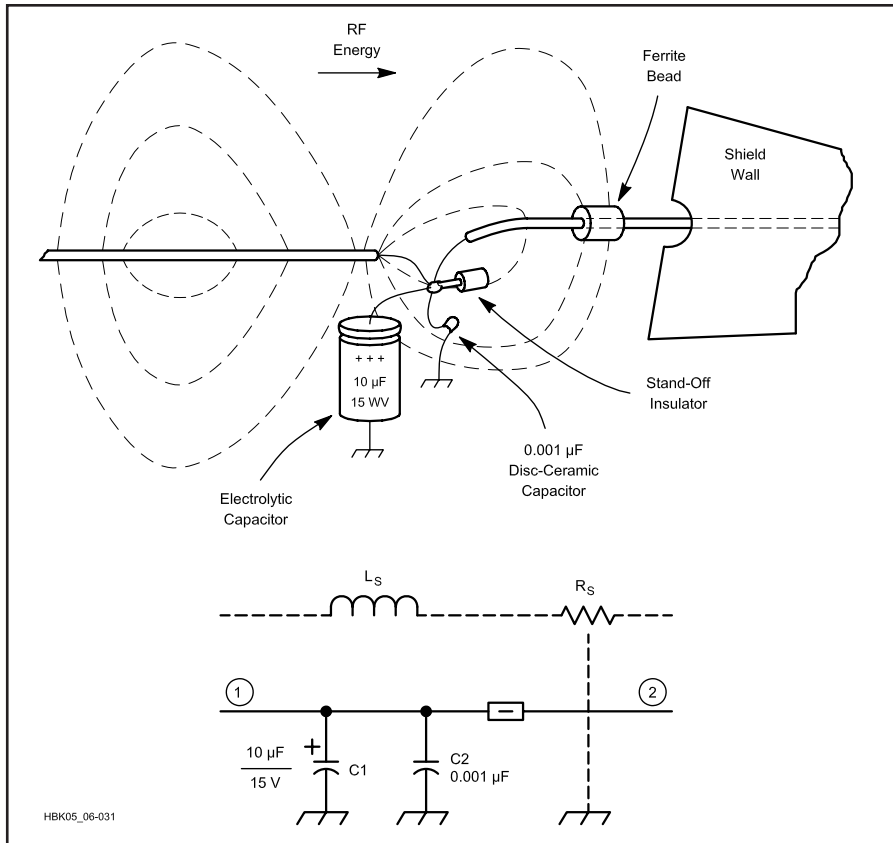

Fig 6.31—A typical method to provide bypassing at high frequencies when a large capacitor with a low-self-resonant frequency is required.

ation, it would be better to use the larger diameter coil.

Q is not the only concern, however. Such coils are often placed in shielded enclosures. Rule of thumb says the enclosure should be at least one coil diameter from the coil on all sides. That is, $3 \times 3 \times 2$ inches for the large coil and $1.5 \times 1.5 \times 1.5$ for the small coil, a volume difference of over 500%.

THERMAL CONSIDERATIONS

Any real energized circuit consumes electric power because any real circuit contains components that convert electricity into other forms of energy.¹ This *dissipated power* appears in many forms. For example, a loudspeaker converts electrical energy into the motion of air molecules we call sound. An antenna (or a light bulb) converts electricity into electromagnetic radiation. Charging a battery converts electrical energy into chemical energy (which is then converted back to electrical energy upon discharge). But the most common transformation by far is the conversion, through some form of *resistance*, of electricity into heat.

Sometimes the power lost to heat serves a useful purpose—toasters and hair dryers come to mind. But most of the time, this heat represents a power loss that is to be minimized wherever possible or at least taken into account. Since all real circuits contain resistance, even those circuits (such as a loudspeaker) whose primary purpose is to convert electricity to some *other* form of energy also convert some part of their input power to heat. Often, such losses are negligible, but sometimes they are not.

If unintended heat generation becomes significant, the involved components will get warm. Problems arise when the temperature increase affects circuit operation by either

- causing the component to fail, by explosion, melting, or other catastrophic event, or, more subtly,
- causing a slight change in the properties of the component, such as through a temperature coefficient (TC).

In the first case, we can design conservatively, ensuring that components are rated to safely handle two, three or more times the maximum power we expect them

to dissipate. In the second case, we can specify components with low TCs, or we can design the circuit to minimize the effect of any one component. Occasionally we even exploit temperature effects (for example, using a resistor, capacitor or diode as a temperature sensor). Let's look more closely at the two main categories of thermal effects.

HEAT DISSIPATION

Not surprisingly, heat dissipation (more correctly, the efficient removal of generated heat) becomes important in medium- to high-power circuits: power supplies, transmitting circuits and so on. While these are not the only examples where elevated temperatures and related failures are of concern, the techniques we will discuss here are applicable to all circuits.

Thermal Resistance

The transfer of heat energy, and thus the change in temperature, between two ends of a block of material is governed by the following heat flow equation (see **Fig 6.32**):

$$P = \frac{k A}{L} \Delta T = \frac{\Delta T}{\theta} \quad (15)$$

where

P = power (in the form of heat) conducted between the two points

k = *thermal conductivity*, measured in $W/(m \text{ } ^\circ C)$, of the material between the two points, which may be steel, silicon, copper, PC board material and so on

L = length of the block

A = area of the block

ΔT = *change* in temperature between the two points;

$\theta = \frac{L}{kA}$ is often called the *thermal resistance* and has units of $^\circ C/W$.

Thermal conductivities of various common materials at room temperature are given in **Table 6.4**.

A very useful property of the above equation is that it is *exactly* analogous to Ohm's Law, and therefore the same principles and methods apply to heat flow problems as circuit problems. The following correspondences hold:

- Thermal conductivity $W/(m \text{ } ^\circ C) \leftrightarrow$ Electrical conductivity (S/m).
- Thermal resistance ($^\circ C/W$) \leftrightarrow Electrical resistance (Ω).
- Thermal current (heat flow) (W) \leftrightarrow Electrical current (A).
- Thermal potential (T) \leftrightarrow Electrical potential (V).
- Heat source \leftrightarrow Current source.

For example, calculate the temperature of a 2-inch (0.05 m) long piece of #12 copper wire at the end that is being heated by a 25 W (input power) soldering iron, and whose other end is clamped to a large metal vise (assumed to be an infinite heat sink), if the ambient temperature is 25 °C (77 °F).

First, calculate the thermal resistance of the copper wire (diameter of #12 wire is 2.052 mm, cross-sectional area is $3.31 \times 10^{-6} \text{ m}^2$)

$$\theta = \frac{L}{kA} = \frac{(0.05 \text{ m})}{(390 \text{ W}/(\text{m}^\circ\text{C})) (3.31 \times 10^{-6} \text{ m}^2)} = 38.7^\circ\text{C}/\text{W}$$

Then, rearranging the heat flow equation above yields (after assuming the heat energy actually transferred to the wire is around 10 W)

$$\Delta T = P\theta = (10 \text{ W})(38.7^\circ\text{C}/\text{W}) = 387^\circ\text{C}$$

So the wire temperature at the hot end is $25^\circ\text{C} + \Delta T = 412^\circ\text{C}$ (or 774°F). If this sounds a little high, remember that this is for the steady state condition, where you've been holding the iron to the wire for a long time.

From this example, you can see that things can get very hot even with application of moderate power levels. In the case of a soldering iron, that's good, but in the case of a 25-W power transistor in a transmitter output stage, it's bad. For this reason, circuits that generate sufficient heat to alter, not necessarily damage, the components must employ some method of cooling, either active or passive. Passive methods include heat sinks or careful component layout for good ventilation. Active methods include forced air (fans) or some sort of liquid cooling (in some high-power transmitters).

Fig 6.32—Physical and “circuit” models for the heat-flow equation.

Heat Sink Design and Use

The purpose of a heat sink is to provide a high-power component with a large surface area through which to dissipate heat. To use the models above, it provides a low thermal-resistance path to a cooler temperature, thus allowing the hot component to conduct a large “thermal current” away from itself.

Power supplies probably represent one of the most common high-power circuits amateurs are likely to encounter. Everyone has certainly noticed that power supplies get warm or even hot if not ventilated properly. Performing the thermal design for a properly cooled power supply is a very well-defined process and is a good illustration of heat-flow concepts.

A 28-V, 10-A power supply will be used for this design example. This material was originally prepared by ARRL Technical Advisor Dick Jansson, WD4FAB, and the steps described below were actually followed during the design of that supply.

An outline of the design procedure shows the logic applied:

1. Determine the expected power dissipation (P_{in}).
2. Identify the requirements for the dissipating elements (maximum component temperature).
3. Estimate heat-sink requirements.
4. Rework the electronic device (if necessary) to meet the thermal requirements.
5. Select the heat exchanger (from heat sink data sheets).

The first step is to estimate the filtered, unregulated supply voltage under full load. Since the transformer secondary output is 32 V ac (RMS) and feeds a full-wave bridge rectifier, let's estimate 40 V as the filtered dc output at a 10-A load.

Table 6.4
Thermal Conductivities of Various Materials

Gases at 0°C, Others at 25°C; from *Physics*, by Halliday and Resnick, 3rd Ed.

Material	(k in units of $\frac{\text{W}}{\text{m}^\circ\text{C}}$)
Aluminum	200
Brass	110
Copper	390
Lead	35
Silver	410
Steel	46
Silicon	150
Air	0.024
Glass	0.8
Wood	0.08

The next step is to determine our critical components and estimate their power dissipations. In a regulated power supply, the pass transistors are responsible for nearly all the power lost to heat. Under full load, and allowing for some small voltage drops in the power-transistor emitter circuitry, the output of the series pass transistors is about 29 V for a delivered 28 V under a 10-A load. With an unregulated input voltage of 40 V, the total energy heat dissipated in the pass transistors is $(40 \text{ V} - 29 \text{ V}) \times 10 \text{ A} = 110 \text{ W}$. The heat sink for this power supply must be able to handle that amount of dissipation and still keep the transistor junctions below the specified safe operating temperature limits. It is a good rule of thumb to select a transistor that has a maximum power dissipation of twice the desired output power.

Now, consider the ratings of the pass transistors to be used. This supply calls for 2N3055s as pass transistors. The data sheet shows that a 2N3055 is rated for 15-A service and 115-W dissipation. But the design uses *four* in parallel. Why? Here we must look past the big, bold type at the top of the data sheet to such subtle characteristics as the junction-to-case thermal resistance, θ_{jc} , and the maximum allowable junction temperature, T_j .

The 2N3055 data sheet shows $\theta_{jc} = 1.52^\circ\text{C}/\text{W}$, and a maximum allowable case (and junction) temperature of 220°C . While it seems that one 2N3055 could barely, on paper at least, handle the electrical requirements, at what temperature would it operate?

To answer that, we must model the entire “thermal circuit” of operation, starting with the transistor junction on one end and ending at some point with the ambient air. A reasonable model is shown in Fig 6.33. The ambient air is considered here as an infinite heat sink; that is, its temperature is assumed to be a constant 25°C (77°F). θ_{jc} is the thermal resistance from the transistor junction to its case. θ_{cs} is the resistance of the mounting interface between the transistor case and the heat sink. θ_{sa} is the thermal resistance between the heat sink and the ambient air. In this “circuit,” the generation of heat (the “thermal current source”) occurs in the transistor at P_{in} .

Proper mounting of most TO-3 package power transistors such as the 2N3055 requires that they have an electrical insulator between the transistor case and the heat sink. However, this electrical insulator must at the same time exhibit a low thermal resistance. To achieve a quality mounting, use thin polyimid or mica formed washers and a suitable thermal compound to exclude air from the intersti-

Fig 6.33—Resistive model of thermal conduction in a power transistor and associated heat sink. See text for calculations.

tial space. “Thermal greases” are commonly available for this function. Any silicone grease may be used, but filled silicone oils made specifically for this purpose are better.

Using such techniques, a conservatively high value for θ_{cs} is 0.50°C/W . Lower values are possible, but the techniques needed to achieve them are expensive and not generally available to the average amateur. Furthermore, this value of θ_{cs} is already much lower than θ_{jc} , which cannot be lowered without going to a somewhat more exotic pass transistor.

Finally, we need an estimate of θ_{sa} . **Fig 6.34** shows the relationship of heat-sink volume to thermal resistance for natural-convection cooling. This relationship presumes the use of suitably spaced fins (0.35 inch or greater) and provides a “rough order-of-magnitude” value for sizing a heat sink. For a first calculation, let’s assume a heat sink of roughly $6 \times 4 \times 2$ inch (48 cubic inches). From **Fig 6.34**, this yields a θ_{sa} of about 1°C/W .

Returning to **Fig 6.33**, we can now calculate the approximate temperature increase of a single 2N3055:

$$\delta T = P \theta_{\text{total}} = (110 \text{ W}) \times (1.52^\circ\text{C/W} + 0.5^\circ\text{C/W} + 1.0^\circ\text{C/W}) = 332^\circ\text{C}$$

Given the ambient temperature of 25°C , this puts the junction temperature T_j of the 2N3055 at $25 + 332 = 357^\circ\text{C}$! This is clearly too high, so let’s work backward from the air end and calculate just how many transistors we need to handle the heat.

First, putting more 2N3055s in parallel means that we will have the thermal model illustrated in **Fig 6.35**, with several identical θ_{jc} and θ_{cs} in parallel, all funneled through the same θ_{as} (we have one heat sink).

Keeping in mind the physical size of the project, we could comfortably fit a heat sink of approximately 120 cubic inches ($6 \times 5 \times 4$ inches), well within the range of commercially available heat sinks. Furthermore, this application can use a heat sink where only “wire access” to the transistor connections is required. This allows the selection of a more efficient design. In contrast, RF designs require the transistor mounting surface to be completely

Fig 6.34—Thermal resistance vs heat-sink volume for natural convection cooling and 50°C temperature rise. The graph is based on engineering data from Wakefield Thermal Solutions, Inc.

exposed so that the PC board can be mounted close to the transistors to minimize parasitics. Looking at **Fig 6.34**, we see that a 120-cubic-inch heat sink yields a θ_{sa} of 0.55°C/W . This means that the temperature of the heat sink when dissipating 110 W will be $25^\circ\text{C} + (110 \text{ W})(0.55^\circ\text{C/W}) = 85.5^\circ\text{C}$.

Industrial experience has shown that silicon transistors suffer substantial failure when junctions are operated at highly elevated temperatures. Most commercial and military specifications will usually not permit design junction temperatures to exceed 125°C . To arrive at a safe figure for our maximum allowed T_j , we must consider the intended use of the power supply. If we are using it in a 100% duty-cycle transmitting application such as RTTY or FM, the circuit will be dissipating 110 W continuously. For a lighter duty-cycle load such as CW or SSB, the “key-down” temperature can be slightly higher as long as the average is less than 125°C . In this intermittent type of service, a good conservative figure to use is $T_j = 150^\circ\text{C}$.

Given this scenario, the temperature rise across each transistor can be $150 - 85.5 = 64.5^\circ\text{C}$. Now, referencing **Fig 6.35**, remembering the total θ for each 2N3055 is $1.52 + 0.5 = 2.02^\circ\text{C/W}$, we can calculate the maximum power each 2N3055 can safely dissipate:

$$P = \frac{\delta T}{\theta} = \frac{64.5^\circ\text{C}}{2.02^\circ\text{C/W}} = 31.9 \text{ W}$$

Thus, for 110 W full load, we need four 2N3055s to meet the thermal requirements of the design. Now comes the big question: What is the “right” heat sink to use? We have already established its requirements: it must be capable of dissipating 110 W, and have a θ_{sa} of 0.55°C/W (see above).

A quick consultation with several manufacturer’s catalogs reveals that Wakefield Thermal Solutions, Inc. model nos. 441 and 435 heat sinks meet the needs of this application.² A Thermalloy model no. 6441 is suitable as well. Data published in the catalogs of these manufacturers show that in natural-convection service, the expected temperature rise for 100 W dissipation would be just under 60°C , an almost perfect fit for this application. Moreover, the no. 441 heat sink can easily mount four TO-3-style 2N3055 transistors. See **Fig 6.36**. Remember: heat sinks should be mounted with the fins and transistor mounting area vertical to promote convection cooling.

The design procedure just described is applicable to any circuit where heat buildup is a potential problem. By using the thermal-resistance model, we can easily calcu-

Fig 6.35—Thermal model for multiple power transistors mounted on a common heat sink.

late whether or not an external means of cooling is necessary, and if so, how to choose it. Aside from heat sinks, forced air cooling (fans) is another common method. In commercial transceivers, heat sinks with forced-air cooling are common.

Transistor Derating

Maximum ratings for power transistors are usually based on a case temperature of 25°C. These ratings will decrease with increasing operating temperature. Manufacturer’s data sheets usually specify a *derating* figure or curve that indicates how the maximum ratings change per degree rise in temperature. If such information is not available (or even if it is!), it is a good rule of thumb to select a power transistor with a maximum power dissipation of at least twice the desired output power.

Rectifiers

Diodes are physically quite small, and they operate at high current densities. As a result their heat-handling capabilities are somewhat limited. Normally, this is not a problem in high-voltage, low-current supplies. The use of high-current (2 A or greater) rectifiers at or near their maximum ratings, however, requires some form of heat sinking. Frequently, mounting the rectifier on the main chassis (directly, or with thin mica insulating washers) will suffice. If the diode is insulated from the chassis, thin layers of silicone grease should be used to ensure good heat conduction. Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling is sometimes used as a further aid.

Forced-Air Cooling

In Amateur Radio today, forced-air cooling is most commonly found in vacuum-tube circuits or in power supplies built in small enclosures, such as those in

solid-state transceivers or computers. Fans or blowers are commonly specified in cubic feet per minute (CFM). While the nomenclature and specifications differ from those used for heat sinks, the idea remains the same: to offer a low thermal resistance between the inside of the enclosure and the (ambient) exterior.

For forced air cooling, we basically use the “one resistor” thermal model of Fig 6.32. The important quantity to be determined is heat generation, P_{in} . For a power supply, this can be easily estimated as the difference between the input power, measured at the transformer primary, and the output power at full load. For variable-voltage supplies, the worst-case output condition is minimum voltage with maximum current.

A discussion of forced-air tube cooling

appears in the **RF Power Amplifiers** chapter.

TEMPERATURE STABILITY

Aside from catastrophic failure, temperature changes may also adversely affect circuits if the TCs of one or more components is too large. If the resultant change is not too critical, adequate temperature stability can often be achieved simply by using higher-precision components with low TCs (such as NP0/COG capacitors or metal-film resistors). For applications where this is impractical or impossible (such as many solid-state circuits), we can minimize temperature sensitivity by *compensation* or *matching*—using temperature coefficients to our advantage.

Compensation is accomplished in one of two ways. If we wish to keep a certain circuit quantity constant, we can interconnect pairs of components that have equal but opposite TCs. For example, a resistor with a negative TC can be placed in series with a positive TC resistor to keep the total resistance constant. Conversely, if the important point is to keep the *difference* between two quantities constant, we can use components with the *same* TC so that the pair “tracks.” That is, they both change by the same amount with temperature.

An example of this is a Zener reference circuit. Since the I-V equation for a diode is strongly affected by operating temperature, circuits that use diodes or transistors to generate stable reference voltages must use some form of temperature compensation. Since, for a constant current, a

Fig 6.36—A Wakefield 441 heat sink with four 2N3055 transistors mounted.

The Thermistor in Homebrew Projects

Thermistors can be used to enhance project performance. Circuit temperature variations affect gain, distortion as well as control functions like receiver AGC or transmitter ALC. Thermistors can compensate for temperature changes. This greatly reduces the dangers of self destruction of overheated power transistors. It also can help reduce oscillator drift. In this sidebar, William Sabin, W0IYH describes how a simple temperature control circuit can be used to protect a MOSFET power amplifier or produce a temperature-stable heater to regulate the temperature of a VFO.

A thermistor is a small bit of intrinsic (no N or P doping) metal-oxide semiconductor compound material between two wire leads. As temperature increases, the number of liberated hole/electron pairs increases exponentially, causing the resistance to decrease exponentially. You can see this in the resistance equation:

$$R(T) = R(T_0) e^{-\beta \left(\frac{1}{T} - \frac{1}{T_0} \right)} \quad (\text{Eq 1})$$

where T is some temperature in kelvins and T₀ is a reference temperature, usually 298 K (25°C), at which the manufacturer specifies R(T₀). The constant β is experimentally determined by measuring resistance at various temperatures and finding the value of β that best agrees with the measurements. A simple way to get an approximate value of β is to make two measurements, one at room temperature, say 25°C (298 K) and one at 100°C (373 K) in boiling water. Suppose the resistances are 10 kΩ and 938 Ω. Eq 1 is solved for β

$$\beta = \frac{\ln \left(\frac{R(T)}{R(T_0)} \right)}{\frac{1}{T} - \frac{1}{T_0}} = \frac{\ln \left(\frac{938}{1000} \right)}{\frac{1}{373} - \frac{1}{298}} = 3507 \quad (\text{Eq 2})$$

For many electronics applications, the exact value of temperature is not as important as the ability to maintain

that temperature. The following examples illustrate some thermistor circuit designs.

MOSFET Power Transistor Protector

It is very desirable to compensate the temperature sensitivity of power transistors. In bipolar (BJT) transistors, thermal runaway occurs because the dc current gain increases as the transistors get hotter. In MOSFET transistors, thermal runaway is less likely to occur. With excessive drain dissipation or inadequate cooling, however, the junction temperature may increase until its maximum allowable value is exceeded. You can place a thermistor on the heat sink close to the transistors so that the bias adjustment tracks the flange temperature. Another good idea is to attach a thermistor to the ceramic case of the FET with a small drop of epoxy. That way it will respond more quickly to a sudden temperature increase, possibly saving the transistor from destruction.

The circuit of **Fig A** uses a thermistor to detect a case temperature of about 93°C, with an ON/OFF operating range of about 0.3°C. A red LED warns of an overtemperature condition that requires attention. The LM339 comparator toggles when R_t = R₅. Resistors R₃, R₄, R₅ and the thermistor form a Wheatstone bridge. R₃ and R₄ are chosen to make the inputs to the LM339 about 0.5 V at the desired temperature. This greatly reduces self-heating of the thermistor, which could cause a substantial error in the circuit behavior.

The RadioShack Precision Thermistor RS 271-110 used in this circuit is rated at 10 kΩ ±1% at 25°C. It comes with a calibration chart from -50°C to +110°C that you can use to get an approximate resistance at any temperature in that range. For many temperature protection applications you don't have to know the exact temperature. You won't need an exact calibration, but you can verify that the thermistor is working properly by measuring its resistance at 20°C (68°F) and in boiling water (≈100°C).

As one example of how you can use this circuit, suppose you want to protect a power amplifier that uses a

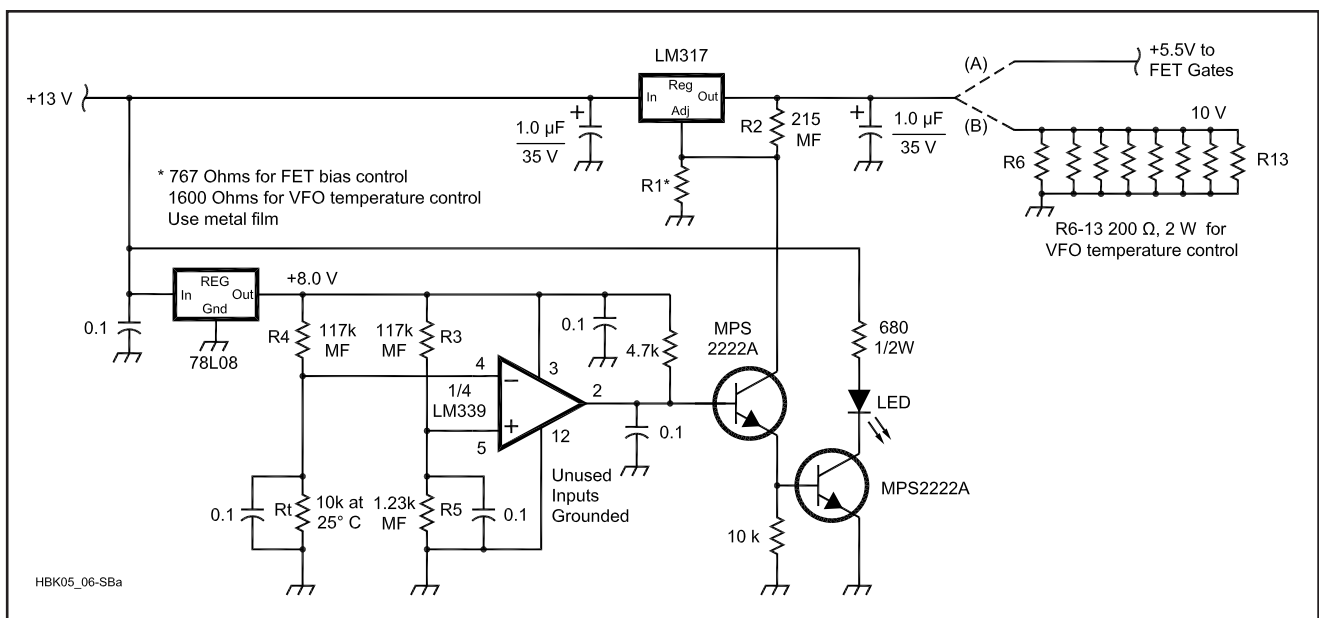

Fig A—Temperature controller for PA (A) or VFO (B).

Fig B—Temperature controlled VFO cabinet. 1/4-inch plexiglass on the outside and 1/4-inch styrofoam panels on the inside are used to improve temperature stability.

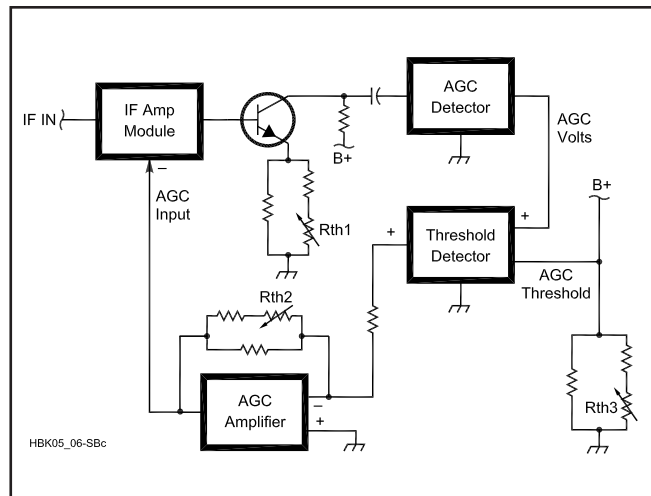

Fig C—Temperature compensation of IF amplifier and AGC circuitry.

pair of MRF150 MOSFETs. Use the following procedure to get the desired temperature control:

The MRF150 MOSFET has a maximum allowed junction temperature of 200°C. The thermal resistance θ_{JC} from junction to case is 0.6°C per watt. The maximum expected dissipation of the FET in normal operation is 110 W. Select

a case temperature of 93°C. This makes the junction temperature $93^\circ\text{C} + (0.6^\circ\text{C/W}) \times (110 \text{ W}) = 159^\circ\text{C}$, which is a safe 41°C below the maximum allowed temperature.

The FET has a rating of 300 W maximum dissipation at a case temperature of 25°C, derated at 1.71 W per °C. At 93°C case temperature the maximum allowed dissipation is $300 \text{ W} - 1.71 \text{ W/}^\circ\text{C} \times (93^\circ\text{C} - 25^\circ\text{C}) = 184 \text{ W}$. The safety margin *at that temperature* is $184 - 110 = 74 \text{ W}$.

A very simple way to determine the correct value of R5 is to put the thermistor in 93°C water (let it stabilize) and adjust R5 so that the circuit toggles. At 93°C, the measured value of the thermistor should be about 1230 Ω.

To use the circuit of Fig A to control the FET bias voltage, set R1 to be 767 Ω. This value, along with R2 adjusts the LM317 voltage regulator output to 5.5V for the FET gate bias. When the thermistor heats to the set point, the LM339 comparator toggles on. This brings the FET gate voltage to a low level and completely turns off the FETs until the temperature drops about 0.3°C. Use metal film resistors throughout the circuit.

Temperature controlled variable frequency oscillator (VFO)

The same circuit can be used to control the temperature of a VFO (variable frequency oscillator) with a few simple

changes. Select R1 to be 1600 Ω (metal film) to adjust the LM317 for 10 V. Add resistors R6 through R13 as a heater element. Place the VFO in a thermally insulated enclosure such as shown in Fig B. The eight 200-Ω, 2-W, metal-oxide resistors at the output of the LM317 supply about 4 W to maintain a temperature of about 33°C inside the enclosure. The resistors are placed so that heat is distributed uniformly. Five are placed near the bottom and three near the top. The thermistor is mounted in the center of the box, close to the tuned circuit and in physical contact with the oscillator groundplane surface, using a small drop of epoxy.

Use a massive and well-insulated enclosure to slow the rate of temperature change. In one project, over a 0.1°C range, the frequency at 5.0 MHz varied up and down ± 20 Hz or less, with a period of about five minutes. Superimposed is a very slow drift of average frequency that is due to settling down of components, including possibly the thermistor. These gradual changes became negligible after a few days of “burn-in.” One problem that is virtually eliminated by the constant temperature is a small but significant “retrace” effect of the cores and capacitors, and perhaps also the thermistor, where a substantial temperature transient of some kind may take from minutes to hours to recover the previous L and C values.

For a much more detailed discussion of this material, see Sabin W.E., WØIYH “Thermistors in Homebrew Projects,” *QEX* Nov/Dec 2000. This article is included (with all *QST*, *QEX* and *NCJ* articles from 2000) on the *2000 ARRL Periodicals* CD-ROM. (Order No. 8209.)

reverse-biased PN junction has a negative voltage TC while a forward-biased junction has a positive voltage TC, a good way to temperature-compensate a Zener reference diode is to place one or more forward-biased diodes in series with it.

RF Heating

RF current often causes component

heating problems where the same level of dc current may not. An example is the tank circuit of an RF oscillator. If several small capacitors are connected in parallel to achieve a desired capacitance, skin effect will be reduced and the total surface area available for heat dissipation will be increased, thus significantly reducing the RF heating effects as compared to a single

large capacitor. This technique can be applied to any similar situation; the general idea is to divide the heating among as many components as possible.

CAD TOOLS FOR CIRCUIT DESIGN

Hams today enjoy the easy availability of tremendous computing power to aid them in their hobby. A commercial appli-

cation that computers perform very well is circuit simulation. Today anyone with access to a computer software bulletin board is likely to find shareware or other inexpensive software to perform such analysis. Indeed, ARRL offers *ARRL Radio Designer*, which provides excellent RF design capabilities at a reasonable price. *Radio Designer* is discussed in October 1994 *QST* and a subsequent *QST* column, “Exploring RF.”

The advantages of computer circuit simulation over pencil-and-paper calculation are many. For example, while the analysis of a small circuit, say 5 to 10 components, may be recomputed without too much effort if the design changes, the same is not true for a 50 to 100-component circuit. Indeed, the larger circuit may require too many simplifying assumptions to calculate by hand at all. It is much faster to watch and adjust the response of a circuit on a computer screen than to breadboard the circuit in search of the same information.

All circuit simulators, including *SPICE*, work from a *netlist* that is simply a component-by-component list of the circuit that tells the program how components are interconnected. The program then uses standard techniques of numerical analysis and matrix mathematics to calculate the analysis you wish to perform. Common analyses include dc and ac bias and operating point calculations, frequency response curves, transient analysis (looking at waveforms in the circuit over a specified period of time), Fourier transforms, transfer functions, two-port parameter calculations, and pole-zero analysis. Many packages also perform sensitivity analyses: calculating what happens to the voltages and currents as you sweep the value(s) of an individual component (or group of components), and statistical analyses: determining the variational “window” of the system response that would result if all component values randomly varied by a given tolerance (also known as *Monte Carlo* analysis).

Beware!

Before we turn to a brief introduction to circuit simulation for the amateur, a *caveat* to the reader is definitely in order: However fast and powerful the computer may seem, keep in mind that it is only another tool in your workshop, just like your ‘scope or soldering iron. Circuit simulations are only meaningful if you can interpret the results correctly, and a good initial circuit design based on real experience and common sense is mandatory. *SPICE* and other programs have no problem with a bench-top power supply delivering 10,000 V to a 5-W resistor because you

made a mistake when specifying the circuit. Software also won’t remind you that the resistor better be rated for 20 megawatts! Remember, the real power behind any simulation software is *your mind*.

SPICE

The electronics industry has been the main consumer of circuit simulation packages ever since the development of *SPICE* (or Simulation Program with Integrated Circuit Emphasis) on mainframe systems in the mid 1970s. While many companies today produce other simulation software, *SPICE* remains the *de facto* industry standard. *SPICE* itself now exists in many “flavors”, and specially tailored versions for desktop computers are sold by several companies, including *PSPICE* by Microsim Corp and *HSPICE* by Intusoft. In fact, an “evaluation” copy of *PSPICE* has been placed in the public domain by Microsim and is probably the easiest and most inexpensive way for amateurs to begin circuit simulation. It may be obtained (with a companion reference book) from technical bookstores, and also from many sites on the Internet.

A Basic Circuit

Consider the simple RC low-pass filter in **Fig 6.37A**. To simulate this circuit, we must first precisely describe it. Convention sets ground as *node 0*, and we label all other nodes (a node is a place where two or more components meet) with numbers, as shown in the figure. We give each element a unique name, and then prepare a *netlist*, listing each element with the numbers of its “+” and “-” nodes (*SPICE* assumes the ground node to be labeled 0), and its value, as shown at B in the figure.

The question we wish to answer by simulation is the following: what is the frequency response of this filter? Of course, for this simple problem we can calculate the answer by hand. The cutoff frequency of a simple RC filter is given by:

$$f_{co} = \frac{1}{2\pi RC} \quad (17)$$

where

- f_{co} = cutoff frequency (–3 dB)
- R = resistance, in ohms
- C = capacitance, in farads.

In this case f_{co} is 1.59 kHz. Beyond this, with one storage element (the capacitor) we expect the output to decrease by 20 dB for each decade of frequency.

Fig 6.38 shows the graph of the ratio of output to input voltages V_{out}/V_{in} , in dB for that frequency range as calculated

by *SPICE*. Note the 3-dB point is indeed 1.59 kHz, and above that frequency the response drops by 20-dB/decade.

At this point we could use this circuit to ask some “What if?” questions, but for a circuit this simple we could answer those questions with pencil and paper. Below is a more extensive design to show the power of simulation, where “What if?” questions and the interaction of numerous components are much more easily and clearly examined with a computer.

A Case Study: Amplifier Distortion

An application where computer circuit simulation does a much faster, easier, and more accurate job than pencil and paper is Fourier analysis. Recall that any periodic signal can be broken down into a sum of sine waves of different amplitudes whose frequencies are multiples of the fundamental frequency of the signal. Performing such an analysis allows us to identify how much signal power is contained in the fundamental frequency and its harmonics. A Fourier *transform* is the representation of a signal by its frequency components, and resembles what you would see if you fed the signal into a spectrum analyzer.

Consider the amplifier circuit in **Fig 6.39**, which is a simple common-emitter audio amplifier. The frequency response of its voltage gain, calculated from *SPICE*, is shown in **Fig 6.40**. Pay particular attention to the voltage gain at 1 kHz, which is 148, or 43.4 dB. If we place a small ac signal on the input as shown in Fig 6.39, the output will be a faithfully amplified sine wave. However, the amplifier is powered from a 9-V supply, so when the output reaches this level, the waveform will begin to show signs of clipping. For a 1-kHz signal, this will occur at roughly $V_{in} = 4.5/148 = 0.03$ V amplitude.

Total Harmonic Distortion is a common figure of merit for audio amplifiers, and is defined as

$$THD = \frac{P_H}{P_F} \times 100 \quad (18)$$

where

- THD = total harmonic distortion, in percent
- P_H = total power in all harmonics above the fundamental
- P_F = power in fundamental.

SPICE readily calculates the Fourier content of a signal and also THD. Assume that we will tolerate 5% THD for our design. What is the maximum swing we can allow the input signal?

Fig 6.41 shows the output waveforms that *SPICE* calculates for our circuit with input signals of 0.001, 0.003, 0.01, 0.03

and 0.1-V amplitude. Note that, as expected, the last two input voltages show definite signs of clipping. What is not so evident is that the smaller inputs have some distortion as well, due to the small but finite nonlinearity of the amplifier even at those voltages.

Fig 6.42 shows the relative amplitudes of the harmonic content (Fourier transform) of the Fig 6.41 waveforms, all normalized to fundamental = 100%. You can see how the higher harmonics grow in strength as the signal increases, especially when the clipping starts. The THD for each case is also shown, and from this simulation we see we must limit our input to somewhere between 0.003 and 0.01 V. We would pin this down more closely by running another simulation around this “window.”

A caution is in order here. Circuit models have limits just as do circuits. The models apply only over a limited dynamic range. That’s why we have both small- and large-signal models. One challenge of CAD is determining the limits of your models. There is more information about this in the sections on modeling transistors.

Conclusion

Start using your computer for more chal-

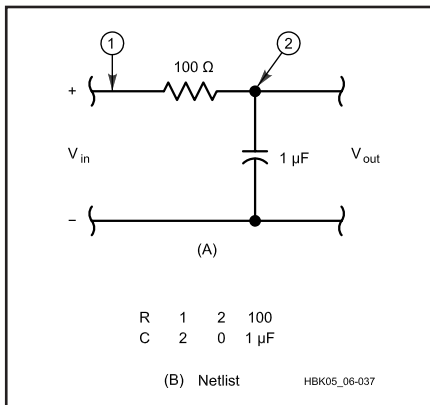

Fig 6.37—A, a simple RC low-pass filter.

lenging tasks than QSL bookkeeping! Just like any other piece of software, you’ll find yourself using *SPICE* to do things you never thought of trying before. It can even do digital circuits, transmission lines and antennas. Remember that a computer is only as smart as the person using it! Have fun!

LOW-FREQUENCY TRANSISTOR MODELS

The Fundamental Equations

Design models are based on the physics of the components we use. The complexity of models can vary widely though, and many times we can use very simple models to achieve our goals. Increasingly complex models are developed and used only when demanded by the circuit application.

In this discussion, we will focus on simple models for bipolar transistors (BJTs) and FETs. These models are reasonably accurate at low frequencies, and they are of some use at RF. For more sophisticated RF models, look to professional RF-design literature. This discussion is adapted from Wes Hayward’s *Introduction to RF Design*. Derivations of the material shown here appear in that book, an excellent text for the beginning RF designer.

This discussion is centered on NPN BJTs and N-channel JFETs. The material here applies to PNPs and P-channel FETs when you simply change the bias polarities.

First, consider the bipolar transistor as a current controlled device. When the base current controls the collector current, this

equation defines the transistor operation

$$I_c = \beta I_b \quad (19)$$

where β = common-emitter current gain.

When we consider a transistor as a voltage-controlled device, this equation describes it (emitter current, I_e , in terms of base-emitter voltage, V_{be}):

$$I_e = I_{es} [\exp(qV/kT) - 1] \approx I_{es} \exp(qV/kT) \quad (20)$$

where

- $V = V_{be}$
- q = electronic charge
- k = Boltzmann’s constant
- T = temperature in kelvins (K)
- I_b = emitter saturation current, typically 1×10^{-13} A.

Both equations approximate models of more complex behavior. Equation 20 is a simplification of the first Ebers-Moll model (Ref 1). More sophisticated models for BJTs are described by Getreu in Ref 2. Equations 19 and 20 apply to both transistor dc biasing and signal design.

The operation of an N-channel JFET can be characterized by

$$I_D = I_{DSS} (1 - V_{sg}/V_p)^2 \quad (21)$$

where

- I_{DSS} = drain saturation current
- V_{sg} = the source-gate voltage
- V_p = the pinch-off voltage.

This equation applies only so long as V_{sg} is between 0 and V_p . JFETs are seldom used with the gate-to-channel diode forward biased. Drain current, I_D , is 0 when V_{sg} exceeds V_p . This equation applies to both biasing and signal design.

Now that we have some basic equations, let’s go on to some other areas:

- Small-signal amplifier design (and application limits).
- Large-signal amplifier design (distortion from nonlinearity).

BIPOLAR TRANSISTORS (SMALL SIGNALS)

Transistors are usually driven by both biasing and signal voltages. Small-signal models treat only the signal components. We will consider bias and nonlinear signal effects later.

A Basic Common-Emitter Model

Fig 6.43 shows a BJT amplifier. The circuit is adequately described by equation 19. A mathematical analysis of the control and output currents and voltages yields the small-signal common-emitter

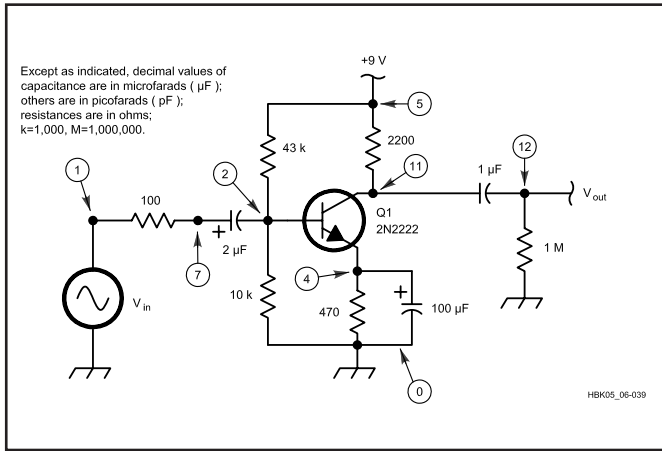

Fig 6.39—Common-emitter audio amplifier used in the text.

amplifier model shown in Fig 6.44

Gain vs Frequency

r_e . That's no trouble, however, $r_e = kT / qI_e$, or $r_e = 26 / I_e$, where I_e is the dc bias current in milliamperes. This value applies at a typical ambient temperature of 300 K.

The device output resistance is infinite because it is a pure current source, which is a good approximation for most silicon transistors at low frequencies. In use, the collector lead would feed a load resistor, R_L . For this model, that resistance must be small enough so that the collector bias volt-

constant through the audio spectrum, but it eventually decreases, and at some high frequency it will drop by a factor of 2 for each doubling of signal frequency. A transistor's frequency vs current gain relationship is specified by its *gain-bandwidth product*

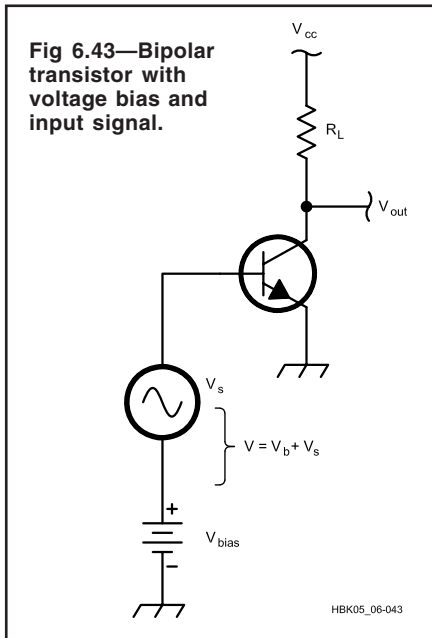

Fig 6.46

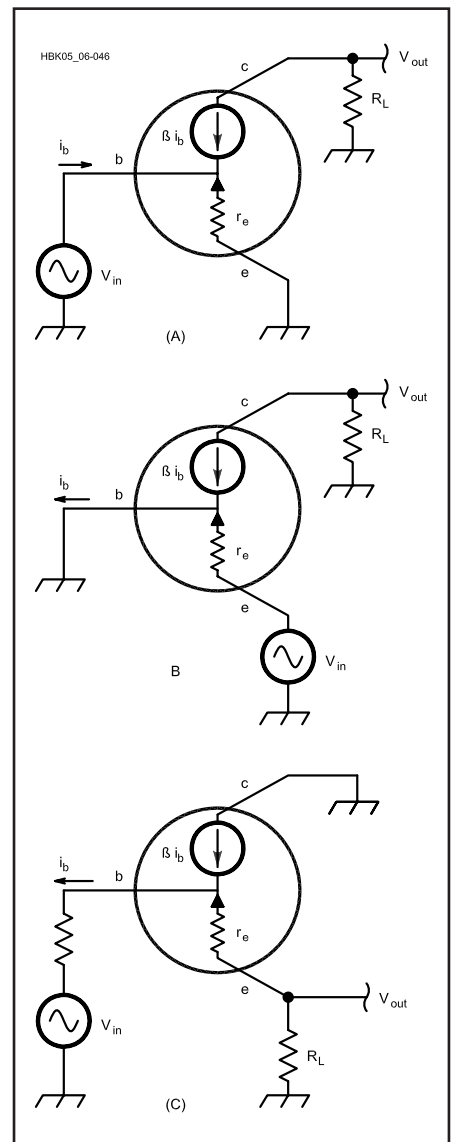

Fig 6.47

that a common-emitter amplifier could be built as shown in Fig 6.43, grounding the emitter and biasing the base with a constant voltage source. Further examination shows that this presents many problems. The worst is that constant-voltage bias ultimately leads to thermal runaway. Constant-voltage biasing applied to the base is almost never used.

Constant base-current biasing is shown in Fig 6.48A

Fig 6.47—A more refined small-signal model for the bipolar transistor. Suitable for many applications near the transistor F_T .

The most common biasing method is shown in Fig 6.49A. The device model used, shown in Fig 6.49B, is based on the Ebers-Moll equation, which shows that virtually no transistor current flows until the base-emitter voltage reaches about 0.6. Then, current increases dramatically with small additional voltage change. The transistor is thus modeled as a current controlled generator with a battery in series with the base. The battery voltage is ΔV .

The circuit is analyzed with nodal equations. The collector resistance, R_5 , is initially assumed to be zero. The analysis results in three equations for V_b , V_c' and I_b :

$$V_b = \frac{V_{cc} R_2 R_3 + \Delta V R_2 \left(\frac{R_4 + R_1}{\beta + 1} \right)}{R_3 R_4 + R_2 R_4 + R_2 R_3 + R_1 R_3 + \frac{R_1 R_2}{\beta + 1}} \quad (22)$$

$$V_c' = \frac{R_1 V_{cc} R_4 V_b + \beta R_1 R_4 \left(\frac{\Delta V - V_b}{R_3 (\beta + 1)} \right)}{R_1 + R_4} \quad (23)$$

$$I_b = \frac{V_b - \Delta V}{R_3 (\beta + 1)} \quad (24)$$

The emitter current is then $I_b(\beta)$

$$V_c = V_c' - \beta I_b R_5$$

6.55

Fig

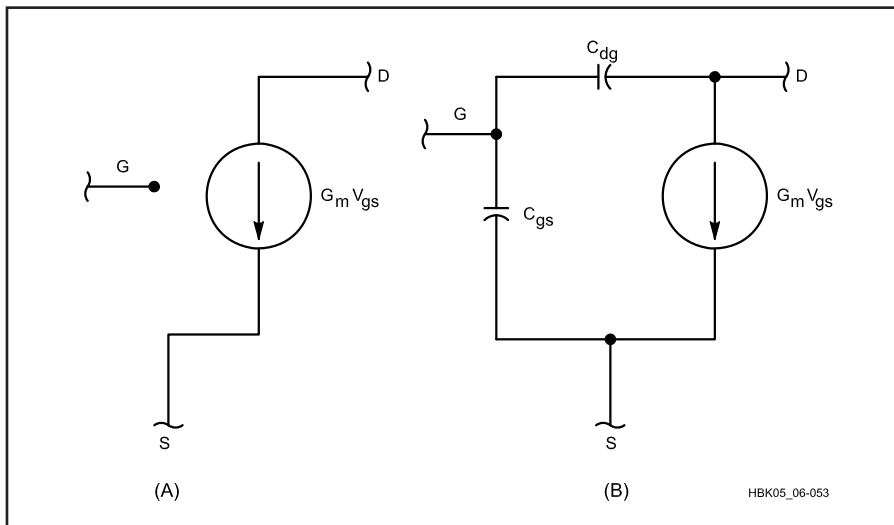

Fig 6.53—Small-signal models for the JFET. (A) is useful at low frequency, (B) is a modification to approximate high-frequency behavior.

Although practical for the JFET, constant-voltage operation in the previous curves is not common. Instead, a resistive bias is usually employed, Fig 6.52B. With this form of bias, the increased current from high signal drive will cause the voltage drop across the bias resistor to increase. This will then move the quiescent operating level closer to pinch-off, accompanied by a reduced small-signal transconductance. This behavior is vital in describing the limiting found in FET oscillators.

The limits on small-signal operation are not as well defined for a FET as they were for the bipolar transistor. Generally, a maximum voltage of 50 to 100 mV is allowed at the input (normalized to a 1-V pinch-off) without severe distortion. The voltages are much higher than they were for the bipolar transistor. However, the input resistance of the usual common source amplifier is so high and the corresponding transconductance low enough that the available gain is no greater than could be obtained with a bipolar transistor. The distortion is generally less with FETs, owing to the lack of high-order curvature in the defining equations.

Many of the standard circuits used with bipolar transistors are also practical with FETs. Noting that the transconductance of a bipolar transistor is $g_m = I_e$ (dc mA) / 26, the previous equations may be applied directly. The “emitter current” is chosen to correspond with the FET transconductance. A very large value is used for current gain. The same calculator or computer program is then used directly. In prac-

$$R_s = \frac{V_p \left(1 - \frac{I_D}{I_{DSS}}\right)^{0.5}}{I_D}$$

Fig 6.53

$$g_m = \frac{dI_D}{dV_{sg}} = \frac{-2 I_{DSS}}{V_p} \left(1 - \frac{V_{sg}}{V_p}\right)$$

Large-Signal Operation

Fig 6.54—Relative normalized drain current for a JFET with constant voltage bias and sinusoidal signals. Relatively “clean” waveforms exist for low signals while large input amplitudes cause severe distortion.

tice, much higher terminating impedances are needed to obtain transducer gain values similar to those of bipolar transistors.

Component Data and References

Component Data

None of us has the time or space to collect all the literature available on the many different commercially available manufactured components. Even if we did, the task of keeping track of new and obsolete devices would surely be formidable. Fortunately, amateurs tend to use a limited number of component types. This section, by Douglas Heacock, AAØMS, provides information on the components most often used by the Amateur Radio experimenter.

COMPONENT VALUES

Throughout this Handbook, composition resistors and small-value capacitors are specified in terms of a system of “preferred values.” This system allows manufacturers to supply these components in a standard set of values, which, when considered along with component tolerances, satisfy the vast majority of circuit requirements.

The preferred values are based on a roughly logarithmic scale of numbers between 1 and 10. One decade of these values for three common tolerance ratings is shown in **Table 7.1**.

Table 7.1 represents the two significant digits in a resistor or capacitor value. Multiply these numbers by multiples of ten to get other standard values. For example, 22 pF, 2.2 μF, 220 μF, and 2200 μF are all standard capacitance values, available in all three tolerances. Standard resistor values include 3.9 Ω, 390 Ω, 39000 Ω and 3.9 MΩ in ±5% and ±10% tolerances. All standard resistance values, from less than 1 Ω to about 5 MΩ are based on this table.

Each value is greater than the next smaller value by a multiplier factor

that depends on the tolerance. For ±5% devices, each value is approximately 1.1 times the next lower one. For ±10% devices, the multiplier is 1.21, and for ±20% devices, the multiplier is 1.47. The resultant values are rounded to make up the series.

Tolerance refers to a range of acceptable values above and below the specified component value. For example, a 4700-Ω resistor rated for ±20% tolerance can have an actual value anywhere between 3760 Ω

and 5640 Ω. You may always substitute a closer-tolerance device for one with a wider tolerance. For projects in this Handbook, assume a 10% tolerance if none is specified.

COMPONENT MARKINGS

The values, tolerances or types of most small components are typically marked with a color code or an alphanumeric code according to standards agreed upon by component manufacturers. The Electronic Industries Alliance (EIA) is a US agency that sets standards for electronic components, testing procedures, performance and device markings. The EIA cooperates with other standards agencies such as the International Electrotechnical Commission (IEC), a worldwide standards agency. You can often find published EIA standards in the engineering library of a college or university.

The standard EIA color code is used to identify a variety of electronic components. Most resistors are marked with color bands according to the code, shown in **Table 7.2**. Some types of capacitors and inductors are also marked using this color code.

Resistor Markings

Carbon-composition, carbon-film, and metal-film resistors are typically manufactured in roughly cylindrical cases with axial leads. They are marked with color bands as shown in **Fig 7.1A**. The first two bands represent the two significant digits of the component value, the third band represents the multiplier, and the fourth band (if there is one) represents the tolerance. Some units

No color	-	-	20	500

*Applies to capacitors only

are marked with a fifth band that represents the percentage of resistance change per 1000 hours of operation: brown = 1%; red = 0.1%; orange = 0.01%; and yellow = 0.001%. Precision resistors (EIA Std RS-279, Fig 7.1B) and some mil-spec (MIL STD-1285A) resistors also use five color bands. On precision resistors, the first *three* bands are used for significant figures and the space between the fourth and fifth bands is wider than the others, to identify the tolerance band. On the military resistors, the fifth band indicates reliability information, such as failure rate.

For example, if a resistor of the type shown in Fig 7.1A is marked with A = red; B = red; C = orange; D = no color, the significant figures are 2 and 2, the multi-

plier is 1000, and the tolerance is $\pm 20\%$. The device is a 22,000- Ω , $\pm 20\%$ unit.

Some resistors are made with radial leads (Fig 7.1C) and are marked with a color code in a slightly different scheme. For example, a resistor as shown in Fig 7.1C is marked as follows: A (body) = blue; B (end) = gray; C (dot) = red; D (end) = gold. The significant figures are 6 and 8, the multiplier is 100, and the tolerance is $\pm 5\%$; 6800 Ω with $\pm 5\%$ tolerance.

Resistor Power Ratings

Carbon-composition and metal-film resistors are available in standard power ratings of $1/10$, $1/8$, $1/4$, $1/2$, 1 and 2 W. The $1/10$ - and $1/8$ -W sizes are relatively expensive and difficult to purchase in small

Fig 7.1—Color coding and body size for fixed resistors. The color code is given in Table 7.2. The colored areas have the following significance.
A—First significant figure of resistance in ohms.
B—Second significant figure.
C—Decimal multiplier.
D—Resistance in percent. If no color is shown the tolerance is $\pm 20\%$.
E—Relative percent change in value per 1000 hours of operation; Brown, 1%; Red 0.1%; Orange 0.01%; Yellow 0.001%.

Fig 7.2—Typical carbon-composition resistor sizes.

quantities. They are used only where miniaturization is essential. The $1/4$, $1/2$, 1, and 2-W composition resistor packages are drawn to scale in Fig 7.2. Metal-film resistors are typically slightly smaller than carbon-composition units of the same power rating. Film resistors can usually be identified by a glossy enamel coating and an hourglass profile. Carbon-film and metal-film are the most commonly available resistors today, having largely replaced the less-stable carbon-composition resistors.

Capacitor Markings

A variety of systems for capacitor markings are in use. Some use color bands, some use combinations of numbers and letters. Capacitors may be marked with their value, tolerance, temperature characteristics, voltage ratings or some subset of these specifications. Fig 7.3 shows several popular capacitor marking systems.

In addition to the value, ceramic capacitors may be marked with an alphanumeric code signifying temperature characteristics. Table 7.3 explains the EIA code for ceramic-disk capacitor temperature characteristics. The code is made up of one character from each column in the table. For example, a capacitor marked Z5U is suitable for use between +10 and +85°C, with a maximum change in capacitance of -56% or +22%.

Capacitors with highly predictable temperature coefficients of capacitance are sometimes used in oscillators that must be frequency stable with temperature. If an application called for a temperature coefficient of -750 ppm/°C (N750), a capacitor marked U2J would be suitable. The older industry code for these ratings is being replaced with the EIA code shown

Fig 7.3—Capacitors can be identified by color codes and markings. Shown here are identifying markings found on many common capacitor types.

in **Table 7.4**. NP0 (that is, N-P-zero) means “negative, positive, zero.” It is a characteristic often specified for RF circuits requiring temperature stability, such as VFOs. A capacitor of the proper value marked C0G is a suitable replacement for an NP0 unit.

Some capacitors, such as dipped silvermica units, have a letter designating the capacitance tolerance. These letters are deciphered in **Table 7.5**.

Surface-Mount Resistor and Capacitor Markings

Many different types of electronic components, both active and passive, are now available in surface-mount packages. These are commonly known as *chip* resistors and capacitors. The very small size of these components leaves little space for marking with conventional codes, so brief alphanumeric codes are used to convey the most information in the smallest possible space.

Surface-mount resistors are typically marked with a three- or four-digit value code and a character indicating tolerance. The nominal resistance, expressed in ohms, is identified by three digits for 2% (and greater) tolerance devices. The first two digits represent the significant figures; the last digit specifies the multiplier as the exponent of ten. (It may be easier to remember the multiplier as the number of zeros you must add to the significant figures.) For values less than 100 Ω, the letter R is substituted for one of the significant digits and represents a decimal point. Here are some examples:

Resistor

Code	Value
101	10 and 1 zero = 100 Ω
224	22 and 4 zeros = 220,000 Ω
1R0	1.0 and no zeros = 1 Ω
22R	22.0 and no zeros = 22 Ω
R10	0.1 and no zeros = 0.1 Ω

If the tolerance of the unit is narrower than ±2%, the code used is a four-digit code where the first three digits are the significant figures and the last is the multiplier. The letter R is used in the same way to represent a decimal point. For example, 1001 indicates a 1000-Ω unit, and 22R0 indicates a 22-Ω unit. The tolerance rating for a surface-mount resistor is expressed with a single character at the end of the numeric value code in **Table 7.6**.

Surface-mount capacitors are marked with a two-character code consisting of a letter indicating the significant digits (see **Table 7.7**) and a number indicating the multiplier (see **Table 7.8**). The code rep-

Inductance and Turns Formula

The turns required for a given inductance or inductance for a given number of turns can be calculated from:

$$N = 100 \sqrt{\frac{L}{A_L}} \quad L = A_L \left(\frac{N^2}{10,000} \right)$$

where N = number of turns; L = desired inductance (μH); A_L = inductance index (μH per 100 turns).*

Note: Color codes hold only for cores manufactured by Micrometals, which makes the cores sold by most Amateur Radio distributors.

may be included (see Fig 7.3E for tolerance codes). Surface-mount capacitors can be very small; you may need a magnifying glass to read the markings.

INDUCTORS AND CORE MATERIALS

Inductors, both fixed and variable, are available in a wide variety of types and packages, and many offer few clues as to their values. Some coils and chokes are marked with the EIA color code shown in Table 7.2. See Fig 7.4 for another marking system for tubular encapsulated RF chokes.

Fig 7.4—Color coding for tubular encapsulated RF chokes. At A, an example of the coding for an 8.2-μH choke is given. At B, the color bands for a 330-μH inductor are illustrated. The color code is given in Table 7.2.

Actual number of turns may differ from above figures according to winding techniques, especially when using the larger size wires. Chart prepared by Michel J. Gordon, Jr, WB9FHC. Courtesy of Amidon Assoc.

Most powdered-iron toroid cores that we amateurs use are manufactured by Micrometals, who uses paint to identify the material used in the core. The Micrometals color code is part of **Table 7.9**. **Table 7.10** gives the physical characteristics of powdered-iron toroids. Ferrite cores are not typically painted, so identification is more difficult. See **Table 7.11** for information about ferrite cores.

TRANSFORMERS

Many transformers, including power transformers, IF transformers and audio transformers, are made to be installed on PC boards, and have terminals designed for that purpose. Some transformers are manufactured with wire leads that are color-coded to identify each connection. When colored wire leads are present, the color codes in **Tables 7.12**, **7.13** and **7.14**

Fig 7.5—Color coding for semi-conductor diodes. At A, the cathode is identified by the double-width first band. At B, the bands are grouped toward the cathode. Two-figure designations are signified by a black first band. The color code is given in Table 7.2. The suffix-letter code is A—Brown, B—red, C—orange, D—yellow, E—green, F—blue. The 1N prefix is understood.

usually apply.

In addition, many miniature IF transformers are tuned with slugs that are color-coded to signify their application. **Table 7.15** lists application vs slug color.

SEMICONDUCTORS

Most semiconductor devices are clearly marked with the part number and in some cases, a manufacturer’s date code as well. Identification of semiconductors can be difficult, however, when the parts are “house-marked” (marked with codes used by an equipment manufacturer instead of the standard part numbers). In such cases, it is often possible to find the standard equivalent or a suitable replacement by using one of the semiconductor cross-reference directories available from various replacement-parts distributors. If you look up the house number and find the recommended replacement part, you can often find other standard parts that are replaced by that same part.

Diodes

Most diodes are marked with a part number and some means of identifying which lead is the cathode. Some diodes are marked with a color-band code (see **Fig 7.5**). Important diode parameters include maximum forward current, maximum peak inverse voltage (PIV) and the power-handling capacity.

Transistors

Some important parameters for transistor selection are voltage and current limits, power-handling capability, beta or

Grid (finish) lead to secondary	Green
Grid return (plain or center tapped)	Black
Grid (start) lead on green center tapped secondaries	Yellow (or if polarity not important)

Note: These markings also apply to line-to-grid and tube-to-line transformers.

gain characteristics and useful frequency range. The case style may also be an issue; some transistors are available in several different case styles.

Integrated Circuits

Integrated circuits (ICs) come in a variety of packages, including transistor-like metal cans, dual and single in-line packages (DIPs and SIPs), flat-packs and surface-mount packages. Most are marked with a part number and a four-digit manufacturer's date code indicating the year (first two digits) and week (last two digits) that the component was made. ICs are frequently house-marked, and the cross-reference directories mentioned above can be helpful in identification and replacement.

Another very useful reference tool for

Notes

- ¹A circular mil (CM) is a unit of area equal to that of a one-mil-diameter circle ($\pi/4$ square mils). The CM area of a wire is the square of the mil diameter.
- ²Figures given are approximate only; insulation thickness varies with manufacturer.
- ³Maximum wire temperature of 212°F (100°C) with a maximum ambient temperature of 13°F (57°C) as specified by the manufacturer. The *National Electrical Code* or local building codes may differ.
- ⁴700 CM per ampere is a satisfactory design figure for small transformers, but values from 500 to 1000 CM are commonly used. The *National Electrical Code* or local building codes may differ.
- ⁵Stranded wire construction is given as "count" × "strand size" (AWG).

Table 7.17**Color Code for Hookup Wire**

Wire Color	Type of Circuit
Black	Grounds, grounded elements and returns
Brown	Heaters or filaments, off ground
Red	Power Supply B plus
Orange	Screen grids and base 2 of transistors
Yellow	Cathodes and transistor emitters
Green	Control grids, diode plates, and base 1 of transistors
Blue	Plates and transistor collectors
Violet	Power supply, minus leads
Gray	Ac power line leads
White	Bias supply, B or C minus, AGC

Note: Wires with tracers are coded in the same manner as solid-color wires, allowing additional circuit identification over solid-color wiring. The body of the wire is white and the color band spirals around the wire lead. When more than one color band is used, the widest band represents the first color.

working with ICs is *IC Master*, a master selection guide that organizes ICs by type, function and certain key parameters. A part number index is included, along with application notes and manufacturer's information for tens of thousands of IC devices. Some of the data from *IC Master* is also available on computer disk.

IC part numbers usually contain a few digits that identify the circuit die or function and several other letters and/or digits that identify the production process, manufacturer and package. For example, a '4066 IC contains four independent SPST switches. Harris (CD74HC4066, CD4066B and CD4066BE), National (MM74HC4066, CD4066BC and CD4066BM) and Panasonic (MN74HC4066 and MN4066B) all make similar devices (as do many other manufacturers) with slight differences. Among the numbers listed, "CD" (CMOS Digital), "MM" (MOS Monolithic), and "MN" indicate CMOS parts. The number "74" indicates a commercial quality product (for applications from 0°C to 70°C), which is pin compatible with the 74/54 TTL families. "HC" means high-speed CMOS family, which is as fast as the LS TTL family. The "B" suffix, as is CD4066B, indicates a buffered output. This is only a small example of the conventions used in IC part numbers. For more information look at data books from the various manufacturers.

When choosing ICs that are not exact replacements, several operating needs and performance aspects should be considered. First, the replacement power requirements must be met: Some ICs require 5 V dc, others 12 V and some need both positive and negative supplies. Current requirements

vary among the various IC families, so be sure that sufficient current is available from the power supply. If a replacement IC uses much more current than the device it replaces, a heat sink or blower may be needed to keep it cool.

Next consider how the replacement interacts with its neighboring components. Input capacitance and "fanout" are critical factors in digital circuits. Increased input capacitance may overload the driving circuits. Overload slows circuit operation, which may prevent lines from reaching the "high" condition. Fanout tells how many inputs a device can drive. The fanout of a replacement should be equal to, or greater than, that required in the circuit. Operating speed and propagation delay are also significant. Choose a replacement IC that operates at or above the circuit clock speed. (Be careful: Increased speed can increase EMI and cause other problems.) Some circuits may not function if the propagation delay varies much from the specified part. Look at the **Electrical Signals and Components** chapter for details of how these operating characteristics relate to circuit performance.

Analog ICs have similar characteristics. Input and output capacities are often defined as how much current an analog IC can "sink" (accept at an input) or "source" (pass to a load). A replacement should be

able to source or sink at least as much current as the device it replaces. Analog speed is sometimes listed as bandwidth (as in discrete-component circuits) or slew rate (common in op amps). Each of these quantities should meet or exceed that of the replaced component.

Some ICs are available in different operating temperature ranges. Op amps, for example, are commonly available in three standard ranges:

- Commercial: 0°C to 70°C
- Industrial: -25°C to 85°C
- Military: -55°C to 125°C

In some cases, part numbers reflect the temperature ratings. For example, an LM301A op amp is rated for the commercial temperature range; an LM201A op amp for the industrial range and an LM101A for the military range.

When necessary, you can add interface circuits or buffer amplifiers that improve the input and output capabilities of replacement ICs, but auxiliary circuits cannot improve basic device ratings, such as speed or bandwidth.

An excellent source of information on many common ICs is *The ARRL Electronics Data Book*, which contains detailed data for digital ICs (CMOS and TTL), op amps and other analog ICs.

Table 7.18**Aluminum Alloy Characteristics****Common Alloy Numbers**

Type	Characteristic
2024	Good formability, high strength
5052	Excellent surface finish, excellent corrosion resistance, normally not heat treatable for high strength
6061	Good machinability, good weldability, can be brittle at high tempers
7075	Good formability, high strength

General Uses

Type	Uses
2024-T3	Chassis boxes, antennas, anything that will be bent or flexed repeatedly
7075-T3	
6061-T6	Mounting plates, welded assemblies or machined parts

Common Tempers

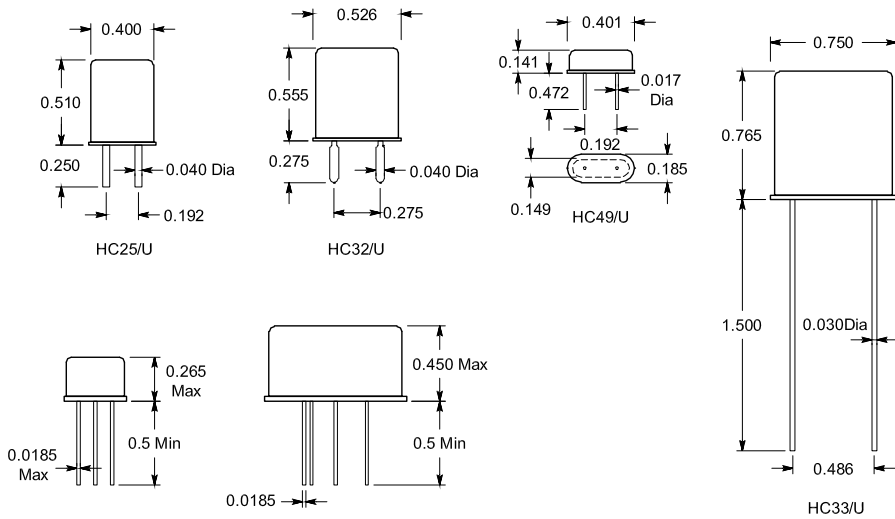

Type	Characteristics
T0	Special soft condition
T3	Hard
T6	Very hard, possibly brittle
TXXX	Three digit tempers—usually specialized high-strength heat treatments, similar to T6

OTHER SOURCES OF COMPONENT DATA

There are many sources you can consult for detailed component data. Many manufacturers publish data books for the components they make. Many distributors will include data sheets for parts you order if you ask for them. Parts catalogs themselves are often good sources of component data. The following list is representative of some of the data resources available from manufacturers and distributors.

THE ARRL TECHNICAL INFORMATION SERVICE (TIS)

The ARRL answers questions of a technical nature for ARRL members and non-members alike through the Technical Information Service. Questions may be submitted via e-mail (tis@arrl.org); Fax (860-594-0259); or mail (TIS, ARRL, 225 Main St, Newington, CT 06111). The TIS also maintains a home page on ARRLWeb: www.arrl.org/tis. This site contains links to several technical areas.

TISfind — This search engine contains over 2000 providers of products, services and information of interest to radio amateurs. Before contacting TIS for the address of someone who can repair your radio, or sells antennas, or has old manuals or schematics, look in *TISfind*. Instructions and categories are on the *TISfind* page on ARRLWeb at: www.arrl.org/tis/tisfind.html.

SOURCING SUPPLIERS AND CONTACTS ON THE WEB

If you need to extend your search area beyond the TIS search engine described above, please refer to the Web section of the **Web, WiFi, Wireless and PC Technology** chapter in this *Handbook*. It contains information on using a search engine on the Web and tips that can help tailor your search.

Table 7.20
Miniature Lamp Guide

HBK05_07-07

** Bulbs are described by a letter indicating shape and a number that is an approximation of diameter expressed in eighths of an inch. For example S - 8 is "S" shape, 8 eighths or 1 inch in diameter.

Manufacturer codes:

MI = Mitsubishi; MO = Motorola; PH Philips;
ST = STMicroelectronics

There is a bewildering variety of package types, sizes and pin-out connections. (For example, for the 137 different transistors in this table there are 54 different packages.) See the data sheets on each manufacturer's Web pages for details.

Mitsubishi: www.mitsubishichips.com/data/datasheets/hf-optic/index.html, then click "Si Modules." Scroll to section for "Si Discrete" and then choose frequency range and device.

Motorola: design-net.com/redirect/books/index.html. Type the part number in the search window at the upper left of the screen. If you receive a message that "No results were found for your search" the part you want is probably obsolete. Click on the text highlighted in red as "Motorola's SPS Literature Distribution Center Archive Site." In the Description box, type the part number you want, click the Search button and then click on the Document Number for the latest Revision level of that obsoleted part number.

Philips: www.semiconductors.philips.com/. Type the part number in the "search" box at the upper right corner of the screen. Click on the highlighted part number in the Description field and then click on Datasheet. Finally, view the PDF by clicking on the highlighted "Download" text or hold down the right-mouse button while clicking on "Download" to save the PDF to disk.

STMicroelectronics: us.st.com/stonline/discretes/index.shtml. Click on "Datasheets" at the top and then scroll down to the bottom of the listing to find "Radio Frequency, RF Power." Then specify the frequency range you want and either view the PDF directly or download the PDF by holding down the right-mouse button while clicking on the device's part number.

50 to 175 MHz							Manufacturer codes: MI = Mitsubishi; MO = Motorola; PH = Philips; ST = STMicroelectronics						
BLF202	2	MOS	10	12.5	SOT409A	PH	There is a bewildering variety of package types, sizes and pin-out connections. (For example, for the 71 different transistors in this table there are 35 different packages.) See the data sheets on each manufacturer's Web pages for details.						
BLF242	5	MOS	13	28	SOT123A	PH	Mitsubishi: www.mitsubishichips.com/data/datasheets/hf-optic/index.html , then click on "Si Modules." Scroll to section for "Si Discrete" and then choose frequency range and device.						
SD1274	30	BJT	10	13.6	M135	ST	Motorola: design-net.com/redirect/books/index.html . Type the part number in the search window at the upper left of the screen. If you receive a message that "No results were found for your search" the part you want is probably obsolete. Click on the text highlighted in red as "Motorola's SPS Literature Distribution Center Archive Site." In the Description box, type the part number you want, click the Search button and then click on the Document Number for the latest Revision level of that obsoleted part number.						
BLF245	30	MOS	13	28	SOT123	PH	Philips: www.semiconductors.philips.com/ . Type the part number in the "search" box at the upper right corner of the screen. Click on the highlighted part number in the Description field and then click on Datasheet. Finally, view the PDF by clicking on the highlighted "Download" text or hold down the right-mouse button while clicking on "Download" to save the PDF to disk.						
SD1275	40	BJT	9	13.6	M135	ST	STMicroelectronics: us.st.com/stonline/discretes/index.shtml . Click on "Datasheets" at the top and then scroll down to the bottom of the listing to find "Radio Frequency, RF Power." Then specify the frequency range you want and either view the PDF directly or download the PDF by holding down the right-mouse button while clicking on the device's part number.

Table 7.35

Three-Terminal Voltage Regulators

Listed numerically by device

Device	Description	Package	Voltage	Current (Amps)	Device	Description	Package	Voltage	Current (Amps)
317	Adj Pos	TO-205	+1.2 to +37	0.5	78TXX		TO-204		3.0
317	Adj Pos	TO-204,TO-220	+1.2 to +37	1.5	79XX	Fixed Neg	TO-204,TO-220	Note 1	1.0
317L	Low Current Adj Pos	TO-205,TO-92	+1.2 to +37	0.1	79LXX		TO-205,TO-92		0.1
317M	Med Current Adj Pos	TO-220	+1.2 to +37	0.5	79MXX		TO-220		0.5
338	Adj Pos	TO-3	+1.2 to +32	5.0					
350	High Current Adj Pos	TO-204,TO-220	+1.2 to +33	3.0					
337	Adj Neg	TO-205	-1.2 to -37	0.5					
337	Adj Neg	TO-204,TO-220	-1.2 to -37	1.5					
337M	Med Current Adj Neg	TO-220	-1.2 to -37	0.5					
309		TO-205	+5	0.2					
309		TO-204	+5	1.0					
323		TO-204,TO-220	+5	3.0					
140-XX	Fixed Pos	TO-204,TO-220	Note 1	1.0					
340-XX		TO-204,TO-220		1.0					
78XX		TO-204,TO-220		1.0					
78LXX		TO-205,TO-92		0.1					
78MXX		TO-220		0.5					

Note 1—XX indicates the regulated voltage; this value may be anywhere from 1.2 V to 35 V. A 7815 is a positive 15-V regulator, and a 7924 is a negative 24-V regulator.

The regulator package may be denoted by an additional suffix, according to the following:

Package	Suffix
TO-204 (TO-3)	K
TO-220	T
TO-205 (TO-39)	H, G
TO-92	P, Z

For example, a 7812K is a positive 12-V regulator in a TO-204 package. An LM340T-5 is a positive 5-V regulator in a TO-220 package. In addition, different manufacturers use different prefixes. An LM7805 is equivalent to a mA7805 or MC7805.

¹Service Class Abbreviations:
 AB₂GD=AB₂ linear with 50-Ω passive grid circuit.
 B=Class-B push-pull
 CP=Class-C plate-modulated phone
 CT=Class-C telegraph

GG=Grounded-grid (grid and screen connected together)
²Maximum signal value
³Peak grid-grid volts
⁴Forced-air cooling required.

⁵Two tubes triode-connected, G2 to G1 through 20kΩ to G2.
⁶Typical operation at 175 MHz.
⁷±1.5 V.
⁸Values are for two tubes.
⁹Single tone.

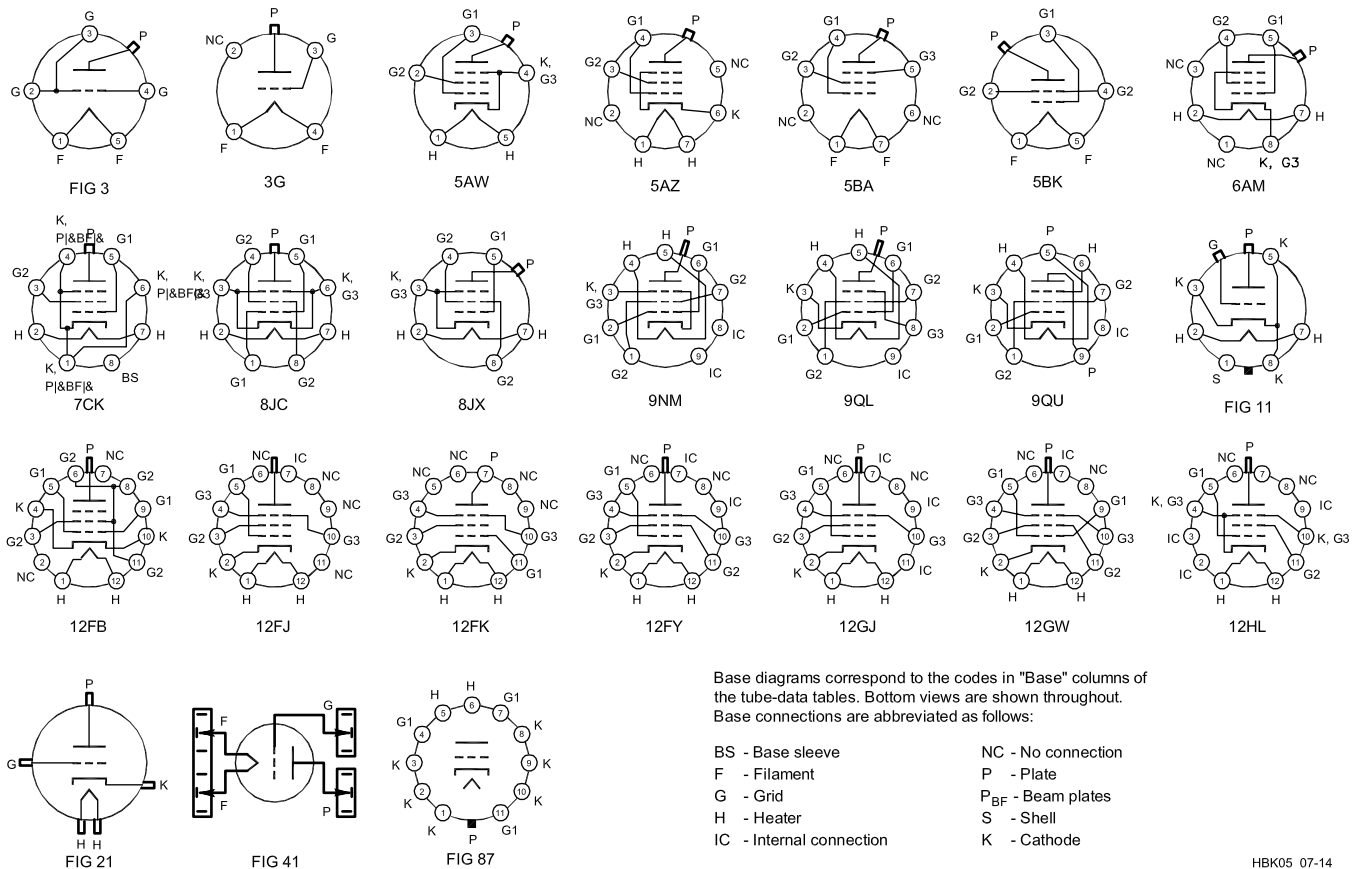

¹⁰24-Ω cathode resistance.
¹¹Base same as 4CX250B. Socket is Russian SK2A.
¹²Socket is Russian SK1A.
¹³Socket is Russian SK3A.

Table 7.40

EIA Vacuum-Tube Base Diagrams

HBK05_07-14

Alphabetical subscripts (D = diode, P = pentode, T = triode and HX = hexode) indicate structures in multistructure tubes. Subscript CT indicates filament or heater center tap.

Generally, when pin 1 of a metal-envelope tube (except all triodes) is shown connected to the envelope, pin 1 of a glass-envelope counterpart (suffix G or GT) is connected to an internal shield.

Table 7.41**Properties of Common Thermoplastics****Polyvinyl Chloride (PVC)***Advantages:*

- Can be compounded with plasticizers, fillers, stabilizers, lubricants and impact modifiers to produce a wide range of physical properties
- Can be pigmented to almost any color
- Rigid PVC has good corrosion and stain resistance, thermal & electrical insulation, and weatherability

Disadvantages:

- Base resin can be attacked by aromatic solvents, ketones, aldehydes, naphthalenes, and some chloride, acetate, and acrylate esters
- Should not be used above 140°

Applications:

- Conduit
- Conduit boxes
- Housings
- Pipe
- Wire and cable insulation

Polystyrene*Advantages:*

- Low cost
- Moderate strength
- Electrical properties only slightly affected by temperature and humidity
- Sparkling clarity
- Impact strength is increased by blending with rubbers, such as polybutadiene

Disadvantages:

- Brittle
- Low heat resistance

Applications:

- Capacitors
- Light shields
- Knobs

Polyphenylene Sulfide (PPS)*Advantages:*

- Excellent dimensional stability
- Strong
- High-temperature stability
- Chemical resistant
- Inherently completely flame retardant
- Completely transparent to microwave radiation

Applications:

- R3-R5 have various glass-fiber levels that are suitable for applications demanding high mechanical and impact strength as well as good dielectric properties
- R8 and R10 are suitable for high arc-resistance applications
- R9-901 is suitable for encapsulation of electronic devices

Polypropylene*Advantages:*

- Low density
- Good balance of thermal, chemical, and electrical properties
- Moderate strength (increases significantly with glass-fiber reinforcement)

Disadvantages:

- Electrical properties affected to varying degrees by temperature (as temperature goes up, dielectric strength increases and volume resistivity decreases)
- Inherently unstable in presence of oxidative and UV radiation

Applications:

- Automotive battery cases
- Blower housings
- Fan blades
- Insulators
- Lamp housings
- Support for current-carrying electrical components
- TV yokes

Polyethylene (PE)*Advantages: Low Density PE*

- Good toughness
- Excellent chemical resistance
- Excellent coefficient of friction
- Near zero moisture absorption
- Easy to process
- Relatively low heat resistance

Disadvantages:

- Susceptible to environmental and some chemical stress cracking
- Wetting agents (such as detergents) accelerate stress cracking

Advantages: High Density PE

- Same as above, plus increased rigidity and tensile strength

Advantages: Ultra-High Molecular Weight PE

- Outstanding abrasion resistance
- Low coefficient of friction
- High impact strength
- Excellent chemical resistance
- Material does not break in impact strength tests using standard notched specimens

Applications:

- Bearings
- Components requiring maximum abrasion resistance, impact strength, and low coefficient of friction

Phenolic*Advantages:*

- Low cost
- Superior heat resistance
- High heat-deflection temperatures
- Good electrical properties
- Good flame resistance
- Excellent moldability
- Excellent dimensional stability
- Good water and chemical resistance

Applications:

- Commutators and housings for small motors
- Heavy duty electrical components
- Rotary-switch wafers
- Insulating spacers

Nylon*Advantages:*

- Excellent fatigue resistance
- Low coefficient of friction
- Toughness as a function of degree of crystallinity
- Resists many fuels and chemicals
- Good creep- and cold-flow resistance as compared to less rigid thermoplastics
- Resists repeated impacts

Disadvantages:

- All nylons absorb moisture
- Nylons that have not been compounded with a UV stabilizer are sensitive to UV light, and thus not suitable for extended outdoor use

Applications:

- Bearings
 - Housings and tubing
 - Rope
 - Wire coatings
 - Wire connectors
 - Wear plates
-

Table 7.42

Coaxial Cable End Connectors

UHF Connectors

Military No.	Style	Cable RG- or Description
PL-259	Str (m)	8, 9, 11, 13, 63, 87, 149, 213, 214, 216, 225
UG-111	Str (m)	59, 62, 71, 140, 210
SO-239	Pnl (f)	Std, mica/phenolic insulation
UG-266	Blkhd (f)	Rear mount, pressurized, copolymer of styrene ins.

Adapters

PL-258	Str (f/f)	Polystyrene ins.
UG-224,363	Blkhd (f/f)	Polystyrene ins.
UG-646	Ang (f/m)	Polystyrene ins.
M-359A	Ang (m/f)	Polystyrene ins.
M-358	T (f/m/f)	Polystyrene ins.

Reducers

UG-175	55, 58, 141, 142 (except 55A)
UG-176	59, 62, 71, 140, 210

Family Characteristics:

All are nonweatherproof and have a nonconstant impedance. Frequency range: 0-500 MHz. Maximum voltage rating: 500 V (peak).

N Connectors

Military No.	Style	Cable RG-	Notes
UG-21	Str (m)	8, 9, 213, 214	50 Ω
UG-94A	Str (m)	11, 13, 149, 216	70 Ω

UG-28A	T (f/f/f)	—
UG-107B	T (f/m/f)	—

Family Characteristics:

N connectors with gaskets are weatherproof. RF leakage: -90 dB min @ 3 GHz. Temperature limits: TFE: -67° to 390°F (-55° to 199°C). Insertion loss 0.15 dB max @ 10 GHz. Copolymer of styrene: -67° to 185°F (-55° to 85°C). Frequency range: 0-11 GHz. Maximum voltage rating: 1500 V P-P. Dielectric withstanding voltage 2500 V RMS. SWR (MIL-C-39012 cable connectors) 1.3 max 0-11 GHz.

Linear

1 meter (m) = 100 centimeters (cm) = 1000 millimeters (mm)

Area

$1 \text{ m}^2 = 1 \times 10^4 \text{ cm}^2 = 1 \times 10^6 \text{ mm}^2$

Volume

$1 \text{ m}^3 = 1 \times 10^6 \text{ cm}^3 = 1 \times 10^9 \text{ mm}^3$

1 liter (l) = 1000 $\text{cm}^3 = 1 \times 10^6 \text{ mm}^3$

Mass

1 kilogram (kg) = 1000 grams (g)

(Approximately the mass of 1 liter of water)

1 metric ton (or tonne) = 1000 kg

Table 7.44**US Customary Units****Linear Units**

12 inches (in) = 1 foot (ft)
 36 inches = 3 feet = 1 yard (yd)
 1 rod = 5¹/₂ yards = 16¹/₂ feet
 1 statute mile = 1760 yards = 5280 feet
 1 nautical mile = 6076.11549 feet

Area

1 ft² = 144 in²
 1 yd² = 9 ft² = 1296 in²
 1 rod² = 30¹/₄ yd²
 1 acre = 4840 yd² = 43,560 ft²
 1 acre = 160 rod²
 1 mile² = 640 acres

Volume

1 ft³ = 1728 in³
 1 yd³ = 27 ft³

Liquid Volume Measure

1 fluid ounce (fl oz) = 8 fluid drams = 1.804 in
 1 pint (pt) = 16 fl oz
 1 quart (qt) = 2 pt = 32 fl oz = 57³/₄ in³
 1 gallon (gal) = 4 qt = 231 in³
 1 barrel = 31¹/₂ gal

Dry Volume Measure

1 quart (qt) = 2 pints (pt) = 67.2 in³
 1 peck = 8 qt
 1 bushel = 4 pecks = 2150.42 in³

Avoirdupois Weight

1 dram (dr) = 27.343 grains (gr) or (gr a)
 1 ounce (oz) = 437.5 gr
 1 pound (lb) = 16 oz = 7000 gr
 1 short ton = 2000 lb, 1 long ton = 2240 lb

Troy Weight

1 grain troy (gr t) = 1 grain avoirdupois
 1 pennyweight (dwt) or (pwt) = 24 gr t
 1 ounce troy (oz t) = 480 grains
 1 lb t = 12 oz t = 5760 grains

Apothecaries' Weight

1 grain apothecaries' (gr ap)
 = 1 gr t = 1 gr
 1 dram ap (dr ap) = 60 gr
 1 oz ap = 1 oz t = 8 dr ap = 480 gr
 1 lb ap = 1 lb t = 12 oz ap = 5760 gr

Metric Unit ÷ Conversion Factor = US Customary Unit

Table 7.45**Abbreviations List**

A	CBBS—computer bulletin-board service	EC—Emergency Coordinator
a—atto (prefix for 10^{-18})	CBMS—computer-based message system	ECL—emitter-coupled logic
A—ampere (unit of electrical current)	CCITT—International Telegraph and Telephone Consultative Committee	EHF—extremely high frequency (30-300 GHz)
ac—alternating current	CCTV—closed-circuit television	EIA—Electronic Industries Alliance
ACC—Affiliated Club Coordinator	CCW—coherent CW	EIRP—effective isotropic radiated power
ACSSB—amplitude-compandored single sideband	ccw—counterclockwise	ELF—extremely low frequency
A/D—analog-to-digital	CD—civil defense	ELT—emergency locator transmitter
ADC—analog-to-digital converter	cm—centimeter	EMC—electromagnetic compatibility
AF—audio frequency	CMOS—complementary-symmetry metal-oxide semiconductor	EME—earth-moon-earth (moonbounce)
AFC—automatic frequency control	coax—coaxial cable	EMF—electromotive force
AFSK—audio frequency-shift keying	COR—carrier-operated relay	EMI—electromagnetic interference
AGC—automatic gain control	CP—code proficiency (award)	EMP—electromagnetic pulse
Ah—ampere hour	CPU—central processing unit	EOC—emergency operations center
ALC—automatic level control	CRT—cathode ray tube	EPROM—erasable programmable read only memory
AM—amplitude modulation	CT—center tap	
AMRAD—Amateur Radio Research and Development Corporation	CTCSS—continuous tone-coded squelch system	F
AMSAT—Radio Amateur Satellite Corporation	cw—clockwise	f—femto (prefix for 10^{-5}); frequency
AMTOR—Amateur Teleprinting Over Radio	CW—continuous wave	F—farad (capacitance unit); fuse
ANT—antenna		fax—facsimile
ARA—Amateur Radio Association	D	FCC—Federal Communications Commission
ARC—Amateur Radio Club	d—deci (prefix for 10^{-1})	FD—Field Day
ARES—Amateur Radio Emergency Service	D—diode	FEMA—Federal Emergency Management Agency
ARQ—Automatic repeat request	da—deca (prefix for 10)	FET—field-effect transistor
ARRL—American Radio Relay League	D/A—digital-to-analog	FFT—fast Fourier transform
ARS—Amateur Radio Society (station)	DAC—digital-to-analog converter	FL—filter
ASCII—American National Standard Code for Information Interchange	dB—decibel (0.1 bel)	FM—frequency modulation
ATV—amateur television	dBi—decibels above (or below) isotropic antenna	FMTV—frequency-modulated television
AVC—automatic volume control	dBi—decibels above (or below) 1 milliwatt	FSK—frequency-shift keying
AWG—American wire gauge	dBm—decibels above/below 1 V (in video, relative to 1 V P-P)	FSTV—fast-scan (real-time) television
az-el—azimuth-elevation	dBW—decibels above/below 1 W	ft—foot (unit of length)
	dBW—decibels above/below 1 W	G
B	dc—direct current	g—gram (unit of mass)
B—bel; blower; susceptance; flux density, (inductors)	D-C—direct conversion	G—giga (prefix for 10^9); conductance
balun—balanced to unbalanced (transformer)	DDS—direct digital synthesis	GaAs—gallium arsenide
BC—broadcast	DEC—District Emergency Coordinator	GB—gigabytes
BCD—binary coded decimal	deg—degree	GDO—grid- or gate-dip oscillator
BCI—broadcast interference	DET—detector	GHz—gigahertz (10^9 Hz)
Bd—baud (bits in single-channel binary data transmission)	DF—direction finding; direction finder	GND—ground
BER—bit error rate	DIP—dual in-line package	H
BFO—beat-frequency oscillator	DMM—digital multimeter	h—hecto (prefix for 10^2)
bit—binary digit	DPDT—double-pole double-throw (switch)	H—henry (unit of inductance)
bit/s—bits per second	DPSK—differential phase-shift keying	HF—high frequency (3-30 MHz)
BM—Bulletin Manager	DPST—double-pole single-throw (switch)	HFO—high-frequency oscillator; heterodyne frequency oscillator
BPF—band-pass filter	DS—direct sequence (spread spectrum); display	HPF—highest probable frequency; high-pass filter
BPL—Brass Pounders League	DSB—double sideband	Hz—hertz (unit of frequency, 1 cycle/s)
BPL—Broadband over Power Line	DSP—digital signal processing	
BT—battery	DTMF—dual-tone multifrequency	I
BW—bandwidth	DVM—digital voltmeter	I—current, indicating lamp
Bytes—Bytes	DX—long distance; duplex	IARU—International Amateur Radio Union
C	DXAC—DX Advisory Committee	IC—integrated circuit
c—centi (prefix for 10^{-2})	DXCC—DX Century Club	ID—identification; inside diameter
C—coulomb (quantity of electric charge); capacitor		IEEE—Institute of Electrical and Electronics Engineers
CAC—Contest Advisory Committee	E	IF—intermediate frequency
CATV—cable television interference	e—base of natural logarithms (2.71828)	IMD—intermodulation distortion
CB—Citizens Band (radio)	E—voltage	
	EA—ARRL Educational Advisor	

in.—inch (unit of length)
in./s—inch per second (unit of velocity)
I/O—input/output
IRC—international reply coupon
ISB—independent sideband
ITF—Interference Task Force
ITU—International Telecommunication Union
ITU-T—ITU Telecommunication Standardization Bureau

J-K

j—operator for complex notation, as for reactive component of an impedance (+*j* inductive; −*j* capacitive)
J—joule (kg m²/s²) (energy or work unit); jack
JFET—junction field-effect transistor
k—kilo (prefix for 10³); Boltzmann's constant (1.38x10⁻²³ J/K)
K—kelvin (used without degree symbol) absolute temperature scale; relay
kB—kilobytes
kBd—1000 bauds
kbit—1024 bits
kbit/s—1024 bits per second
kbyte—1024 bytes
kg—kilogram
kHz—kilohertz
km—kilometer
kV—kilovolt
kW—kilowatt
kΩ—kilohm

L

l—liter (liquid volume)
L—lambert; inductor
lb—pound (force unit)
LC—inductance-capacitance
LCD—liquid crystal display
LED—light-emitting diode
LF—low frequency (30-300 kHz)
LHC—left-hand circular (polarization)
LO—local oscillator; Leadership Official
LP—log periodic
LS—loudspeaker
lsb—least significant bit
LSB—lower sideband
LSI—large-scale integration
LUF—lowest usable frequency

M

m—meter (length); milli (prefix for 10⁻³)
M—mega (prefix for 10⁶); meter (instrument)
mA—milliampere
mAh—milliampere hour
MB—megabytes
MCP—multimode communications processor
MDS—Multipoint Distribution Service; minimum discernible (or detectable) signal
MF—medium frequency (300-3000 kHz)

mH—millihenry
MHz—megahertz
mi—mile, statute (unit of length)
mi/h (MPH)—mile per hour
mi/s—mile per second
mic—microphone
min—minute (time)
MIX—mixer
mm—millimeter
MOD—modulator
modem—modulator/demodulator
MOS—metal-oxide semiconductor
MOSFET—metal-oxide semiconductor field-effect transistor
MS—meteor scatter
ms—millisecond
m/s—meters per second
msb—most-significant bit
MSI—medium-scale integration
MSK—minimum-shift keying
MSO—message storage operation
MUF—maximum usable frequency
mV—millivolt
mW—milliwatt
MΩ—megohm

N

n—nano (prefix for 10⁻⁹); number of turns (inductors)
NBFM—narrow-band frequency modulation
NC—no connection; normally closed
NCS—net-control station; National Communications System
nF—nanofarad
NF—noise figure
nH—nanohenry
NiCd—nickel cadmium
NM—Net Manager
NMOS—N-channel metal-oxide silicon
NO—normally open
NPN—negative-positive-negative (transistor)
NPRM—Notice of Proposed Rule Making (FCC)
ns—nanosecond
NTIA—National Telecommunications and Information Administration
NTS—National Traffic System

O

OBS—Official Bulletin Station
OD—outside diameter
OES—Official Emergency Station
OO—Official Observer
op amp—operational amplifier
ORS—Official Relay Station
OSC—oscillator
OSCAR—Orbiting Satellite Carrying Amateur Radio
OTC—Old Timer's Club
oz—ounce (1/16 pound)

P

p—pico (prefix for 10⁻¹²)
P—power; plug
PA—power amplifier
PACTOR—digital mode combining aspects of packet and AMTOR

PAM—pulse-amplitude modulation
PBS—packet bulletin-board system
PC—printed circuit
PD—power dissipation
PEP—peak envelope power
PEV—peak envelope voltage
pF—picofarad
pH—picoHenry
PIC—Public Information Coordinator
PIN—positive-intrinsic-negative (semiconductor)
PIO—Public Information Officer
PIV—peak inverse voltage
PLC—Power Line Carrier
PLL—phase-locked loop
PM—phase modulation
PMOS—P-channel (metal-oxide semiconductor)
PNP—positive negative positive (transistor)
pot—potentiometer
P-P—peak to peak
ppd—postpaid
PROM—programmable read-only memory
PSAC—Public Service Advisory Committee
PSHR—Public Service Honor Roll
PTO—permeability-tuned oscillator
PTT—push to talk

Q-R

Q—figure of merit (tuned circuit); transistor
QRP—low power (less than 5-W output)
R—resistor
RACES—Radio Amateur Civil Emergency Service
RAM—random-access memory
RC—resistance-capacitance
R/C—radio control
RCC—Rag Chewer's Club
RDF—radio direction finding
RF—radio frequency
RFC—radio-frequency choke
RFI—radio-frequency interference
RHC—right-hand circular (polarization)
RIT—receiver incremental tuning
RLC—resistance-inductance-capacitance
RM—rule making (number assigned to petition)
r/min (RPM)—revolutions per minute
rms—root mean square
ROM—read-only memory
r/s—revolutions per second
RS—Radio Sputnik (Russian ham satellite)
RST—readability-strength-tone (CW signal report)
RTTY—radioteletype
RX—receiver, receiving

S

s—second (time)
S—siemens (unit of conductance); switch

SASE—self-addressed stamped envelope
 SCF—switched capacitor filter
 SCR—silicon controlled rectifier
 SEC—Section Emergency Coordinator
 SET—Simulated Emergency Test
 SGL—State Government Liaison
 SHF—super-high frequency (3-30 GHz)
 SM—Section Manager; silver mica (capacitor)
 S/N—signal-to-noise ratio
 SPDT—single-pole double-throw (switch)
 SPST—single-pole single-throw (switch)
 SS—ARRL Sweepstakes; spread spectrum
 SSB—single sideband
 SSC—Special Service Club
 SSI—small-scale integration
 SSTV—slow-scan television
 STM—Section Traffic Manager
 SX—simplex
 sync—synchronous, synchronizing
 SWL—shortwave listener
 SWR—standing-wave ratio

T
 T—tera (prefix for 10^{12}); transformer
 TA—ARRL Technical Advisor
 TC—Technical Coordinator
 TCC—Transcontinental Corps (NTS)
 TCP/IP—Transmission Control Protocol/ Internet Protocol
 tfc—traffic
 TNC—terminal node controller (packet radio)
 TR—transmit/receive
 TS—Technical Specialist
 TTL—transistor-transistor logic
 TTY—teletypewriter
 TU—terminal unit
 TV—television
 TVI—television interference
 TX—transmitter, transmitting

U
 U—integrated circuit
 UHF—ultra-high frequency (300 MHz to 3 GHz)
 USB—upper sideband
 UTC—Coordinated Universal Time (also abbreviated Z)
 UV—ultraviolet

V
 V—volt; vacuum tube

VCO—voltage-controlled oscillator
 VCR—video cassette recorder
 VDT—video-display terminal
 VE—Volunteer Examiner
 VEC—Volunteer Examiner Coordinator
 VFO—variable-frequency oscillator
 VHF—very-high frequency (30-300 MHz)
 VLF—very-low frequency (3-30 kHz)
 VLSI—very-large-scale integration
 VMOS—V-topology metal-oxide-semiconductor
 VOM—volt-ohmmeter
 VOX—voice-operated switch
 VR—voltage regulator
 VSWR—voltage standing-wave ratio
 VTVM—vacuum-tube voltmeter
 VUCC—VHF/UHF Century Club
 VXO—variable-frequency crystal oscillator

W
 W—watt ($\text{kg m}^2\text{s}^{-3}$), unit of power
 WAC—Worked All Continents
 WAS—Worked All States
 WBFM—wide-band frequency modulation
 WEFAX—weather facsimile
 Wh—watthour
 WPM—words per minute
 WRC—World Radiocommunication Conference
 WVDC—working voltage, direct current

X
 X—reactance
 XCVR—transceiver
 XFMR—transformer
 XIT—transmitter incremental tuning
 XO—crystal oscillator
 XTAL—crystal
 XVTR—transverter

Y-Z
 Y—crystal; admittance
 YIG—yttrium iron garnet
 Z—impedance; also see UTC

Numbers/Symbols

5BDXCC—Five-Band DXCC
 5BWAC—Five-Band WAC
 5BWAS—Five-Band WAS
 6BWAC—Six-Band WAC
 °—degree (plane angle)
 °C—degree Celsius (temperature)
 °F—degree Fahrenheit (temperature)
 α —(alpha) angles; coefficients, attenuation constant, absorption factor, area, common-base forward

current-transfer ratio of a bipolar transistor
 β —(beta) angles; coefficients, phase constant, current gain of common-emitter transistor amplifiers
 γ —(gamma) specific gravity, angles, electrical conductivity, propagation constant
 Γ —(gamma) complex propagation constant
 δ —(delta) increment or decrement; density; angles
 Δ —(delta) increment or decrement determinant, permittivity
 ϵ —(epsilon) dielectric constant; permittivity; electric intensity
 ζ —(zeta) coordinates; coefficients
 η —(eta) intrinsic impedance; efficiency; surface charge density; hysteresis; coordinate
 θ —(theta) angular phase displacement; time constant; reluctance; angles
 ι —(iota) unit vector
 K —(kappa) susceptibility; coupling coefficient
 λ —(lambda) wavelength; attenuation constant
 Λ —(lambda) permeance
 μ —(mu) permeability; amplification factor; micro (prefix for 10^{-6})
 μF —microfarad
 μH —microhenry
 μP —microprocessor
 ξ —(xi) coordinates
 π —(pi) ≈ 3.14159
 ρ —(rho) resistivity; volume charge density; coordinates; reflection coefficient
 σ —(sigma) surface charge density; complex propagation constant; electrical conductivity; leakage coefficient; deviation
 Σ —(sigma) summation
 τ —(tau) time constant; volume resistivity; time-phase displacement; transmission factor; density
 ϕ —(phi) magnetic flux angles
 Φ —(phi) summation
 χ —(chi) electric susceptibility; angles
 Ψ —(psi) dielectric flux; phase difference; coordinates; angles
 ω —(omega) angular velocity $2\pi\text{F}$
 Ω —(omega) resistance in ohms; solid angle

100.0 V	282.8 V	100.0	200.0 W	53.01
200.0 V	565.7 V	106.0	800.0 W	59.03
223.6 V	632.4 V	107.0	1,000.0 W	60.0
400.0 V	1,131.0 V	112.0	3,200.0 W	65.05
800.0 V	2,263.0 V	118.1	12,800.0 W	71.07
1000.0 V	2,828.0 V	120.0	20,000 W	73.01
2000.0 V	5,657.0 V	126.0	80,000 W	79.03
4000.0 V	11,310.0 V	132.0	320,000 W	85.05
8000.0 V	22,630.0 V	138.1	1.28 MW	91.07
10,000.0 V	28,280.0 V	140.0	2.0 MW	93.01

Voltage, $V_{p-p} = V_{RMS} \times 2\sqrt{2}$

Voltage, dBmV = $20 \times \log_{10} \left[\frac{V_{RMS}}{0.001V} \right]$ or $20 \times \log_{10} [mV_{RMS}]$

Power, watts = $\left[\frac{V_{RMS}^2}{50 \Omega} \right]$

Power, dBm = $10 \times \log_{10} \left[\frac{\text{Power (watts)}}{0.001W} \right]$ or $10 \times \log_{10} [mW_{RMS}]$

Table 7.49
Inductance Factor for Large Machine-Wound Coils

Factor to be applied to the inductance of large coils for coil lengths up to 5 inches.

Table 7.51
Inductance Factor for Small Machine-Wound Coils

Factor to be applied to the inductance of small coils as a function of coil length. Use curve A for coils marked A, and curve B for coils marked B.

Table 7.52

Measured Inductance for #12 Wire Windings

Values are for inductors with half-inch leads and wound with eight turns per inch.

Table 7.53

Relationship Between Noise Figure and Noise Temperature

Table 7.54

Antenna Wire Strength

American Wire Gauge	Recommended Tension ¹ (pounds)		Weight (pounds per 1000 feet)	
	Copper-clad steel ²	Hard-drawn copper	Copper-clad steel ²	Hard-drawn copper
4	495	214	115.8	126
6	310	130	72.9	79.5
8	195	84	45.5	50
10	120	52	28.8	31.4
12	75	32	18.1	19.8
14	50	20	11.4	12.4
16	31	13	7.1	7.8
18	19	8	4.5	4.9
20	12	5	2.8	3.1

¹Approximately one-tenth the breaking load. Might be increased 50% if end supports are firm and there is no danger of ice loading.

²"Copperweld," 40% copper.

$$\rho = \frac{SWR - 1}{SWR + 1}$$

where $\rho = 0.01 \times$ (reflection coefficient in %)

$$\rho = 10^{\frac{-RL}{20}}$$

where RL = return loss (dB)

$$\rho = \sqrt{1 - (0.1^X)}$$

where X = A/10 and A = attenuation (dB)

$$SWR = \frac{1 + \rho}{1 - \rho}$$

Return loss (dB) = $-8.68589 \ln(\rho)$

where ln is the natural log (log to the base e)

Attenuation (dB) = $-4.34295 \ln(1 - \rho^2)$

where ln is the natural log (log to the base e)

Table 7.61

Guy Wire Lengths to Avoid

The black bars indicate ungrounded guy wire lengths to avoid for the eight HF amateur bands. This chart is based on resonance within 10% of any frequency in the band. Grounded wires will exhibit resonance at odd multiples of a quarter wavelength. (Jerry Hall, K1TD)

Table 7.62

Morse Code Character Set¹

A	didah	• –	Period [.]:	didahdidahdidah	• – • – • –	AAA

X	dahdididah	– •• –				
Y	dahdidahdah	– • – –				
Z	dahdahdidit	– – ••				

Notes:

1. Not all Morse characters shown are used in FCC code tests. License applicants are responsible for knowing, and may be tested on, the 26 letters, the numerals 0 to 9, the period, the comma, the question mark, AR, SK, BT and fraction bar [DN].

2. The following letters are used in certain European languages which use the Latin alphabet:

Ä, Å	didahdidah	• – • –
À, Á, Â, Ã	didahdahdidah	• – – • –
Ç, Ç	dahdidahdidit	– • – ••
É, Ê, Ë	dididahdidit	•• – ••
È	didahdididah	• – •• –
Ê	dahdididahdit	– •• – •
Ö, Ø, Ó	dahdahdahdit	– – – •
Ñ	dahdahdidahdah	– • – • – –
Ü	dididahdah	•• – –
Ž	dahdahdidit	– – ••
Z	dahdahdididah	– – •• –
CH, Ş	dahdahdahdah	– – – –

3. Special Esperanto characters:

^	dahdidahdidit	– • – ••
^	didididahdit	••• – •
^	didahdahdahdit	• – – – •
^	dahdidahdahdit	– • – – •
^	dididahdah	•• – –
^	dahdahdidahdit	– – • – •

4. Signals used in other radio services:

Interrogatory	dididahdidah	•• – • –	INT
Emergency silence	dididididahdah	••• – –	HM
Executive follows	dididahdididah	•• – •• –	IX
Break-in signal	dahdahdahdahdah	– – – – –	TTTTT
Emergency signal	didididahdahdididit	••• – – •••	SOS
Relay of distress	dahdididahdididahdidit	– •• – •• – ••	DDD

Morse Abbreviated Numbers

Numeral	Long Number	Abbreviated Number	Equivalent Character
1	didahdahdahdah	didah	A
2	dididahdahdah	dididah	U
3	didididahdah	didididah	V
4	dididididah	dididididah	4
5	dididididit	dididididit	5 or E
6	dahdidididit	dahdidididit	6
7	dahdahdididit	dahdididit	B
8	dahdahdahdidit	dahdidit	D
9	dahdahdahdahdit	dahdit	N
0	dahdahdahdahdah	dah	T

Note: These abbreviated numbers are not legal for use in call signs. They should be used only where there is agreement between operators and when no confusion will result.

Table 7.63

Morse Abbreviated (“Cut”) Numbers

<i>Numeral</i>		<i>Long Number</i>		<i>Abbreviated Number</i>	<i>Equivalent Character</i>
1	didahdahdahdah	•-----	didah	•-	A
2	dididahdahdah	••-----	dididah	••-	U
3	didididahdah	•••-----	didididah	•••-	V
4	dididididah	••••-	dididididah	••••-	4
5	dididididit	•••••	dididididit	••••• or •	5 or E
6	dahdidididit	-•••••	dahdidididit	-•••••	6
7	dahdahdididit	---••••	dahdididit	-••••	B
8	dahdahdahdidit	----•••	dahdidit	-•••	D
9	dahdahdahdahdit	-----•	dahdit	-•	N
0	dahdahdahdahdah	-----	dah	-	T

Note: These abbreviated numbers are not legal for use in call signs. They should be used only where there is agreement between operators and when no confusion will result.

STX	start of text
SUB	substitute
SYN	synchronous idle
US	unit separator
VT	vertical tab

Table 7.65

Voluntary HF Band Plans

The following frequencies are generally recognized for certain modes or activities (all frequencies are in MHz). Nothing in the rules recognizes a net's, group's or any individual's special privilege to any specific frequency. Section 97.101(b) of the Rules states that "Each station licensee and each control operator must cooperate in selecting transmitting channels and in making the most effective use of the amateur service frequencies. No frequency will be assigned for the exclusive use of any station." No one "owns" a frequency. It's good practice—and plain old common sense—for any operator, regardless of mode, to check to see if the frequency is in use prior to engaging operation. If you are there first, other operators should make an effort to protect you from interference to the extent possible given that 100% inter-ference-free operation is an unrealistic expectation in today's congested bands.

1.800-1.810	Digital Modes	14.285	QRP SSB calling frequency
1.810	CW QRP	14.286	AM calling frequency
1.800-2.000	CW		
1.843-2.000	SSB, SSTV and other wideband modes	18.100-18.105	Data
1.910	SSB QRP	18.105-18.110	Automatically controlled data stations
1.995-2.000	Experimental		
1.999-2.000	Beacons	21.060	QRP CW calling frequency
		21.070-21.090	Data
3.500-3.510	CW DX	21.090-21.100	Automatically controlled data stations
3.590	RTTY DX	21.340	SSTV
3.580-3.620	Data	21.385	QRP SSB calling frequency
3.620-3.635	Automatically controlled data stations		
3.790-3.800	DX window	24.920-24.925	Data
3.845	SSTV	24.925-24.930	Automatically controlled data stations
3.885	AM calling frequency		
3.985	QRP SSB calling frequency	28.060	QRP CW calling frequency
		28.070-28.120	Data
7.040	RTTY DX	28.120-28.189	Automatically controlled data stations
	QRP CW calling frequency	28.190-28.225	Beacons
7.075-7.100	Phone in KH/KL/KP <i>only</i>	28.385	QRP SSB calling frequency
7.080-7.100	Data	28.680	SSTV
7.100-7.105	Automatically controlled data stations		
7.171	SSTV	29.000-29.200	AM
7.290	AM calling frequency	29.300-29.510	Satellite downlinks
		29.520-29.580	Repeater inputs
10.106	QRP CW calling frequency	29.600	FM simplex
10.130-10.140	Data	29.620-29.680	Repeater outputs
10.140-10.150	Automatically controlled data stations		
14.060	QRP CW calling frequency		
14.070-14.095	Data		
14.095-14.0995	Automatically controlled data stations		
14.100	IBP/NCDXF beacons		
14.1005-14.112	Automatically controlled data stations		
14.230	SSTV		

Notes

ARRL band plans for frequencies above 28.300 MHz are shown in *The ARRL Repeater Directory* *The FCC Rule Book* *QST*

Table 7.66

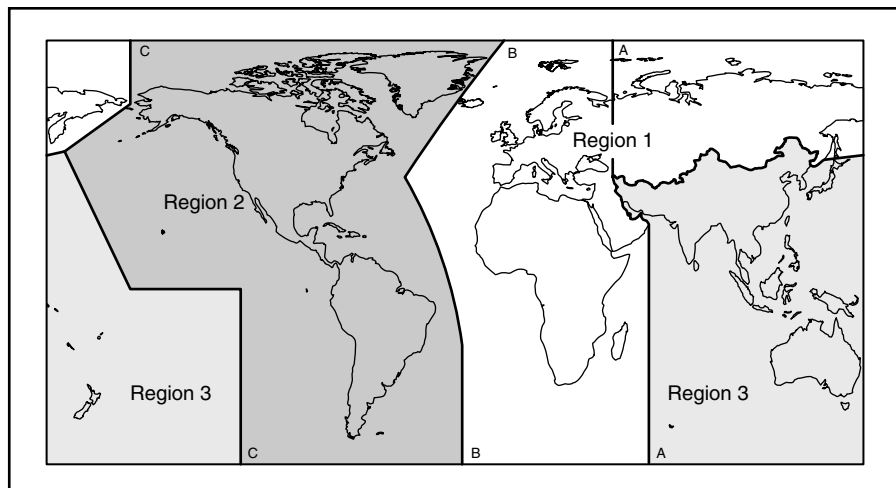

VHF/UHF/EHF Calling Frequencies

		1296	1294.500 National FM simplex frequency

Table 7.70**DX Operating Code***For W/VE Amateurs*

Some DXers have caused considerable confusion and interference in their efforts to work DX stations. The points below, if observed by all W/VE amateurs, will help make DX more enjoyable for all.

- 1) Call DX only after he calls CQ, QRZ? or signs \overline{SK} , or voice equivalents thereof. Make your calls short.
- 2) Do not call a DX station:
 - a) On the frequency of the station he is calling until you are sure the QSO is over (\overline{SK}).
 - b) Because you hear someone else calling him.
 - c) When he signs KN, AR or CL.
 - d) Exactly on his frequency.
 - e) After he calls a directional CQ, unless of course you are in the right direction or area.
- 3) Keep within frequency band limits. Some DX stations can get away with working outside, but you cannot.
- 4) Observe calling instructions given by DX stations. Example: 15U means "call 15 kHz up from my frequency." 15D means down, etc.
- 5) Give honest reports. Many DX stations depend on W/VE reports for adjustment of station and equipment.
- 6) Keep your signal clean. Key clicks, ripple, feedback or splatter gives you a bad reputation and may get you a citation from the FCC.
- 7) Listen and call the station you want. Calling CQ DX is not the best assurance that the rare DX will reply.
- 8) When there are several W or VE stations waiting, avoid asking DX to "listen for a friend." Also avoid engaging him in a ragchew against his wishes.

For Overseas Amateurs

To all overseas amateur stations:

- In their eagerness to work you, many W and VE amateurs resort to practices that cause confusion and QRM. Most of this is good-intentioned but ill-advised; some of it is intentional and selfish. The key to the cessation of unethical DX operating practices is in your hands. We believe that your adoption of certain operating habits will increase your enjoyment of Amateur Radio and that of amateurs on this side who are eager to work you. We recommend your adoption of the following principles:
- 1) Do not answer calls on your own frequency.
 - 2) Answer calls from W/VE stations only when their signals are of good quality.
 - 3) Refuse to answer calls from other stations when you are already in contact with someone, and do not acknowledge calls from amateurs who indicate they wish to be "next."
 - 4) Give *everybody* a break. When many W/VE amateurs are patiently and quietly waiting to work you, avoid complying with requests to "listen for a friend."
 - 5) Tell listeners where to call you by indicating how many kilohertz up (U) or down (D) from your frequency you are listening.
 - 6) Use the ARRL-recommended ending signals, especially \overline{KN} to indicate to impatient listeners the status of the QSO. \overline{KN} means "Go ahead (specific station); all others keep out."
 - 7) Let it be known that you avoid working amateurs who are constant violators of these principles.
-

W1AW SCHEDULE

Pacific	Mtn	Central	East	Mon	Tue	Wed	Thu	Fri
6 AM	7 AM	8 AM	9 AM		Fast Code	Slow Code	Fast Code	Slow Code
7 AM - 1 PM	8 AM - 2 PM	9 AM - 3 PM	10 AM - 4 PM	Visiting Operator Time (12 PM - 1 PM closed for lunch)				
1 PM	2 PM	3 PM	4 PM	Fast Code	Slow Code	Fast Code	Slow Code	Fast Code
2 PM	3 PM	4 PM	5 PM	Code Bulletin				
3 PM	4 PM	5 PM	6 PM	Teleprinter Bulletin				
4 PM	5 PM	6 PM	7 PM	Slow Code	Fast Code	Slow Code	Fast Code	Slow Code
5 PM	6 PM	7 PM	8 PM	Code Bulletin				
6 PM	7 PM	8 PM	9 PM	Teleprinter Bulletin				
6:45 PM	7:45 PM	8:45 PM	9:45 PM	Voice Bulletin				
7 PM	8 PM	9 PM	10 PM	Fast Code	Slow Code	Fast Code	Slow Code	Fast Code
8 PM	9 PM	10 PM	11 PM	Code Bulletin				

W1AW's schedule is at the same local time throughout the year. The schedule according to your local time will change if your local time does not have seasonal adjustments that are made at the same time as North American time changes between standard time and daylight time. From the first Sunday in April to the last Sunday in October, UTC = Eastern Time + 4 hours. For the rest of the year, UTC = Eastern Time + 5 hours.

Morse code transmissions:

Frequencies are 1.818, 3.5815, 7.0475, 14.0475, 18.0975, 21.0675, 28.0675 and 147.555 MHz.

Slow Code = practice sent at 5, 7 1/2, 10, 13 and 15 wpm.

Fast Code = practice sent at 35, 30, 25, 20, 15, 13 and 10 wpm.

Code practice text is from the pages of *QST*. The source is given at the beginning of each practice session and alternate speeds within each session. For example, "Text is from June 2003 *QST*, pages 9 and 81," indicates that the plain text is from the article on page 9 and mixed number/letter groups are from page 81.

Code bulletins are sent at 18 wpm.

W1AW qualifying runs are sent on the same frequencies as the Morse code transmissions. West Coast qualifying runs are transmitted on approximately 3.590 MHz by K6YR. At the beginning of each code practice session, the schedule for the next qualifying run is presented. Underline one minute of the highest speed you copied, certify that your copy was made without aid, and send it to ARRL for grading. Please include your name, call sign (if any) and complete mailing address. The fee structure is \$10 for a certificate and \$7.50 for endorsements.

Teleprinter transmissions:

Frequencies are 3.625, 7.095, 14.095, 18.1025, 21.095, 28.095 and 147.555 MHz.

Bulletins are sent at 45.45-baud Baudot and 100-baud AMTOR, FEC Mode B. 110-baud ASCII will be sent only as time allows.

On Tuesdays and Fridays at 6:30 PM Eastern Time, Keplerian elements for many amateur -satellites are sent on the regular teleprinter frequencies.

Voice transmissions:

Frequencies are 1.855, 3.99, 7.29, 14.29, 18.16, 21.39, 28.59 and 147.555 MHz.

Miscellanea:

On Fridays, UTC, a DX bulletin replaces the regular bulletins.

W1AW is open to visitors from 10 AM until noon and from 1 PM until 3:45 PM on Monday through Friday. FCC-licensed amateurs may operate the station during that time. Be sure to bring your current FCC amateur license or a photocopy.

In a communication emergency, monitor W1AW for special bulletins as follows: voice on the hour, teleprinter at 15 minutes past the hour, and CW on the half hour.

Headquarters and W1AW are closed on New Year's Day, President's Day, Good Friday, Memorial Day, Independence Day, Labor Day, Thanksgiving and the following Friday, and Christmas Day and the following day.

Table 7.72**ARRL Procedural Signals (Prosigns)**

In general, the CW prosigns are used on all data modes as well, although word abbreviations may be spelled out. That is, "CLEAR" might be used rather than "CL" on radioteletype. Additional radioteletype conventions appear at the end of the table.

<i>Situation</i>	<i>CW</i>	<i>Voice</i>
check for a clear frequency	QRL?	Is the frequency in use?
seek contact with any station	CQ	CQ
after call to specific named station or to indicate end of message	AR	over, end of message
invite any station to transmit	K	go
invite a specific named station to transmit	KN	go only
invite receiving station to transmit	BK	back to you
all received correctly	R	received
please stand by	AS	wait, stand by
end of contact (sent before call sign)	SK	clear
going off the air	CL	closing station

Additional RTTY prosigns

SK QRZ—Ending contact, but listening on frequency.

SK KN—Ending contact, but listening for one last transmission from the other station.

SK SZ—Signing off and listening on the frequency for any other calls.

Table 7.73**Q Signals**

These Q signals most often need to be expressed with brevity and clarity in amateur work. (Q abbreviations take the form of questions only when each is sent followed by a question mark.)

QRA	What is the name of your station? The name of your station is _____.	QSA	What is the strength of my signals (or those of _____)? The strength of your signals (or those of _____) is _____ (1. Scarcely perceptible; 2. Weak; 3. Fairly good; 4. Good; 5. Very good).
QRG	Will you tell me my exact frequency (or that of _____)? Your exact frequency (or that of _____) is _____ kHz.	QSB	Are my signals fading? Your signals are fading.
QRH	Does my frequency vary? Your frequency varies.	QSD	Is my keying defective? Your keying is defective.
QRI	How is the tone of my transmission? The tone of your transmission is _____ (1. Good; 2. Variable; 3. Bad).	QSG	Shall I send _____ messages at a time? Send _____ messages at a time.
QRJ	Are you receiving me badly? I cannot receive you. Your signals are too weak.	QSK	Can you hear me between your signals and if so can I break in on your transmission? I can hear you between my signals; break in on my transmission.
QRK	What is the intelligibility of my signals (or those of _____)? The intelligibility of your signals (or those of _____) is _____ (1. Bad; 2. Poor; 3. Fair; 4. Good; 5. Excellent).	QSL	Can you acknowledge receipt? I am acknowledging receipt.
QRL	Are you busy? I am busy (or I am busy with _____). Please do not interfere.	QSM	Shall I repeat the last message which I sent you, or some previous message? Repeat the last message which you sent me [or message(s) number(s) _____].
QRM	Is my transmission being interfered with? Your transmission is being interfered with (1. Nil; 2. Slightly; 3. Moderately; 4. Severely; 5. Extremely.)	QSN	Did you hear me (or _____) on _____ kHz? I did hear you (or _____) on _____ kHz.
QRN	Are you troubled by static? I am troubled by static _____ (1-5 as under QRM).	QSO	Can you communicate with _____ direct or by relay? I can communicate with _____ direct (or by relay through _____).
QRO	Shall I increase power? Increase power.	QSP	Will you relay to _____? I will relay to _____
QRP	Shall I decrease power? Decrease power.	QST	General call preceding a message addressed to all amateurs and ARRL members. This is in effect "CQ ARRL."
QRQ	Shall I send faster? Send faster (_____ WPM).	QSU	Shall I send or reply on this frequency (or on _____ kHz)? Send or reply on this frequency (or _____ kHz).
QRS	Shall I send more slowly? Send more slowly (_____ WPM).	QSV	Shall I send a series of Vs on this frequency (or on _____ kHz)? Send a series of Vs on this frequency (or on _____ kHz).
QRT	Shall I stop sending? Stop sending.	QSW	Will you send on this frequency (or on _____ kHz)? I am going to send on this frequency (or on _____ kHz).
QRU	Have you anything for me? I have nothing for you.	QSX	Will you listen to _____ on _____ kHz? I am listening to _____ on _____ kHz.
QRV	Are you ready? I am ready.	QSY	Shall I change to transmission on another frequency? Change to transmission on another frequency (or on _____ kHz).
QRW	Shall I inform _____ that you are calling on _____ kHz? Please inform _____ that I am calling on _____ kHz.		
QRX	When will you call me again? I will call you again at _____ hours (on _____ kHz).		
QRY	What is my turn? Your turn is numbered _____		
QRZ	Who is calling me? You are being called by _____ (on _____ kHz).		

QSZ	Shall I send each word or group more than once? Send each word or group twice (or _____ times).	QNL	Your net frequency is Low.
QTA	Shall I cancel message number _____? Cancel message number _____	QNM*	You are QRMing the net. Stand by.
QTB	Do you agree with my counting of words? I do not agree with your counting of words. I will repeat the first letter or digit of each word or group.	QNN	Net control station is _____. What station has net control?
QTC	How many messages have you to send? I have _____ messages for you (or for _____).	QNO	Station is leaving the net.
QTH	What is your location? My location is _____	QNP	Unable to copy you. Unable to copy _____.
QTR	What is the correct time? The correct time is _____	QNQ*	Move frequency to _____ and wait for _____ to finish handling traffic. Then send him traffic for _____.
QTV	Shall I stand guard for you? Stand guard for me.	QNR*	Answer _____ and Receive traffic.
QTX	Will you keep your station open for further communication with me? Keep your station open for me.	QNS	Following Stations are in the net.* (follow with list.) Request list of stations in the net.
QUA	Have you news of _____? I have news of _____.	QNT	I request permission to leave the net for _____ minutes.
<i>ARRL QN Signals</i>		QNU*	The net has traffic for <i>you</i> . Stand by.
QNA*	Answer in prearranged order.	QNV*	Establish contact with _____ on this frequency. If successful, move to _____ and send him traffic for _____.
QNB	Act as relay between _____ and _____.	QNW	How do I route messages for _____?
QNC	All net stations copy. I have a message for all net stations.	QNX	You are excused from the net.*
QND*	Net is Directed (Controlled by net control station.)	QNY*	Shift to another frequency (or to _____ kHz) to clear traffic with _____.
QNE*	Entire net stand by.	QNZ	Zero beat your signal with mine.
QNF	Net is Free (not controlled).	*For use only by the Net Control Station.	
QNG	Take over as net control station	Notes on Use of QN Signals	
QNH	Your net frequency is High.	These QN signals are special ARRL signals for use in amateur CW nets <i>only</i> . They are not for use in casual amateur conversation. Other meanings that may be used in other services do not apply. Do not use QN signals on phone nets. <i>Say it with words</i> . QN signals need not be followed by a question mark, even though the meaning may be interrogatory.	
QNI	Net stations report in. I am reporting into the net. (Follow with a list of traffic or QRU.)		
QNJ	Can you copy me?		
QNK*	Transmit messages for _____ to _____.		

Table 7.74
The RST System

Readability

- 1—Unreadable.
- 2—Barely readable, occasional words distinguishable.
- 3—Readable with considerable difficulty.
- 4—Readable with practically no difficulty.
- 5—Perfectly readable.

Signal Strength

- 1—Faint signals, barely perceptible.
- 2—Very weak signals.
- 3—Weak signals.
- 4—Fair signals.
- 5—Fairly good signals.
- 6—Good signals.
- 7—Moderately strong signals.
- 8—Strong signals.
- 9—Extremely strong signals.

Tone

- 1—Sixty-cycle ac or less, very rough and broad.
 - 2—Very rough ac, very harsh and broad.
 - 3—Rough ac tone, rectified but not filtered.
 - 4—Rough note, some trace of filtering.
 - 5—Filtered rectified ac but strongly ripple-modulated.
 - 6—Filtered tone, definite trace of ripple modulation.
 - 7—Near pure tone, trace of ripple modulation.
 - 8—Near perfect tone, slight trace of modulation.
 - 9—Perfect tone, no trace of ripple of modulation of any kind.
- If the signal has the characteristic steadiness of crystal control, add the letter X to the RST report. If there is a chirp, add the letter C. Similarly for a click, add K. (See FCC Regulations §97.307, Emissions Standards.) The above reporting system is used on both CW and voice; leave out the "tone" report on voice.

Table 7.75

CW Abbreviations

AA	All after	GUD	Good	SIG	Signature; signal
AB	All before	HI	The telegraphic laugh; high	SINE	Operator's personal initials or nickname
AB	About	HR	Here, hear	SKED	Schedule
ADR	Address	HV	Have	SRI	Sorry
AGN	Again	HW	How	SSB	Single sideband
ANT	Antenna	LID	A poor operator	SVC	Service; prefix to service message
BCI	Broadcast interference	MA, MILS	Milliamperes	T	Zero
BCL	Broadcast listener	MSG	Message; prefix to radiogram	TFC	Traffic
BK	Break; break me; break in	N	No	TMW	Tomorrow
BN	All between; been	NCS	Net control station	TNX-TKS	Thanks
BUG	Semi-automatic key	ND	Nothing doing	TT	That
B4	Before	NIL	Nothing; I have nothing for you	TU	Thank you
C	Yes	NM	No more	TVI	Television interference
CFM	Confirm; I confirm	NR	Number	TX	Transmitter
CK	Check	NW	Now; I resume transmission	TXT	Text
CL	I am closing my station; call	OB	Old boy	UR-URS	Your; you're; yours
CLD-CLG	Called; calling	OC	Old chap	VFO	Variable-frequency oscillator
CQ	Calling any station	OM	Old man	VY	Very
CUD	Could	OP-OPR	Operator	WA	Word after
CUL	See you later	OT	Old timer; old top	WB	Word before
CW	Continuous wave (i.e., radiotelegraph)	PBL	Preamble	WD-WDS	Word; words
DE	From	PSE	Please	WKD-WKG	Worked; working
DLD-DLVD	Delivered	PWR	Power	WL	Well; will
DR	Dear	PX	Press	WUD	Would
DX	Distance, foreign countries	R	Received as transmitted; are	WX	Weather
ES	And, &	RCD	Received	XCVR	Transceiver
FB	Fine business, excellent	RCVR (RX)	Receiver	XMTR (TX)	Transmitter
FM	Frequency modulation	REF	Refer to; referring to; reference	XTAL	Crystal
GA	Go ahead (or resume sending)	RFI	Radio Frequency Interference	XYL (YF)	Wife
GB	Good-by	RIG	Station equipment	YL	Young lady
GBA	Give better address	RPT	Repeat; I repeat; report	73	Best regards
GE	Good evening	RTTY	Radioteletype	88	Love and Kisses
GG	Going	RX	Receiver	Although abbreviations help to cut down unnecessary transmission, make it a rule not to abbreviate unnecessarily when working an operator of unknown experience.	
GM	Good morning	SASE	Self-addressed, stamped envelope		
GN	Good night	SED	Said		
GND	Ground				

Table 7.76

ITU Recommended Phonetics

A — Alfa (AL FAH)	Q — Quebec (KEH BECK)
B — Bravo (BRAH VOH)	R — Romeo (ROW ME OH)
C — Charlie (CHAR LEE OR SHAR LEE)	S — Sierra (SEE <i>AIR</i> RAH)
D — Delta (DELL TAH)	T — Tango (TANG GO)
E — Echo (ECK OH)	U — Uniform (YOU NEE FORM or OO NEE FORM)
F — Foxtrot (FOKS TROT)	V — Victor (VIK TAH)
G — Golf (GOLF)	W — Whiskey (WISS KEY)
H — Hotel (HOH TELL)	X — X-Ray (ECKS RAY)
I — India (IN DEE AH)	Y — Yankee (YANG KEY)
J — Juliet (JEW LEE ETT)	Z — Zulu (ZOO LOO)
K — Kilo (KEY LOH)	
L — Lima (LEE MAH)	
M — Mike (MIKE)	
N — November (NO VEM BER)	
O — Oscar (OSS CAH)	
P — Papa (PAH PAH)	

Note: The **Boldfaced** syllables are emphasized. The pronunciations shown in the table were designed for speakers from all international languages. The pronunciations given for "Oscar" and "Victor" may seem awkward to English-speaking people in the U.S.

Table 7.77

9 Nov	21	CW	10	1642	G4BUE	339	449	1657		I watt!						

The ARRL Log is adaptable for all types of operating—ragchewing, contesting, DXing. References are to pages in the ARRL Log.

Table 7.78
ARRL Operating Awards

Award

- Worked All States (WAS)
- Worked All Continents (WAC)
- DX Century Club (DXCC)
- VHF/UHF Century Club (VUCC)
- A-1 Operator Club
- Code Proficiency
- ARRL Membership

Qualification

- QSLs from all 50 US states
- QSLs from all six continents
- QSLs from at least 100 different countries
- QSLs from many grid squares
- Recommendation by two A-1 operators
- One minute of perfect copy from W1AW qualifying run
- ARRL membership for 25, 40, 50, 60 or 70 years

Table 7.79
ARRL Membership QSL Card

The ARRL membership QSL card. This example is from Harris Ruben, N2ERN, who designed the card. Your card would reflect your own call sign and address; awards and VUCC grid-square are optional. ARRL does not print or sell the cards. Inquire with printers who advertise in the *QST* Ham Ads.

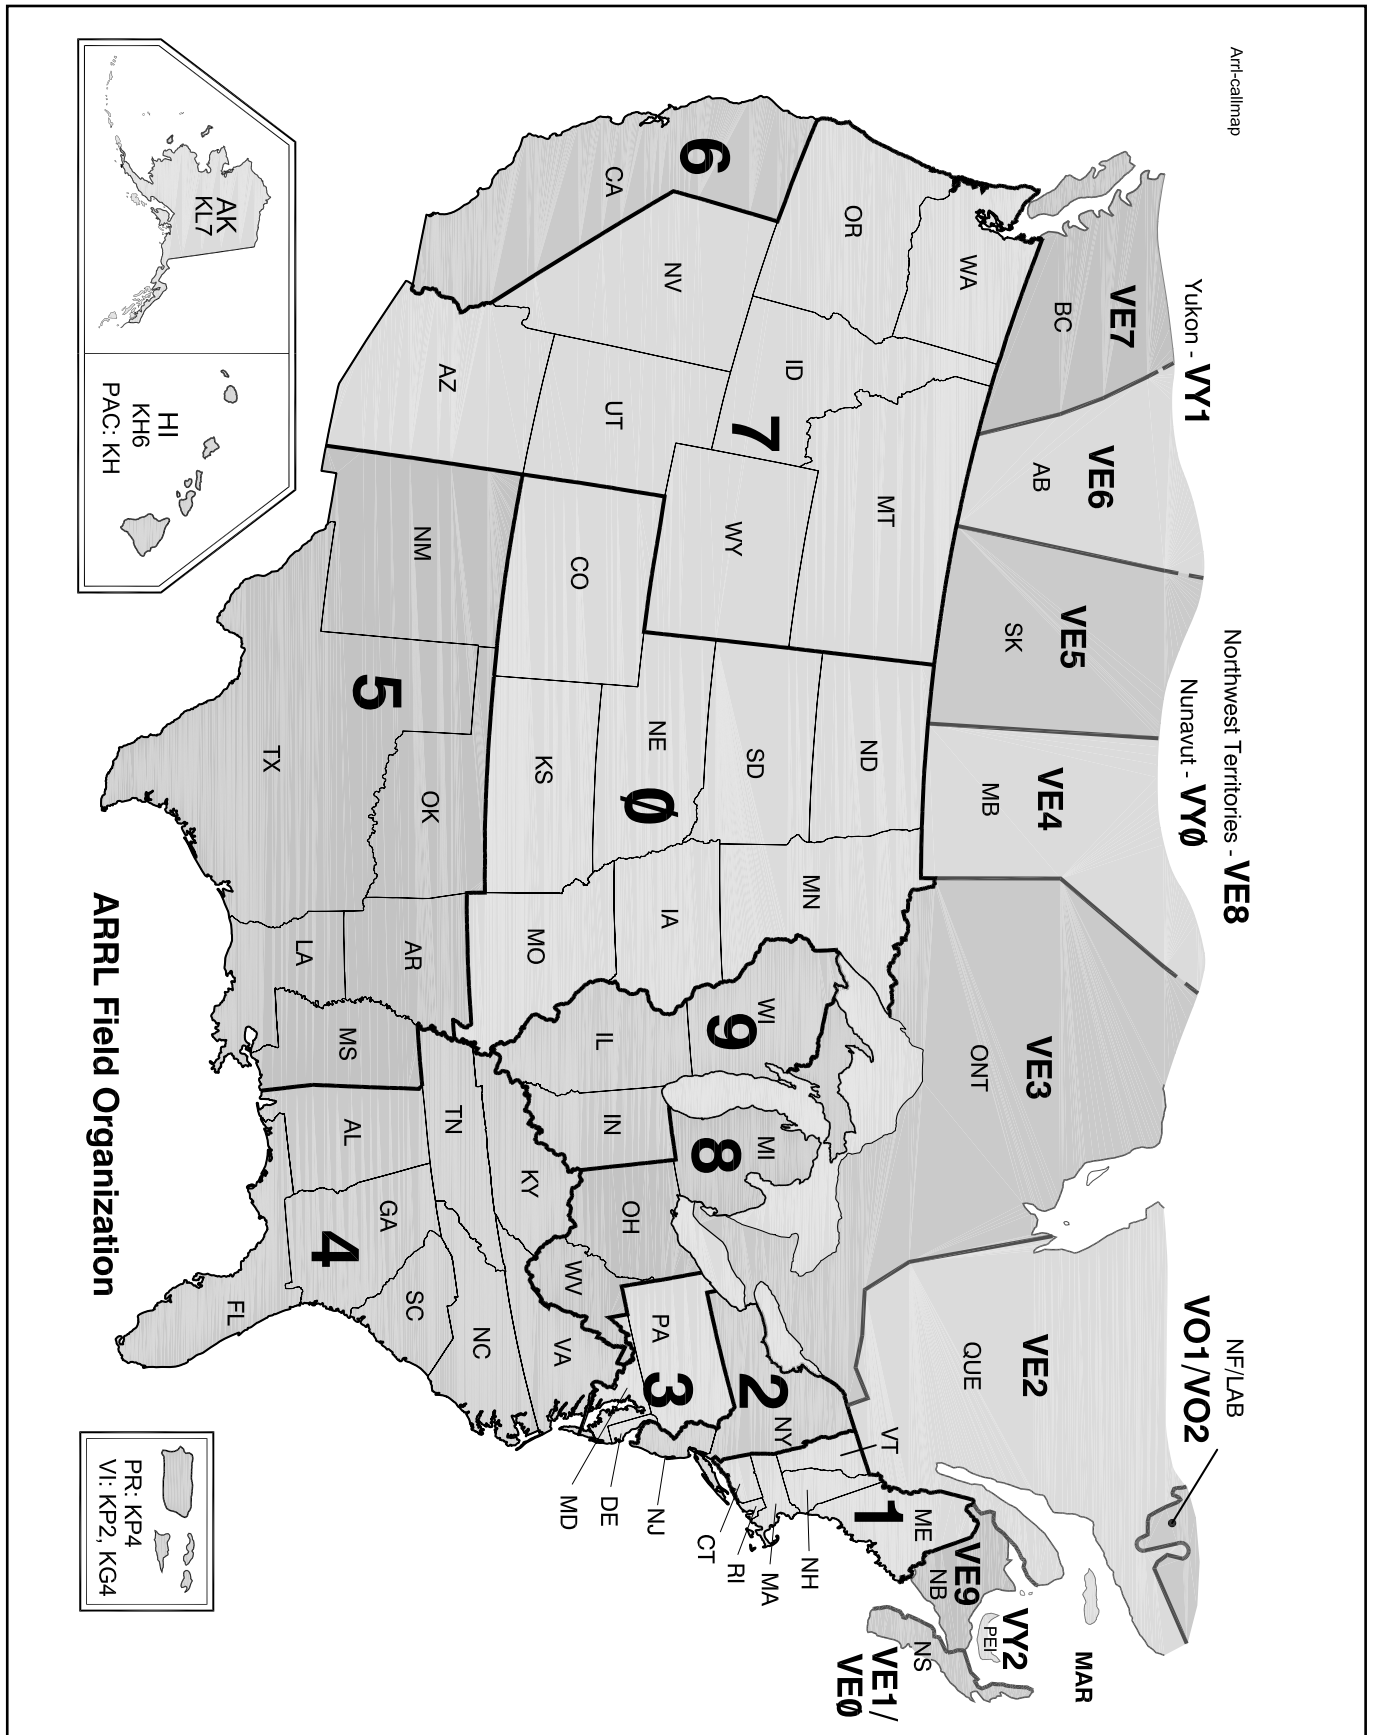

Table 7.80
Mode Abbreviations for QSL Cards

Abbreviation	Explanation
CW	Telegraphy
DATA	Telemetry, telecommand and computer communications (includes packet radio)
IMAGE	Facsimile and television
MCW	Tone-modulated telegraphy
PHONE	Speech and other sound
PULSE	Modulated main carrier
RTTY	Direct-printing telegraphy (includes AMTOR)
SS	Spread Spectrum
TEST	Emissions containing no information

Note: For additional information on emission types refer to latest edition of *The FCC Rule Book*.

Table 7.81

US/Canada Map

A map showing US states, Canadian provinces and ARRL/RAC Sections.

Table 7.82

ARRL Grid Locator Map for North America

This and a World Grid Locator Map are available from ARRL.

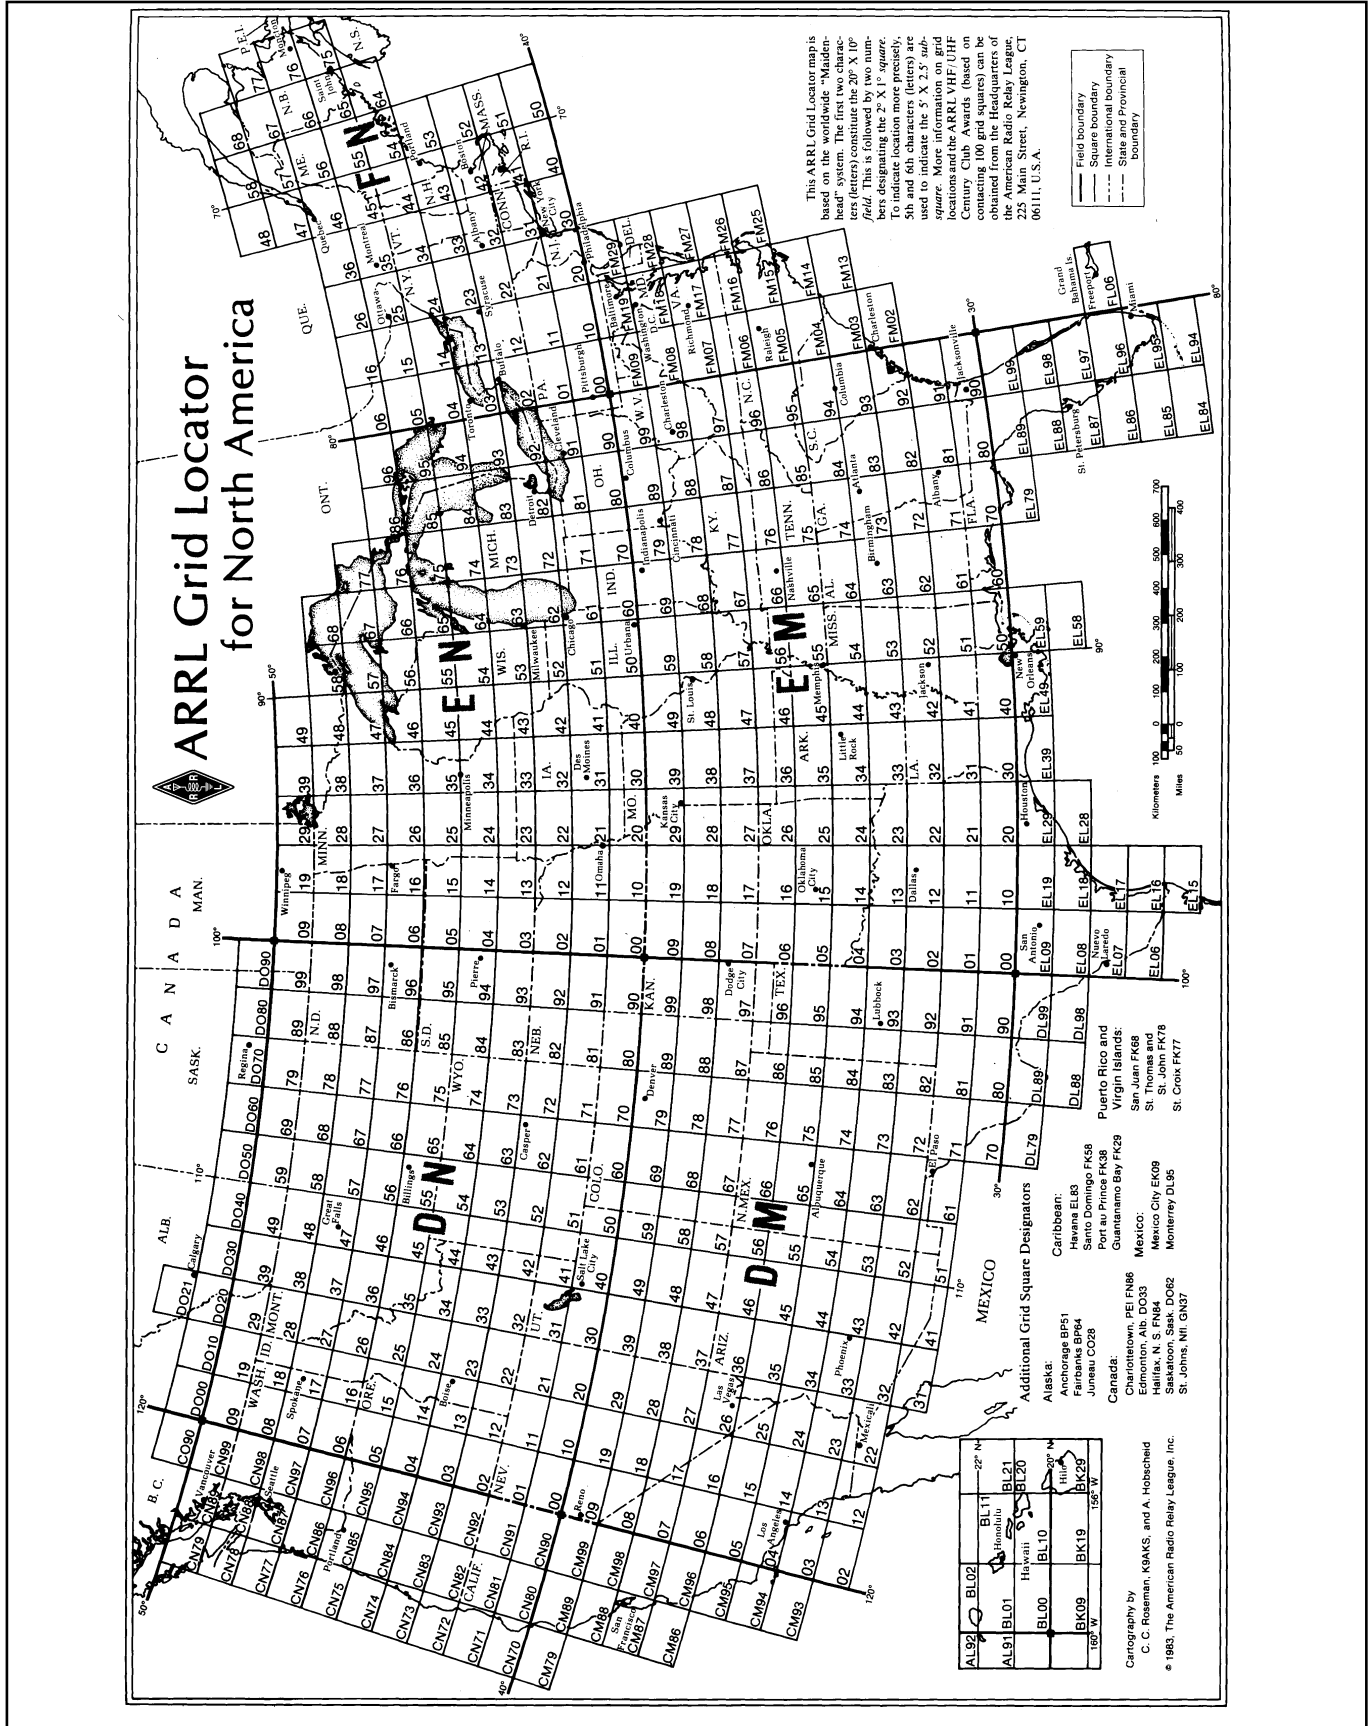

Table 7.83

Amateur Message Form

Every formal radiogram message originated and handled should contain the following component parts in the order given.

I PREAMBLE

- a. Number (begin with I each month or year)
- b. Precedence (R, W, P or EMERGENCY)
- c. Handling Instructions (optional, see text)
- d. Station of Origin (first amateur handler)
- e. Check (number of words/groups in text only)
- f. Place of Origin (not necessarily location of station of origin)
- g. Time Filed (optional with originating station)
- h. Date (must agree with date of time filed)

II ADDRESS (as complete as possible, include zip code and telephone number)

III TEXT (limit to 25 words or less, if possible)

IV SIGNATURE

CW MESSAGE EXAMPLE

I NR 1 R HXG WIAW 8 NEWINGTON CT 1830Z JULY 1
a b c d e f g h

II DONALD SMITH \overline{AA}
 160 EAST SIXTH AVE \overline{AA}
 NORTH RIVER CITY MO 00789 \overline{AA}
 733 4868 \overline{BT}

III HAPPY BIRTHDAY X SEE YOU SOON X LOVE \overline{BT}

IV DIANA \overline{AR}

Note that X, when used in the text as punctuation, counts as a word.

CW: The prosign \overline{AA} separates the parts of the message. \overline{BT} separates the address from the text the text from the signature. \overline{AR} marks the end of message; this is followed by B if there is another message to follow, by N if this is the only or last message. It is customary to copy the preamble, parts of the address, text and signature on separate lines.

RTTY: Same as CW procedure above, except (1) use extra space between parts of address, instead of \overline{AA} ; (2) omit CW procedure sign \overline{BT} to separate text from address and signature, using line spaces instead; (3) add a CFM line under the signature, consisting of all names, numerals and unusual words in the message in the order transmitted.

PACKET/AMTOR BBS: Same format as shown in the CW message example above, except that the \overline{AA} and \overline{AR} prosigns may be omitted. Most AMTOR and Packet BBS software in use today allow formal message traffic to be sent with the "ST" command. Always avoid the use of spectrum-wasting multiple line feeds and indentations.

PHONE: Use prowords instead of prosigns, but it is not necessary to name each part of the message as you send it. For example, the above message would be sent on phone as follows: "Number one routine HX

Golf WIAW eight Newington Connecticut one eight three zero zulu July one Donald Smith *Figures* one six four East Sixth Avenue North River City Missouri zero zero seven eight nine *Telephone* seven three three four nine six eight *Break* Happy Birthday X-ray see you soon X-ray love *Break* Diana *End of Message Over*. "End of Message" is followed by "More" if there is another message to follow, "No More" if it is the only or last message. Speak clearly using VOX (or pause frequently on push-to-talk) so that the receiving station can get his fills. Spell phonetically all difficult or unusual words—do not spell out common words. Do not use CW abbreviations or Q-signals in phone traffic handling.

PRECEDENCES

The precedence will fill the message number. For example, on CW 207 R or 207 EMERGENCY. On phone, "Two Zero Seven Routine (or Emergency)."

EMERGENCY—Any message having life and death urgency to any person or group of persons, which is transmitted by Amateur Radio in the absence of regular commercial facilities. This includes official messages of welfare agencies during emergencies requesting supplies, materials or instructions vital to relief of stricken populace in emergency areas. During normal times, it will be *very rare*. On CW, RTTY and other digital modes this designation will always be spelled out. When in doubt, *do not* use it.

PRIORITY—Important messages having a specific time limit. Official messages not covered in the Emergency category. Press dispatches and other emergency-related traffic not of the utmost urgency. Notification of death or injury in a disaster area, personal or official. Use the abbreviation P on CW.

WELFARE—A message that is either (a) an inquiry as to the health and welfare of an individual in the disaster area (b) an advisory or reply from the disaster area that indicates that all is well should carry this precedence, which is abbreviated W on CW. These messages are handled *after* Emergency and Priority traffic but before Routine.

ROUTINE—Most traffic normal times will bear this designation. In disaster situations, traffic labeled Routine (R on CW) should be handled *last*, or not at all when circuits are busy with Emergency, Priority or Welfare traffic.

Handling Instructions (Optional)

- HXA**—(Followed by number.) Collect landline delivery authorized by addressee withinmiles. (If no number, authorization is unlimited.)
- HXB**—(Followed by number.) Cancel message if not delivered withinhours of filing time; service originating station.
- HXC**—Report date and time of delivery (TOD) to originating station.
- HXD**—Report to originating station the identify of station from which received, plus date and time. Report identity of station to which relayed, plus date and time, or if delivered report date, time and method of delivery.
- HXE**—Delivering station get reply from addressee, originate message back.
- HXF**—(Followed by number.) Hold delivery until.....(date).
- HXG**—Delivery by mail or landline toll call not required. If toll or other expense involved, cancel message and service originating station.

For further information on traffic handling, consult the *Public Service Communications Manual* or *The ARRL Operating Manual*, both published by the ARRL.

Table 7.84
A Simple NTS Formal Message

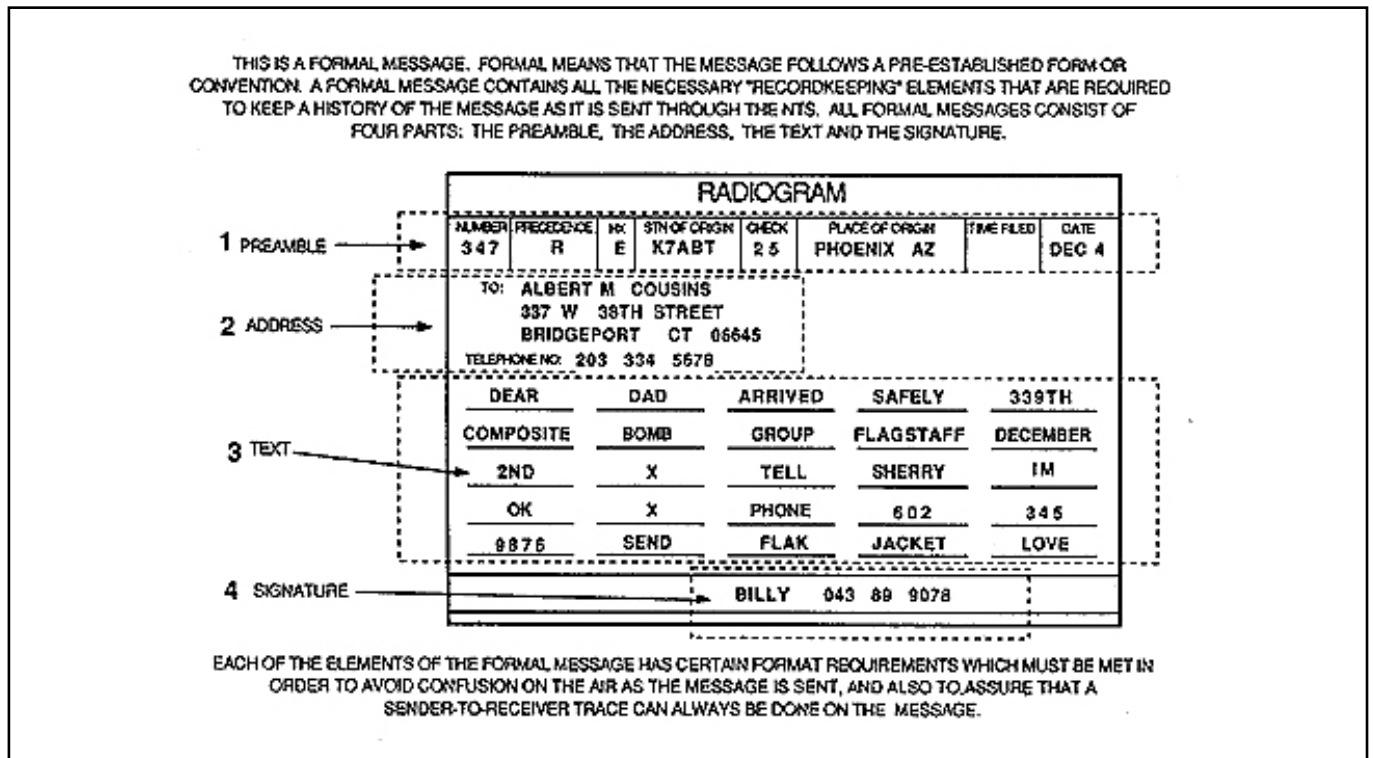

Table 7.85
Handling Instructions

HXA—(Followed by number.) Collect landline delivery authorized by addressee within ____ miles. (If no number, authorization is unlimited.)

HXB—(Followed by number.) Cancel messages if not delivered within ____ hours of filing time; service originating station.

HXC—Report date and time of delivery (TOD) to originating station.

HXD—Report to originating station the identity of station from which received, plus date and time. Report identity of station to which relayed, plus date and time, or if delivered report date, time and method of delivery.

HXE—Delivering station get reply from addressee, originate message back.

HXF—(Followed by number.) Hold delivery until ____ (date).

HXG—Delivery by mail or landline toll call not required. If toll or other expense involved, cancel message and service originating station.

An HX prosign (when used) will be inserted in the message preamble before the station of origin, thus: NR 207 R HXA50 W1AW 12...(etc). If more than one HX prosign is used they can be combined if no numbers are to be inserted; otherwise the HX should be repeated, thus: NR 207 R HXAC W1AW... (etc), but: NR 207 R HXA50 HXC W1AW...(etc). On phone, use phonetics for the letter or letters following the HX, to ensure accuracy.

Table 7.86**ARL Numbered Radiograms**

The letters ARL are inserted in the preamble in the check and in the text before spelled out numbers, which represent texts from this list. Note that some ARL texts include insertion of numerals. *Example:* NR 1 R W1AW ARL 5 NEWINGTON CONN DEC 25 DONALD R SMITH AA 164 EAST SIXTH AVE AA NORTH RIVER CITY MO AA PHONE 733 3968 BT ARL FIFTY ARL SIXTY ONE BT DIANA AR.

Group One—For possible “Relief Emergency” Use

ONE	Everyone safe here. Please don't worry.	TWENTY SIX	Help and care for evacuation of sick and injured from this location needed at once.
TWO	Coming home as soon as possible.		
THREE	Am in _____ hospital. Receiving excellent care and recovering fine.		Emergency/priority messages originating from official sources must carry the signature of the originating official.
FOUR	Only slight property damage here. Do not be concerned about disaster reports.		<i>Group Two—Routine messages</i>
FIVE	Am moving to new location. Send no further mail or communication. Will inform you of new address when relocated.	FORTY SIX	Greetings on your birthday and best wishes for many more to come.
SIX	Will contact you as soon as possible.	FIFTY	Greetings by Amateur Radio.
SEVEN	Please reply by Amateur Radio through the amateur delivering this message. This is a free public service.	FIFTY ONE	Greetings by Amateur Radio. This message is sent as a free public service by ham radio operators here at _____. Am having a wonderful time.
EIGHT	Need additional _____ mobile or portable equipment for immediate emergency use.	FIFTY TWO	Really enjoyed being with you. Looking forward to getting together again.
NINE	Additional _____ radio operators needed to assist with emergency at this location.	FIFTY THREE	Received your _____. It's appreciated; many thanks.
TEN	Please contact _____. Advise to standby and provide further emergency information, instructions or assistance.	FIFTY FOUR	Many thanks for your good wishes.
ELEVEN	Establish Amateur Radio emergency communications with _____ on _____ MHz.	FIFTY FIVE	Good news is always welcome. Very delighted to hear about yours.
TWELVE	Anxious to hear from you. No word in some time. Please contact me as soon as possible.	FIFTY SIX	Congratulations on your _____, a most worthy and deserved achievement.
THIRTEEN	Medical emergency situation exists here.	FIFTY SEVEN	Wish we could be together.
FOURTEEN	Situation here becoming critical. Losses and damage from _____ increasing.	FIFTY EIGHT	Have a wonderful time. Let us know when you return.
FIFTEEN	Please advise your condition and what help is needed.	FIFTY NINE	Congratulations on the new arrival. Hope mother and child are well.
SIXTEEN	Property damage very severe in this area.	*SIXTY	Wishing you the best of everything on _____.
SEVENTEEN	REACT communications services also available. Establish REACT communications with _____ on channel _____.	SIXTY ONE	Wishing you a very merry Christmas and a happy New Year.
EIGHTEEN	Please contact me as soon as possible at _____.	*SIXTY TWO	Greetings and best wishes to you for a pleasant _____ holiday season.
NINETEEN	Request health and welfare report on _____. (State name, address and telephone number.)	SIXTY THREE	Victory or defeat, our best wishes are with you. Hope you win.
TWENTY	Temporarily stranded. Will need some assistance. Please contact me at _____.	SIXTY FOUR	Arrived safely at _____.
TWENTY ONE	Search and Rescue assistance is needed by local authorities here. Advise availability.	SIXTY FIVE	Arriving _____ on _____. Please arrange to meet me there.
TWENTY TWO	Need accurate information on the extent and type of conditions now existing at your location. Please furnish this information and reply without delay.	SIXTY SIX	DX QSLs are on hand for you at the _____ QSL Bureau. Send _____ self-addressed envelopes.
TWENTY THREE	Report at once the accessibility and best way to reach your location.	SIXTY SEVEN	Your message number _____ undeliverable because of _____. Please advise.
TWENTY FOUR	Evacuation of residents from this area urgently needed. Advise plans for help.	SIXTY EIGHT	Sorry to hear you are ill. Best wishes for a speedy recovery.
TWENTY FIVE	Furnish as soon as possible the weather conditions at your location.	SIXTY NINE	Welcome to the _____. We are glad to have you with us and hope you will enjoy the fun and fellowship of the organization.

* Can be used for all holidays.

Note: ARL numbers should be spelled out at all times.

Table 7.87

How to be the Kind of Net Operator the Net Control Station (NCS) Loves

As a net operator, you have a duty to be self-disciplined. A net is only as good as its worst operator. You can be an exemplary net operator by following a few easy guidelines.

- 1) *Zero beat the NCS.* The NCS doesn't have time to chase all over the band for you. Make sure you're on frequency, and you will never be known at the annual net picnic as "old so-and-so who's always off frequency."
- 2) *Don't be late.* There's no such thing as "fashionably late" on a net. Liaison stations are on a tight timetable. Don't hold them up by checking in 10 minutes late with three pieces of traffic.
- 3) *Speak only when spoken to by the NCS.* Unless it is a bona fide emergency situation, you don't need to "help" the NCS unless asked. If you need to contact the NCS, make it brief. Resist the urge to help clear the frequency for the NCS or to "advise" the NCS. The NCS, not you, is boss.
- 4) Unless otherwise instructed by the NCS, *transmit only to*

the NCS. Side comments to another station in the net are out of order.

- 5) *Stay until you are excused.* If the NCS calls you and you don't respond because you're getting a "cold one" from the fridge, the NCS may assume you've left the net, and net business may be stymied. If you need to leave the net prematurely, contact the NCS and simply ask to be excused (QNX PSE ON CW).
 - 6) *Be brief when transmitting to the NCS.* A simple "yes" (C) or "no" (N) will usually suffice. Shaggy dog tales only waste valuable net time.
 - 7) *Know how the net runs.* The NCS doesn't have time to explain procedure to you. After you have been on the net for a while, you should already know these things.
-

Table 7.88

Checking Your Message

Traffic handlers don't have to dine out to fight over the check! Even good ops find much confusion when counting up the text of a message. You can eliminate some of this confusion by remembering these basic rules:

- 1) Punctuation ("X-rays," "Querys") count separately as a word.
- 2) Mixed letter-number groups (1700Z, for instance) count as one word.
- 3) Initial or number groups count as one word if sent together, two if sent separately.
- 4) The signature does not count as part of the text, but any closing lines, such as "Love" or "Best wishes" do.

Here are some examples:

- Charles J McClain—3 words
- W B Stewart—3 words
- St Louis—2 words
- 3 PM—2 words

- SASE—1 word
- ARL FORTY SIX—3 words
- 2N1601—1 word
- Seventy-three—2 words
- 73—1 word

Telephone numbers count as 3 words (area code, prefix, number), and ZIP codes count as one, ZIP + 4 codes count as two words. Canadian postal codes count as two words (first three characters, last three characters.)

Although, it is improper to change the text of a message, you may change the check. Always do this by following the original check with a slash bar, then the corrected check. On phone, use the words "corrected to."

Table 7.89

Tips on Handling NTS Traffic by Packet Radio

Listing Messages

- After logging on to your local NTS-supported bulletin board, type the command LT, meaning List Traffic. The BBS will sort and display an index of all NTSXX traffic awaiting delivery.

Receiving Messages

- To take a message off the Bulletin Board for telephone delivery to the third party, or for relay to a NTS Local or Section Net, type the R command, meaning Read Traffic, and the message number. R 188 will cause the BBS to find the BBS message number 188. This RADIOGRAM will look like any other, with preamble, address, text and signature; only some additional packet-related message header information is added. This information includes the routing path of the message for auditing purposes; e.g., to discern any excessive delays in the system.
- After the message is saved to the printer or disk, the message should be KILLED by using the KT command, meaning Kill Traffic, and the message number. In the above case, at the BBS prompt, type KT 188. This prevents the message from being delivered twice. Some of the newer BBS software requires use of K rather than KT.
- At the time the message is killed, many BBSs will automatically send a message back to the station in the FROM field with information on who took the traffic, and when it was taken!

Delivering or Relaying A Message

- A downloaded RADIOGRAM should, of course, be handled expeditiously in the traditional way: telephone delivery, or relay to another net.

Sending Messages

- To send a RADIOGRAM, use the ST command meaning Send Traffic. The BBS will prompt you for the NTS routing

(0611@NTSCT, for example), the message title which should contain the city in the address of the RADIOGRAM (QTC 1 Dayton), and the text of the message in RADIOGRAM format. The BBS, usually within the hour, will check its outgoing mailpouch, find the NTSCT message and automatically forward it to the next packet station in line to the NTSCT node. Note: Some states have more than one ARRL Section. If you do not know the destination ARRL Section (“Is San Angelo in the ARRL North, South or West Texas Section?”), then simply use the state designator NTSTX.

*Note: While NTS/packet radio message forwarding is evolving rapidly, there are still some gaps. When uploading an NTS message destined for a distant state, use handling instruction “HXC” to ask the delivering station to report back to you the date and time of delivery.

We Want You!

Local and Section BBSs need to be checked daily for NTS traffic. SYSOPs and STMs can't do it alone. They need your help to clear NTS RADIOGRAMs every day, seven days a week, for delivery and relay. If you are a traffic handler/packeteer, contact your Section Traffic Manager or Section Manager for information on existing NTS/packet procedures in your Section.

If you are a packeteer, and know nothing of NTS traffic handling, contact ARRL HQ, your Section Manager or Section Traffic Manager for information on how you can put your packet radio gear to use in serving the public in routine times, but especially in time of emergency!

And, if you enjoy phone/CW traffic handling, but aren't on packet yet, discover the incredible speed and accuracy of packet radio traffic handling. You probably already have a small computer and 2-meter rig; all you need is a packet radio “black box” to connect between your 2-meter rig and computer. For more information on packet radio, see *Practical Packet Radio*, published by the ARRL.

Chapter 8

Circuit Construction

Home construction of electronics projects can be a fun part of Amateur Radio. Some folks have said that hams don't build things nowadays; this just isn't so! An ARRL survey shows that 53% of active hams build some electronic projects. When you go to any ham flea market, you see row after row of dealers selling electronic components; people are leaving those tables with bags of parts. They must be doing something with them.

Even experienced constructors will find valuable tips in this chapter. It discusses tools and their uses, electronic construction techniques, tells how to turn a schematic into a working circuit and then summarizes common mechanical construction practices. This chapter was written by Ed Hare, W1RFI, and includes material contributions from Bruce Hale, KB1MW, Ian White, G3SEK, and Chuck Adams, K7QO.

SHOP SAFETY

All the fun of building a project will be gone if you get hurt. To make sure this doesn't happen, let's first review some safety rules.

- Read the manual! The manual tells all you need to know about the operation and safety features of the equipment you are using.
- Do not work when you are tired. You will be more likely to make a mistake or forget an important safety rule.
- Never disable any safety feature of any tool. If you do, sooner or later someone will make the mistake the safety feature was designed to prevent.
- Never fool around in the shop. Practical jokes and horseplay are in bad taste at social events; in a shop they are downright dangerous. A work area is a dangerous place at all times; even hand tools can hurt someone if they are misused.
- Keep your shop neat and organized. A

messy shop is a dangerous shop. A knife left laying in a drawer can cut someone looking for another tool; a hammer left on top of a shelf can fall down at the worst possible moment; a sharp tool left on a chair can be a dangerous surprise for the weary constructor who sits down.

- Wear the proper safety equipment. Wear eye-protection goggles when working with chemicals or tools. Use earplugs or earphones when working near noise. If you are working with dangerous chemicals, wear the proper protective clothing.
- Make sure your shop is well ventilated. Paint, solvents, cleaners or other chemicals can create dangerous fumes. If you feel dizzy, get into fresh air immediately, and seek medical help if you do not recover quickly.
- Get medical help when necessary. Every workshop should contain a good first-aid kit. Keep an eye-wash kit near any dangerous chemicals or power tools that can create chips. If you become injured, apply first aid and then seek medical help if you are not sure that you are okay. Even a small burn or scratch on your eye can develop into a serious problem.
- Respect power tools. Power tools are not forgiving. A drill can go through your hand a lot easier than metal. A power saw can remove a finger with ease. Keep away from the business end of power tools. Tuck in your shirt, roll up your sleeves and remove your tie before using any power tool. If you have long hair, tie it back so it can't become entangled in power equipment.
- Don't work alone. Have someone nearby who can help if you get into trouble when working with dangerous equipment, chemicals or voltages.
- Think! Pay attention to what you are doing. No list of safety rules can cover

all possibilities. Safety is always your responsibility. You must think about what you are doing, how it relates to the tools and the specific situation at hand.

TOOLS AND THEIR USES

All electronic construction makes use of tools, from mechanical tools for chassis fabrication to the soldering tools used for circuit assembly. A good understanding of tools and their uses will enable you to perform most construction tasks.

While sophisticated and expensive tools often work better or more quickly than simple hand tools, with proper use, simple hand tools can turn out a fine piece of equipment. **Table 8.1** lists tools indispensable for construction of electronic equipment. These tools can be used to perform nearly any construction task. Add tools to your collection from time to time, as finances permit.

Sources of Tools

Radio-supply houses, mail-order stores and most hardware stores carry the tools required to build or service Amateur Radio equipment. Bargains are available at ham flea markets or local neighborhood sales, but beware! Some flea-market bargains are really shoddy imports that won't work very well or last very long. Some used tools are offered for sale because the owner is not happy with their performance.

There is no substitute for quality! A high-quality tool, while a bit more expensive, will last a lifetime. Poor quality tools don't last long and often do a poor job even when brand new. You don't need to buy machinist-grade tools, but stay away from cheap tools; they are not the bargains they might appear to be.

Care of Tools

The proper care of tools is more than a matter of pride. Tools that have not been cared for properly will not last long or

Table 8.1**Recommended Tools and Materials****Simple Hand Tools****Screwdrivers**

Slotted, 3-inch, 1/8-inch blade
 Slotted, 8-inch, 1/8-inch blade
 Slotted, 3-inch, 3/16-inch blade
 Slotted, stubby, 1/4-inch blade
 Slotted, 4-inch, 1/4-inch blade
 Slotted, 6-inch, 5/16-inch blade
 Phillips, 2 1/2-inch, #0 (pocket clip)
 Phillips, 3-inch, #1
 Phillips, stubby, #2
 Phillips, 4-inch, #2
 Phillips, 4-inch, #2
 Long-shank screwdriver with holding clip on blade
 Jeweler's set
 Right-angle, slotted and Phillips

Pliers, Sockets and Wrenches

Long-nose pliers, 6- and 4-inch
 Diagonal cutters, 6- and 4-inch
 Channel-lock pliers, 6-inch
 Slip-joint pliers
 Locking pliers (Vise Grip or equivalent)
 Socket nut-driver set, 1/16- to 1/2-inch
 Set of socket wrenches for hex nuts
 Allen (hex) wrench set
 Wrench set
 Adjustable wrenches, 6- and 10-inch
 Tweezers, regular and reverse-action
 Retrieval tool/parts holder, flexible claw
 Retrieval tool, magnetic

Cutting and Grinding Tools

File set consisting of flat, round, half-round, and triangular. Large and miniature types recommended
 Burnishing tool
 Wire strippers
 Wire crimper
 Hemostat, straight
 Scissors
 Tin shears, 10-inch
 Hacksaw and blades
 Hand nibbling tool (for chassis-hole cutting)
 Scratch awl or scribe (for marking metal)
 Heavy-duty jackknife
 Knife blade set (X-ACTO or equivalent)
 Machine-screw taps, #4-40 through #10-32 thread
 Socket punches, 1/2 in, 5/8 in, 3/4 in, 1 1/8 in, 1 1/4 in, and 1 1/2 in
 Tapered reamer, T-handle, 1/2-inch maximum width
 Deburring tool

Miscellaneous Hand Tools

Combination square, 12-inch, for layout work
 Hammer, ball-peen, 12-oz head
 Hammer, tack
 Bench vise, 4-inch jaws or larger
 Center punch
 Plastic alignment tools
 Mirror, inspection
 Flashlight, penlight and standard
 Magnifying glass
 Ruler or tape measure

Dental pick
 Calipers
 Brush, wire
 Brush, soft
 Small paintbrush
 IC-puller tool

Hand-Powered Tools

Hand drill, 1/4-inch chuck or larger
 High-speed drill bits, #60 through 3/8-inch diameter

Power Tools

Motor-driven emery wheel for grinding
 Electric drill, hand-held
 Drill press
 Miniature electric motor tool (Dremel or equivalent) and accessory drill press

Soldering Tools and Supplies

Soldering pencil, 30-W, 1/8-inch tip
 Soldering iron, 200-W, 5/8-inch tip
 Solder, 60/40, resin core
 Soldering gun, with assorted tips
 Desoldering tool
 Desoldering wick

Safety

Safety glasses
 Hearing protector, earphones or earplugs
 Fire extinguisher
 First-aid kit

Useful Materials

Medium-weight machine oil
 Contact cleaner, liquid or spray can
 Duco modeling cement or equivalent
 Electrical tape, vinyl plastic
 Sandpaper, assorted
 Emery cloth
 Steel wool, assorted
 Cleaning pad, Scotchbrite or equivalent
 Cleaners and degreasers
 Contact lubricant
 Sheet aluminum, solid and perforated, 16- or 18-gauge, for brackets and shielding.
 Aluminum angle stock, 1/2 x 1/2-inch x 1/4-inch-diameter round brass or aluminum rod (for shaft extensions)
 Machine screws: Round-head and flat head, with nuts to fit. Most useful sizes: 4-40, 6-32 and 8-32, in lengths from 1/4-inch to 1 1/2 inches. (Nickel-plated steel is satisfactory except in strong RF fields, where brass should be used.)
 Bakelite, Lucite, polystyrene and copper-clad PC-board scraps.
 Soldering lugs, panel bearings, rubber grommets, terminal-lug wiring strips, varnished-cambric insulating tubing, heat-shrinkable tubing
 Shielded and unshielded wire
 Tinned bare wire, #22, #14 and #12
 Enameled wire, #20 through #30

work well. Dull or broken tools can be safety hazards. Tools that are in good condition do the work for you; tools that are misused or dull are difficult to use.

Store tools in a dry place. Tools do not fit in with most living-room decors, so they are often relegated to the basement or garage. Unfortunately, many basements or garages are not good places to store tools; dampness and dust are not good for tools. If your tools are stored in a damp place, use a dehumidifier. Sometimes you can minimize rust by keeping your tools lightly oiled, but this is a second-best solution. If you oil your tools, they may not rust, but you will end up covered in oil every time you use them. Wax or silicone spray is a better alternative.

Store tools neatly. A messy toolbox, with tools strewn about haphazardly, can be more than an inconvenience. You may waste a lot of time looking for the right tool and sharp edges can be dulled or nicked by tools banging into each other in the bottom of the box. As the old adage says, every tool should have a place, and every tool should be in its place. If you must search the workbench, garage, attic and car to find the right screwdriver, you'll spend more time looking for tools than building projects.

Sharpening

Many cutting tools can be sharpened. Send a tool that has been seriously dulled to a professional sharpening service. These services can sharpen saw blades, some files, drill bits and most cutting blades. Touch up the edge of cutting tools with a whetstone to extend the time between sharpenings.

Sharpen drill bits frequently to minimize the amount of material that must be removed each time. Frequent sharpening also makes it easier to maintain the critical surface angles required for best cutting with least wear. Most inexpensive drill-bit sharpeners available for shop use do a poor job, either from the poor quality of the sharpening tool or inexperience of the operator. Also, drills should be sharpened at different angles for different applications. Commercial sharpening services do a much better job.

Intended Purpose

Don't use tools for anything other than their intended purpose! If you use a pair of wire cutters to cut sheet metal, pliers as a vise or a screwdriver as a pry bar, you ruin a good tool. Although an experienced constructor can improvise with tools, most take pride in not abusing them.

Tool Descriptions and Uses

Specific applications for tools are discussed throughout this chapter. Hand tools are used for so many different applications that they are discussed first, followed by some tips for proper use of power tools.

Soldering Iron

Soldering is used in nearly every phase of electronic construction so you'll need soldering tools. A soldering tool must be hot enough to do the job and lightweight enough for agility and comfort. A 100-W soldering gun is overkill for printed-circuit work, for example. A temperature-controlled iron works well, although the cost is not justified for occasional projects. Get an iron with a small conical or chisel tip.

You may need an assortment of soldering irons to do a wide variety of soldering tasks. They range in size from a small 25-W iron for delicate printed-circuit work to larger 100 to 300-W sizes used to solder large surfaces. Several manufacturers also sell soldering guns. Small "pencil" butane torches are also available, with optional soldering-iron tips. A small butane torch is available from the Solder-It Company. This company also sells a soldering kit that contains paste solders (in syringes) for electronics, pot metal and plumbing.

Keep soldering tools in good condition by keeping the tips well tinned with solder. Do not run them at full temperature for long periods when not in use. After each period of use, remove the tip and clean off any scale that may have accumulated. Clean an oxidized tip by dipping the hot tip in sal ammoniac (ammonium chloride) and then wiping it clean with a rag. Sal ammoniac is somewhat corrosive, so if you don't wipe the tip thoroughly, it can contaminate electronic soldering.

If a copper tip becomes pitted, file it smooth and bright and then tin it immediately with solder. Modern soldering iron tips are nickel or iron clad and should not be filed.

The secret of good soldering is to use the right amount of heat. Many people who have not soldered before use too little heat, dabbing at the joint to be soldered and making little solder blobs that cause unintended short circuits.

Solders have different melting points, depending on the ratio of tin to lead. Tin melts at 450°F and lead at 621°F. Solder made from 63% tin and 37% lead melts at 361°F, the lowest melting point for a tin and lead mixture. Called 63-37 (or eutectic), this type of solder also provides the most rapid solid-to-liquid transition and

the best stress resistance.

Solders made with different lead/tin ratios have a plastic state at some temperatures. If the solder is deformed while it is in the plastic state, the deformation remains when the solder freezes into the solid state. Any stress or motion applied to "plastic solder" causes a poor solder joint.

60-40 solder has the best wetting qualities. Wetting is the ability to spread rapidly and bond materials uniformly. 60-40 solder also has a low melting point. These factors make it the most commonly used solder in electronics.

Some connections that carry high current can't be made with ordinary tin-lead solder because the heat generated by the current would melt the solder. Automotive starter brushes and transmitter tank circuits are two examples. Silver-bearing solders have higher melting points, and so prevent this problem. High-temperature silver alloys become liquid in the 1100°F to 1200°F range, and a silver-manganese (85-15) alloy requires almost 1800°F.

Because silver dissolves easily in tin, tin bearing solders can leach silver plating from components. This problem can be greatly reduced by partially saturating the tin in the solder with silver or by eliminating the tin. Tin-silver or tin-lead-silver alloys become liquid at temperatures from 430°F for 96.5-3.5 (tin-silver), to 588°F for 1.0-97.5-1.5 (tin-lead-silver). A 15.0-80.0-5.0 alloy of lead-indium-silver melts at 314°F.

Never use acid-core solder for electrical work. It should be used only for plumbing or chassis work. For circuit construction, only use fluxes or solder-flux combinations that are labeled for electronic soldering.

The resin or the acid is a *flux*. Flux removes oxide by suspending it in solution and floating it to the top. Flux is not a cleaning agent! Always clean the work before soldering. Flux is not a part of a soldered connection—it merely aids the soldering process. After soldering, remove any remaining flux. Resin flux can be removed with isopropyl or denatured alcohol. A cotton swab is a good tool for applying the alcohol and scrubbing the excess flux away. Commercial flux-removal sprays are available at most electronic-part distributors.

The two key factors in quality soldering are time and temperature. Generally, rapid heating is desired, although most unsuccessful solder jobs fail because insufficient heat has been applied. Be careful; if heat is applied too long, the components or PC board can be damaged, the flux may be used up and surface oxidation can become a problem. The soldering-iron tip

should be hot enough to readily melt the solder without burning, charring or discoloring components, PC boards or wires. Usually, a tip temperature about 100°F above the solder melting point is about right for mounting components on PC boards. Also, use solder that is sized appropriately for the job. As the cross section of the solder decreases, so does the amount of heat required to melt it. Diameters from 0.025 to 0.040 inches are good for nearly all circuit wiring.

Here's how to make a good solder joint. This description assumes that solder with a flux core is used to solder a typical PC board connection such as an IC pin.

- Prepare the joint. Clean all conductors thoroughly with fine steel wool or a plastic scrubbing pad. Do the circuit board at the beginning of assembly and individual parts such as resistors and capacitors immediately before soldering. Some parts (such as ICs and surface-mount components) cannot be easily cleaned; don't worry unless they're exceptionally dirty.
- Prepare the tool. It should be hot enough to melt solder applied to its tip quickly (half a second when dry, instantly when wet with solder). Apply a little solder directly to the tip so that the surface is shiny. This process is called "tinning" the tool. The solder coating helps conduct heat from the tip to the joint.
- Place the tip in contact with one side of the joint. If you can place the tip on the underside of the joint, do so. With the tool below the joint, convection helps transfer heat to the joint.
- Place the solder against the joint directly opposite the soldering tool. It should melt within a second for normal PC connections, within two seconds for most other connections. If it takes longer to melt, there is not enough heat for the job at hand.
- Keep the tool against the joint until the solder flows freely throughout the joint. When it flows freely, solder tends to form concave shapes between the conductors. With insufficient heat solder does not flow freely; it forms convex shapes—blobs. Once solder shape changes from convex to concave, remove the tool from the joint.
- Let the joint cool without movement at room temperature. It usually takes no more than a few seconds. If the joint is moved before it is cool, it may take on a dull, satin look that is characteristic of a "cold" solder joint. Reheat cold joints until the solder flows freely and hold them still until cool.
- When the iron is set aside, or if it loses its shiny appearance, wipe away any dirt

with a wet cloth or sponge. If it remains dull after cleaning, tin it again.

Overheating a transistor or diode while soldering can cause permanent damage. Use a small heat sink when you solder transistors, diodes or components with plastic parts that can melt. Grip the component lead with a pair of pliers up close to the unit so that the heat is conducted away (be careful—it is easy to damage delicate component leads). A small alligator clip also makes a good heat sink.

Mechanical stress can damage components, too. Mount components so there is no appreciable mechanical strain on the leads.

Soldering to the pins of coil forms or male cable plugs can be difficult. Use a suitable small twist drill to clean the inside of the pin and then tin it with resin-core solder. While it is still liquid, clear the surplus solder from each pin with a whipping motion or by blowing through the pin from the inside of the form or plug. Watch out for flying hot solder! Next, file the nickel plate from the pin tip. Then insert the wire and solder it. After soldering, remove excess solder with a file, if necessary.

When soldering to the pins of plastic coil forms, hold the pin to be soldered with a pair of heavy pliers to form a heat sink. Do not allow the pin to overheat; it will loosen and become misaligned.

In order to remove components, you need to learn the art of desoldering—removing solder from components and PC boards so they can be separated easily. Use commercially made wicking material (braid) to soak up excess solder from a joint. Another useful tool is an air-suction solder remover. Another method is to heat the joint and “flick” the wet solder off. (Watch out for solder splashes!)

Soldering equipment gets *hot!* Be careful. Treat a soldering burn as you would any other. Handling lead or breathing soldering fumes is also hazardous. Observe these precautions to protect yourself and others:

- Properly ventilate the work area. If you can smell fumes, you are breathing them.
- Wash your hands after soldering, especially before handling food.
- Minimize direct contact with flux and flux solvents.

For more information about soldering hazards and the ways to make soldering safer, see “Making Soldering Safer,” by Brian P. Bergeron, MD, NU1N (Mar 1991 *QST*, pp 28-30) and “More on Safer Soldering,” by Gary E. Meyers, K9CZB (Aug 1991 *QST*, p 42).

Screwdrivers

For construction or repair, you need to have an assortment of screwdrivers. Each blade size is designed to fit a specific range of screw-head sizes. Using the wrong size blade usually damages the blade, the screw head or both. You may also need stubby sizes to fit into tight spaces. Right-angle screwdrivers are inexpensive and can get into tight spaces that can’t otherwise be reached.

Electric screwdrivers are relatively inexpensive. If you have a lot of screws to fasten, they can save a lot of time and effort. They come with a wide assortment of screwdriver and nut-driver bits. An electric drill can also function as an electric screwdriver, although it may be heavy and over-powered for some applications.

Keep screwdriver blades in good condition. If a blade becomes broken or worn out, replace the screwdriver. A screwdriver only costs a few dollars; do not use one that is not in perfect condition. Save old screwdrivers to use as pry bars and levers, but use only good ones on screws. Filing a worn blade seldom gives good results.

Pliers and Locking-Grip Pliers

Pliers and locking-grip pliers are used to hold or bend things. They are not wrenches! If pliers are used to remove a nut or bolt, the nut or the pliers is usually damaged. Pliers are not intended for heavy-duty applications. Use a metal brake to bend heavy metal; use a vise to hold a heavy component. To remove a nut, use a wrench or nut driver. There is one exception to this rule of thumb: To remove a nut that is stripped too badly for a wrench, use a pair of pliers, locking-grip pliers, or a diagonal cutter to bite into the nut and turn it a bit. If you do this, use an old tool or one dedicated to just this purpose; this technique is not good for the tool. If the pliers’ jaws or teeth become worn, replace the tool.

Wire Cutters

Wire cutters are primarily used to cut wires or component leads. The choice of diagonal blades (sometimes called “dikes”) or end-nip blades depends on the application. Diagonal blades are most often used to cut wires, while the end-nip blades are useful to cut off the ends of components that have been soldered into a printed-circuit board. Some delicate components can be damaged by cutting their leads with dikes. Scissors designed to cut wire can be used.

Wire strippers are handy, but you can

usually strip wires using a diagonal cutter or a knife. This is not the only use for a knife, so keep an assortment handy.

Do not use wire cutters or strippers on anything other than wire! If you use a cutter to trim a protruding screw head, or cut

a hardened-steel spring, you will usually damage the blades.

Files

Files are used for a wide range of tasks. In addition to enlarging holes and slots, they are used to remove burrs, shape metal, wood or plastic and clean some surfaces in preparation for soldering. Files are especially prone to damage from rust and moisture. Keep them in a dry place. The cutting edge of the blades can also become clogged with the material you are removing. Use file brushes (also called file cards) to keep files clean. Most files cannot be sharpened easily, so when the teeth become worn, the file must be replaced. A worn file is sometimes worse than no file at all. At best, a worn file requires more effort.

Drill Bits

Drill bits are made from carbon steel, high-speed steel or carbide. Carbon steel is more common and is usually supplied unless a specific request is made for high-speed bits. Carbon-steel drill bits cost less than high-speed or carbide types; they are sufficient for most equipment construction work. Carbide drill bits last much longer under heavy use. One disadvantage of carbide bits is that they are brittle and break easily, especially if you are using a hand-held power drill.

Twist drills are available in a number of sizes. Those listed in bold type in **Table 8.2** are the most commonly used in construction of amateur equipment. You may not use all of the drills in a standard set, but it is nice to have a complete set on hand. You should also buy several spares of the more common sizes. Although Table 8.2 lists drills down to #54, the series extends to number #80.

Specialized Tools

Most constructors know how to use common tools, such as screwdrivers, wrenches and hammers. Let's discuss other tools that are not so common.

A hand nibbling tool is shown in **Fig 8.1**. Use this tool to remove small "nibbles" of metal. It is easy to use; posi-

Fig 8.1—A nibbling tool is used to remove small sections of sheet metal.

Fig 8.2—A deburring tool is used to remove the burrs left after drilling a hole.

Fig 8.3—A socket punch is used to easily punch a hole in sheet metal.

tion the tool where you want to remove metal and squeeze the handle. The tool takes a small bite out of the metal. When you use a nibbler, be careful that you don't remove too much metal, clip the edge of a component mounted to the sheet metal or grab a wire that is routed near the edge of a chassis. Fixing a broken wire is easy, but something to avoid if possible. It is easy to remove metal but nearly impossible to put it back. Do it right the first time!

Deburring Tool

A deburring tool is just the thing to remove the sharp edges left on a hole after most drilling or punching operations. See **Fig 8.2**. Position the tool over the hole and rotate it around the hole edge to remove burrs or rough edges. As an alternative, select a drill bit that is somewhat larger than the hole, position it over the hole, and spin it lightly to remove the burr.

Socket Punches

Greenlee is the most widely known of the socket-punch manufacturers. Most socket punches are round, but they do come in other shapes. To use one, drill a pilot hole large enough to clear the bolt that runs through the punch. Then, mount the punch as shown in **Fig 8.3**, with the cutter on one side of the sheet metal and the socket on the other. Tighten the nut with a wrench until the cutter cuts all the way through the sheet metal.

Useful Shop Materials

Small stocks of various materials are used when constructing electronics equipment. Most of these are available from hardware or radio-supply stores. A representative list is shown at the end of Table 8.1.

Small parts, such as machine screws, nuts, washers and soldering lugs can be economically purchased in large quantities (it doesn't pay to buy more than a lifetime supply). For items you don't use often, many radio-supply stores or hardware stores sell small quantities and assortments.

A DELUXE SOLDERING STATION

The simple tool shown in Figs 8.4 through 8.6 can enhance the usefulness and life of a soldering iron as well as make electronic assembly more convenient. It includes a protective heat sink and a tip-cleaning sponge rigidly attached to a sturdy base for efficient one-handed operation.

Soldering-iron tips and heating elements last longer if operated at a reduced temperature when not being used. Temperature reduction is accomplished by half-wave rectification of the applied ac. D1 conducts during only one-half of the ac cycle. With current flowing only in one direction, only one electrode of the neon bulb glows. Closing S1 short-circuits the diode and applies full power to the soldering iron, igniting both bulb electrodes brightly.

The base for the unit is a 2 × 6 × 4-inch (HWD) aluminum chassis (Bud AC-431 or equivalent). A 30- or 40-W soldering iron fits neatly on the chassis top. The holder has two mounting holes in each foot. A sponge tray nests between the feet and the case. In this model, a sardine tin is used for the sponge tray.

The tray and iron holder are secured to

Fig 8.4—A compact assembly of commonly available items, this soldering station makes soldering easier. Miniature toggle switches are used because they are easy to operate.

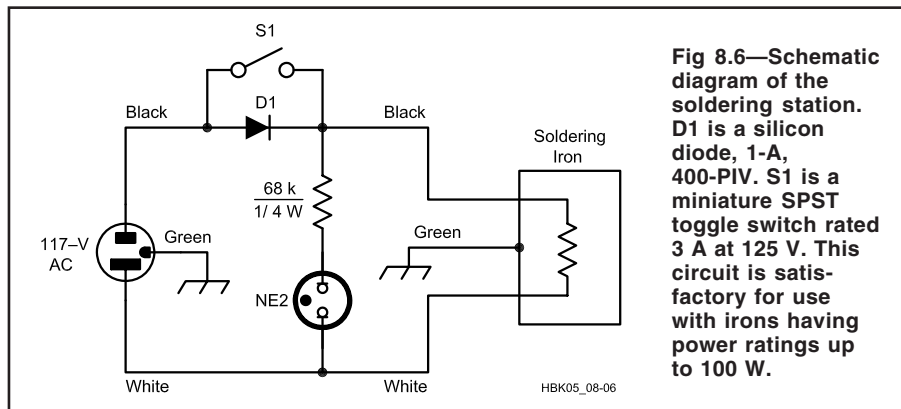

Fig 8.6—Schematic diagram of the soldering station. D1 is a silicon diode, 1-A, 400-PIV. S1 is a miniature SPST toggle switch rated 3 A at 125 V. This circuit is satisfactory for use with irons having power ratings up to 100 W.

the chassis by 6-32 × 1/2-inch pan-head machine screws and nuts, with flat washers under the screw heads (sponge tray) and lock washers under the nuts (chassis

Fig 8.5—View of the soldering-station chassis underside with the bottom plate removed. #24 hookup wire is adequate for all connections. Make sure no possibility of a short circuit exists.

underside). One of these nuts fastens a six-lug tie point strip to the chassis bottom. Use the soldering-iron holder base as a template for drilling the chassis and sponge tray. The floor of the sponge tray must be sealed around the screw heads to prevent moisture from leaking into the electrical components below the chassis. RTV compound was used for this purpose in the unit pictured.

Notice that the soldering iron and the soldering station use separate ac line cords. This ensures that the cord of the soldering iron will be long enough to do useful work. Bushings are used to anchor both cords. If these aren't available, grommets and cable clamps work well. Knotting the cords inside the chassis is a simple technique that normally provides adequate strain relief.

The underchassis assembly is shown in Fig 8.5. The neon bulb is installed in a 3/16-inch-ID grommet. The leads are insulated with spaghetti insulation or heat-shrink tubing to prevent short circuits. If you mount the bulb in a fixture or socket, use a clear lens to ensure that the electrodes are distinctly visible. Install a cover on the bottom of the chassis to prevent accidental contact with the live ac wiring. Stick-on rubber feet prevent the bottom of the unit from scratching your work surface.

SOLDERING-IRON TEMPERATURE CONTROL

A temperature control gives greater flexibility than the simple control just described. An incandescent-light dimmer can be used to control the working temperature of the tip. **Fig 8.7** shows a temperature control built into an electrical box. A dimmer and a duplex outlet are mounted in the box; the wiring diagram is shown in **Fig 8.8**. Only one of the two ac outlets is controlled by the dimmer. A jumper on the duplex outlet connects the hot terminals of both outlets together. This jumper must be removed. The hot terminal is narrower than the neutral one and its connecting screw is usually brass. Neutral terminals remain interconnected.

Fig 8.7—An incandescent-light dimmer controls soldering-iron tip temperature. Only one of the duplex outlets is connected through the dimmer.

Fig 8.8—Schematic diagram of the soldering-iron temperature control.

The dimmer shown in Fig 8.7 can be purchased at any hardware or electrical-supply store. The knob is capable of fine control of the soldering temperature.

Electronic Circuits

Most of the construction projects undertaken by the average amateur involve electronic circuitry. The circuit is the “heart” of most amateur equipment. It might seem obvious, but in order for you to build it, the circuit must work! Don’t always assume that a “cookbook” circuit that appears in an applications note or electronics magazine is flawless. These are sometimes design examples that have not always been thoroughly debugged. Many home-construction projects are “one-time” deals; the author has put one together and it worked. In some cases, component tolerances or minor layout changes might make it difficult to get a second unit working.

Protecting Components

You need to take steps to protect the electronic and mechanical components you use in circuit construction. Some components can be damaged by rough handling. Dropping a $\frac{1}{4}$ -W resistor causes no harm, but dropping a vacuum tube or other delicate subassemblies usually causes damage.

Some components are easily damaged by heat. Some of the chemicals used to clean electronic components (such as flux removers, degreasers or control-lubrication sprays) can damage plastic. Check them for safety before you use them.

Electrostatic Discharge

Some components, especially high-impedance components such as FETs and CMOS gates, can be damaged by electrostatic discharge (ESD). Protect these parts from static charges. Most people are familiar with the static charge that builds up

when one walks across a carpet then touches a metal object; the resultant spark can be quite lively. Walking across a carpet on a dry day can generate 35 kV! A worker sitting at a bench can generate voltages up to 6 kV, depending on conditions, such as when relative humidity is less than 20%.

You don’t need this much voltage to damage a sensitive electronic component; damage can occur with as little as 30 V. The damage is not always catastrophic. A MOSFET can become noisy, or lose gain; an IC can suffer damage that causes early failure. To prevent this kind of damage, you need to take some precautions.

The energy from a spark can travel inside a piece of equipment to effect internal components. Protection of sensitive electronic components involves the prevention of static build-up together with the removal of any existing charges by dissipating any energy that does build up.

Several techniques can be used to minimize static build-up. First, remove any carpet in your work areas. You can replace it with special antistatic carpet, but this is expensive. It’s less expensive to treat the carpet with antistatic spray, which is available from Chemtronics, GC Thorsen and other lines carried by electronics wholesalers.

Even the choice of clothing you wear can affect the amount of ESD. Polyester has a much greater ESD potential than cotton.

Many builders who have their workbench on a concrete floor use a rubber mat to minimize the risk of electric shocks from the ac line. Unfortunately, the rubber mat increases the risk of ESD. An antistatic rubber mat can serve both purposes.

Many components are shipped in anti-static packaging. Leave components in their conductive packaging. Other components, notably MOSFETs, are shipped with a small metal ring that temporarily shorts all of the leads together. Leave this ring in place until the device is fully installed in the circuit.

These precautions help reduce the build-up of electrostatic charges. Other techniques offer a slow discharge path for the charges or keep the components and the operator handling them at the same ground potential.

One of the best techniques is to connect the operator and the devices being handled to earth ground, or a common reference point. It is not a good idea to directly ground an operator working on electronic equipment, though; the risk of shock is too great. If the operator is grounded through a high-value resistor, ESD protection is still offered but there is no risk of shock.

The operator is usually grounded through a conductive wrist strap. 3M makes a grounding wrist band. This wrist band is equipped with a snap-on ground lead. A 1-M Ω resistor is built into the snap of the strap to protect the user should a live circuit be contacted. Build a similar resistor into any homemade ground strap.

The devices and equipment being handled are also grounded, by working on a charge-dissipating mat that is connected to ground. The mat should be an insulator that has been impregnated with a resistance material. Suitable mats and wrist straps are made by 3M, GC Electronics and others; they are available from most electronics supply houses. **Fig 8.9** shows a typical ESD-safe work station.

The work area should also be grounded, directly or through a conductive mat. Use a soldering iron with a grounded tip to solder sensitive components. Most irons that have three-wire power cords are properly grounded. When soldering static-sensitive devices, use two or three jumpers to ground you, the work and the iron. If the iron does not have a ground wire in the power cord, clip a jumper from the metal part of the iron near the handle to the metal box that houses the temperature control. Another jumper connects the box to the work. Finally, a jumper goes from the box to an elastic wrist band for static grounding.

Use antistatic bags to transport susceptible components or equipment. Keep your workbench free of objects such as paper, plastic and other static-generating items. Use conductive containers with a dissipative surface coating for equipment storage.

All of the antistatic products described above are available from Newark Electronics and other suppliers.

Electronics Construction Techniques

Several different point-to-point wiring techniques or printed-circuit boards (PC boards) can be used to construct electronic circuits. Most circuit projects use a combination of techniques. The selection of techniques depends on many different factors and builder preferences.

The simple audio amplifier shown in Fig 8.10 will be built using various point-to-point or PC-board techniques. This shows how the different construction methods are applied to a typical circuit.

Point-to-Point Techniques

Point-to-point techniques include all circuit construction techniques that rely on tie points and wiring, or component leads, to build a circuit. This is the technique used in most home-brew construction projects. It is sometimes used in commercial construction, such as old vacuum-tube receivers and modern tube amplifiers.

Point-to-point is also used to connect the “off-board” components used in a printed-circuit project. It can be used to interconnect the various modules and printed-circuit boards used in more complex electronic systems. Most pieces of electronic equipment have at least some point-to-point wiring.

Ground-Plane Construction

A point-to-point construction technique that uses the leads of the components as tie points for electrical connections is known as “ground-plane construction,” “dead-bug” or

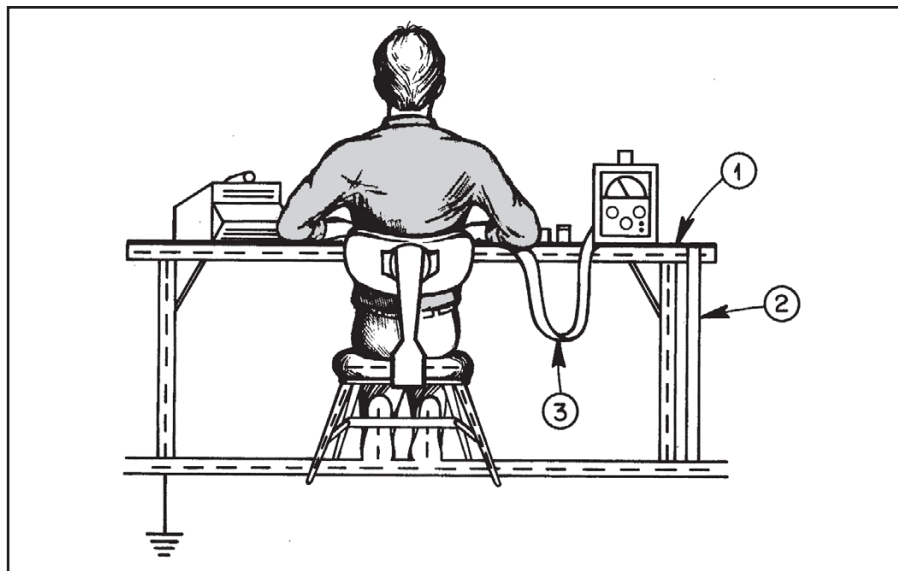

Fig 8.9—A work station that has been set up to minimize ESD features (1) a grounded dissipative work mat and (2) a wrist strap that (3) grounds the worker through high resistance.

Fig 8.10—Schematic diagram of the audio amplifier used as a design example of various construction techniques.

Fig 8.11—The example audio amplifier of Fig 8.10 built using ground-plane construction.

“ugly construction.” (The term “ugly construction” was coined by Wes Hayward, W7ZOI.) “Dead-bug construction” gets its name from the appearance of an IC with its leads sticking up in the air. In most cases, this technique uses copper-clad circuit-board material as a foundation and ground plane on which to build a circuit using point-to-point wiring, so in this chapter it is called “ground-plane construction.” An example is shown in Fig 8.11.

Ground-plane construction is quick and simple: You build the circuit on an unetched piece of copper-clad circuit board. Wherever a component connects to ground, you solder it to the copper board. Ungrounded connections between components are made point-to-point. Once you learn how to build with a ground-plane board, you can grab a piece of circuit board and start building any time you see an interesting circuit.

A PC board has strict size limits; the components must fit in the space allotted. Ground-plane construction is more flexible; it allows you to use the parts on hand. The circuit can be changed easily—a big help when you are experimenting. The greatest virtue of ground-plane construction is that it is fast.

Ground-plane construction is something like model building, connecting parts using solder almost—but not exactly—like glue. In ground-plane construction you build the circuit directly from the schematic, so it can help you get familiar with a circuit and how it works. You can build subsections of a large circuit on small ground-plane modules and string them together into a larger design.

Circuit connections are made directly, minimizing component lead length. Short lead lengths and a low-impedance ground conductor help prevent circuit instability.

There is usually less intercomponent capacitive coupling than would be found between PC-board traces, so it is often better than PC-board construction for RF, high-gain or sensitive circuits.

Use circuit components to support other circuit components. Start by mounting one component onto the ground plane, building from there. There is really only one two-handed technique to mount a component to the ground plane. Bend one of the component leads at a 90° angle, and then trim off the excess. Solder a blob of solder to the board surface, perhaps about 0.1 inch in diameter, leaving a small dome of solder. Using one hand, hold the component in place on top of the soldered spot and reheat the component and the solder. It should flow nicely, soldering the component securely. Remove the iron tip and hold the component perfectly still until the solder cools. You can then make connections to the first part.

Connections should be mechanically secure before soldering. Bend a small hook in the lead of a component, then “crimp” it to the next component(s). Do not rely only on the solder connections to provide mechanical strength; sooner or later one of these connections will fail, resulting in a dead circuit.

In most cases, each circuit has enough grounded components to support all of the components in the circuit. This is not always possible, however. In some circuits, high-value resistors can be used as standoff insulators. One resistor lead is soldered to the copper ground plane; the other lead is used as a circuit connection point. You can use 1/4- or 1/2-W resistors in values from 1 to 10 MΩ. Such high-value resistors permit almost no current to flow, and in low-impedance circuits they act more like insulators than resistors. As a rule of thumb, resistors used as standoff insulators should have a value that is at least 10 times the circuit impedance at that circuit point.

Fig 8.12A shows how to use the standoff technique to wire the circuit shown at Fig 8.12C. Fig 8.12B shows how the resistor leads are bent before the standoff component is soldered to the ground plane. Components E1 through E5 are resistors that are used as standoff insulators. They do not appear in the schematic diagram. The base circuitry at Q1 of Fig 8.12A has been stretched out to reduce clutter in the drawing. In a practical circuit, all of the signal leads should be kept as short as possible. E4 would, therefore, be placed much closer to Q1 than the drawing indicates.

No standoff posts are required near R1 and R2 of Fig 8.12. These two resistors serve two purposes: They are not only the normal circuit resistances, but function as standoff posts as well. Follow this prac-

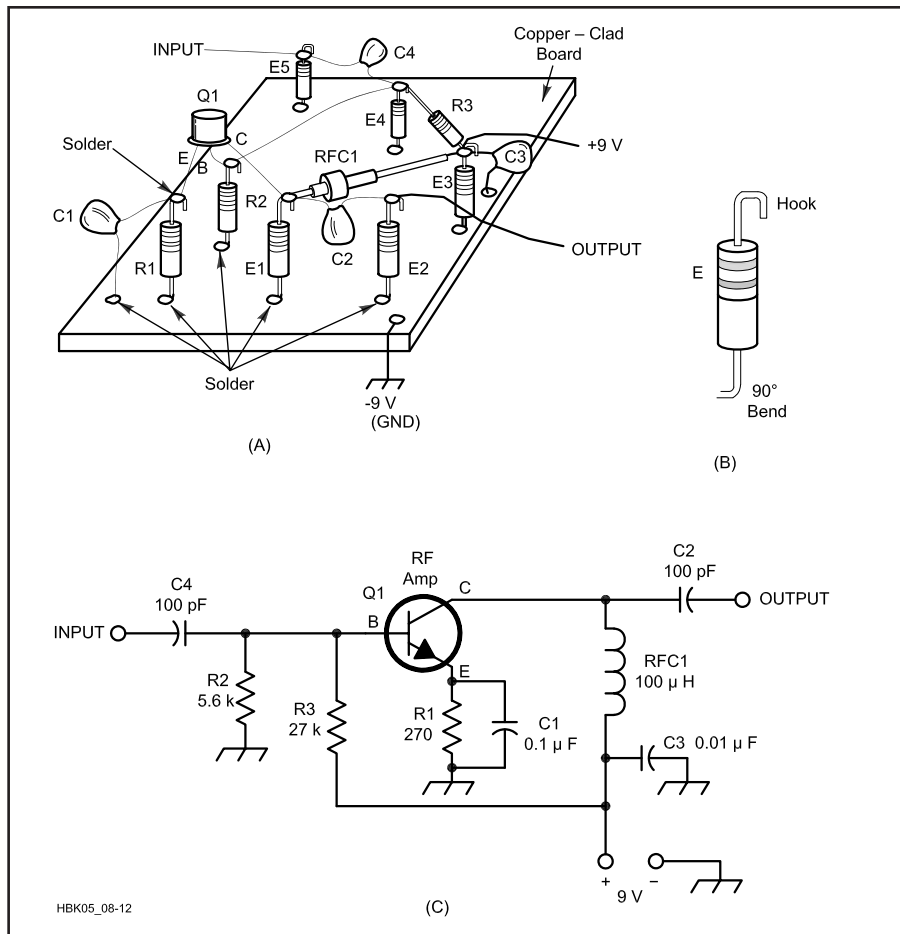

Fig 8.12—Pictorial view of a circuit board that uses ground-plane construction is shown at A. A close-up view of one of the standoff resistors is shown at B. Note how the leads are bent. The schematic diagram at C shows the circuit displayed at A.

Fig 8.13—The audio amplifier built using wired-traces construction.

tice wherever a capacitor or resistor can be employed in the dual role.

Wired Traces—the Lazy PC Board

If you already have a PC-board design, but don't want to copy the entire circuit—or you don't want to make a double-sided PC board—then the easiest construction technique is to use a bare board (or

perfboard) and hard-wire the traces.

Drill the necessary holes in a piece of single-sided board, remove the copper ground plane from around the holes, and then wire up the back using component leads and bits of wire instead of etched traces (Fig 8.13).

To transfer an existing board layout, make a 1:1 photocopy and tape it to your

piece of PC board. Prick through the holes with an automatic (one-handed) center punch or by firm pressure with a sharp scribe, remove the photocopy and drill all the holes. Holes for ground leads are optional—you generally get a better RF ground by bending the component lead flat to the board and soldering it down. Remove the copper around the rest of the holes by pressing a drill bit lightly against the hole and twisting it between your fingers. A drill press can also be used, but either way, don't remove too much board material. Then wire up the circuit beneath the board. The results look very neat and tidy—from the top, at least!

Circuits that contain components originally designed for PC-board mounting are good candidates for this technique. Wired traces would also be suitable for circuits involving multipin RF ICs, double-balanced mixers and similar components. To bypass the pins of these components to ground, connect a miniature ceramic capacitor on the bottom of the board directly from the bypassed pin to the ground plane.

A wired-trace board is fairly sturdy, even though many of the components are only held in by their bent leads and blobs of solder. A drop of cyanoacrylate “super glue” can hold down any larger components, components with fragile leads or wires that might move.

Perforated Construction Board

A simple approach to circuit building uses a perforated board (perfboard). Perfboard is available with many different hole patterns. Choose the one that suits your needs. Perfboard is usually unclad, although it is made with pads that facilitate soldering.

Circuit construction on perforated board is easy. Start by placing the components loosely on the board and moving them around until a satisfactory layout is obtained. Most of the construction techniques described in this chapter can be applied to perfboard. The audio amplifier of Fig 8.10 is shown constructed with this technique in Fig 8.14.

Perfboard and accessories are widely available. Accessories include mounting hardware and a variety of connection terminals for solder and solderless construction.

Terminal and Wire

A perfboard is usually used for this technique (Fig 8.15). Push terminals are inserted into the hole in a perfboard. Components can then be easily soldered to the terminals. As an alternative, drill holes into a bare or copper-clad board wherever they are needed. The compo-

nents are usually mounted on one side of the board and wires are soldered to the bottom of the board, acting as wired PC-board “traces.” If a component has a reasonably rigid lead to which you can attach other components, use that instead of a push terminal, a modification of the ground-plane construction technique.

If you are using a bare board to provide a ground plane, drill holes for your terminals with a high-speed PC-board drill and drill press. Mark the position of the hole with a center punch to prevent the drill from skidding. The hole should provide a snug fit for the push terminal.

Mount RF components on top of the

board, keeping the dc components and much of the interconnecting wiring underneath. Make dc feed-through connections with terminals having bypass capacitors on top of the board. Use small solder-in feedthrough capacitors for more critical applications.

Solderless Prototype Board

One construction alternative that works well for audio and digital circuits is the solderless prototype board (proto-board), shown in Fig 8.16. It is usually not suitable for RF circuits.

A proto-board has rows of holes with spring-loaded metal strips inside the board. Circuit components and hookup wire are inserted into the holes, making contact with the metal strips. Components that are inserted into the same row are connected together. Component and interconnection changes are easy to make.

Proto-boards have some minor disadvantages. The boards are not good for building RF circuits; the metal strips add too much stray capacitance to the circuit.

Fig 8.14—The audio amplifier built on perforated board. Top view at A; bottom view at B.

Fig 8.16—The audio amplifier built on a solderless prototyping board.

Fig 8.15—The audio amplifier built using terminal-and-wire construction.

Fig 8.17—The audio amplifier built using wire-wrap techniques.

Large component leads can deform the metal strips.

Wire Wrap

Wire-wrap techniques can be used to quickly construct a circuit without solder. Low- and medium-speed digital circuits are often assembled on a wire-wrap board. The technique is not limited to digital circuits, however. **Fig 8.17** shows the audio amplifier built using wire wrap. Circuit changes are easy to make, yet the method is suitable for permanent assemblies.

Wire wrap is done by wrapping a wire around a small square post to make each connection. A wrapping tool resembles a thick pencil. Electric wire-wrap guns are convenient when many connections must be made. The wire is almost always #30 wire with thin insulation. Two wire-wrap methods are used: the standard and the modified wrap (**Fig 8.18**). The modified wrap is more secure. The wrap-post termi-

Fig 8.18—Wire-wrap connections. Standard wrap is shown at A; modified wrap at B.

nals are square (wire wrap works only on posts with sharp corners). They should be long enough for at least two connections. **Fig 8.18** and **Fig 8.19** show proper and improper wire-wrap techniques. Mount small components on an IC header plug. Insert the header into a wire-wrap IC socket as shown in **Fig 8.17**. The large capacitor in that figure has its leads soldered directly to wire-wrap posts.

Surface Mounting

Surface mounting is not new—it was an established ground-plane and professional technique for years before its appearance in consumer and amateur electronics. This technique is particularly suitable for PC-board construction, although it can be applied to many other construction techniques. Surface-mounted components take up very little space on a PC board.

Modern automated manufacturing techniques and surface-mount technology have evolved together; most modern ICs are being made specifically for this technique. Chip resistors and capacitors are common in UHF and microwave designs. Chip devices have low stray inductance and capacitance, making them excellent components to use in this frequency range. Other components, such as transistors and diode arrays are also available in this space-saving format.

Surface-mount techniques are not limited to “surface-mount” ICs, however. This technique can be used to mount standard resistors, capacitors or ICs. See the sidebar “Surface Mount Construction Techniques.”

Removing SMT Components

The surface-mount ICs used in commercial equipment are not easy for experimenters to replace. They have tiny pins designed for precision PC boards. Sooner or later, you may need to replace one, though. If you do, don’t try to get the old IC out in one piece! This will damage the

Fig 8.19—Improper wire-wrap connections. Insufficient insulation for modified wrap is shown at A; a spiral wrap at B, where there is too much space between turns; an open wrap at C, where one or more turns are improperly spaced and an overwrap at D, where the turns overlap on one or more turns.

IC beyond use anyway, and will probably damage the PC board in the process.

Although it requires a delicate touch and small tools, it’s possible to change a surface mount IC at home. To remove the old one, use small, sharp wire cutters to cut the IC pins flush with the IC. This usually leaves just enough old pin to grab with a tiny pair of needle-nose pliers or a hemostat. Heat the soldered connection with a small iron and use the pliers to gently pull the pin from the PC board. Solder in the new component using the techniques discussed in the sidebar.

Printed-Circuit Boards

Many builders prefer the neatness and miniaturization made possible by the use of etched printed-circuit boards (PC boards). Once designed, a PC board is easily duplicated, making PC boards ideal for group projects. To make a PC board, resist material is applied to a copper-clad bare PC board, which is then immersed into an acid etching bath to remove selected areas of copper. In a finished board, the conductive copper is formed into a pattern of conductors or “traces” that form the actual wiring of the circuit.

PC Board Stock

PC board stock consists of a sheet made from insulating material, usually glass epoxy or phenolic, coated with conduc-

Surface Mount Construction Techniques

“Oh no, this project uses SMT parts!” Some homebrewers recoil at the thought of assembling a kit that uses surface mount technology (SMT) components. They fear the parts are too small to see, handle, solder or debug when assembled. I had these same concerns until I tried it and found that it wasn’t so difficult when using the right tools. Further, I discovered some benefits of using SMT parts that made my QRP projects smaller, lighter and more portable for optimized field use.

I’ve chosen two quite different projects to illustrate some successful SMT assembly techniques. One is a small DDS signal generator “daughtercard” kit that comes with an assortment of SMT capacitors, resistors and inductors, and an SOIC integrated circuit. The other example circuit is a small one-stage audio amplifier built “Manhattan-style”! Yes, you *can* homebrew using SMT parts—results can sometimes be even better than when using conventional leaded parts.

But first, here is some component history and what you need to do to get your work area ready for constructing an SMT project.

What is an SMT component?

Resistors and capacitors with axial or radial leads have been most common over the years. Same too for integrated circuits arranged in dual in-line package (DIP) format with rows of leads separated by a generous 0.3 inch or so. This open-leaded component and easily accessed IC pins made for easy circuit board assembly back in the Heathkit days. Although these types of components are still available today, parts miniaturization has brought about more compact and less expensive products. Discrete components packaging has shrunk to 0.12×0.06 inches, as shown in the ‘1206’ capacitor in **Fig A** compared to a penny. Even smaller packages are common today, requiring much less pc board area for the same equivalent circuits. Integrated circuit packaging has also been miniaturized to create 10×5 mm SOIC packages with lead separations of 0.025 inches. You need some extra skills beyond what was necessary when assembling that Heath SB-104 transceiver back in 1974!

Fig A—SMT components are small. Clockwise from left: MMIC RF amp, 1206 resistor, SOIC integrated circuit, 1206 capacitor and ferrite inductor.

Fig B—A magnifying visor is great for close-up work on a circuit board. These headsets are often available for less than \$10 at hamfests and some even come with superbright LEDs mounted on the side to illuminate the components being soldered.

Fig C—This DDS Daughtercard has all interconnections on the top side. Connections to the ground plane on the backside of the board are made by the use of “vias,” wires through the PC board. Pin 28 of the SMT IC is shown being tack-soldered to hold it to the board, keeping all other pins carefully aligned on their pads. Then the other pins are carefully soldered, starting with pin 14 (opposite pin 28). Finally, pin 28 is reheated to ensure a good connection there. If you bridge solder across adjacent pads or pins, use solder wick or a vacuum solder sucker to draw off the excess solder.

Preparing for the job

The key to success with any construction project is selecting and using the proper tools. A magnifying lamp is essential for well-lighted, close-up work on the components. **Fig B** shows a convenient magnifying visor. Tweezers or fine-tipped pliers allow you to grab the small chip components with dexterity. Thinner solder (0.015 inches) than you might normally use is preferred because it melts more quickly and leaves a smaller amount of solder on the component lead. Use of a super fine-tipped soldering iron make soldering the leads of these small parts straightforward and easy. A clean work surface is of paramount importance because SMT components have a tendency to fly away even when held with the utmost care by tweezers—you’ll have the best chance of recovering your wayward part if your table is clear. When the inevitable happens, you’ll have lots of trouble finding it if the part falls onto a rug. It’s best to have your work area in a non-carpeted room, for this reason as well as to protect static-sensitive parts.

Assembling SMT parts on a PC board

The first project example is the **DDS Daughtercard**—a small module that generates precision RF signals for a variety of projects. This kit has become immensely popular in homebrew circles and is supplied with the chip components contained in color-coded packaging that makes an easy job of identifying the little parts, a nice touch by a kit supplier.

Fig C shows the DDS PC board, a typical layout for SMT components. All traces are on one side, since the component leads are not “through-hole.” The little square pads are the places where the 1206 package-style chips will eventually be soldered.

The trick to soldering surface-mount devices to PC boards is to (a) pre-solder (“tin”) one of the pads on the board where the component will ultimately go by placing a small blob of solder there; (b) carefully hold the component in place with small needle-nose pliers or sharp tweezers on the tinned pad; (c) reheat the tinned pad and component to reflow the solder onto the component lead, thus temporarily holding the component in place; and (d) solder the other end of the component to its pad. Finally, check all connections to

make sure there are no bridges or shorts. **Fig D** illustrates how to use this technique. **Fig E** shows the completed DDS board.

Homebrewing with SMT parts

The second project example is the **K8IQY Audio Amp**—a discrete component audio amplifier that is constructed “Manhattan-style.” You glue little pads to the board wherever you need to attach component leads or wires. See **Fig F**.

Instead of using little squares or dots of pcb material for pads, you might decide to create isolated connection points by cutting an “island” in the copper using an end mill. No matter how the pads are created, SMT components may be easily soldered from pad-to-pad, or from pad-to-ground plane to build up the circuit. **Fig G** shows the completed board, combining SMT and

Fig E—The fully-populated DDS Daughtercard PC board contains a mix of SMT and through-hole parts, showing how both packaging technologies can be used together.

Fig D—Attaching an SMT part. Things are a lot easier attaching capacitors, resistors and other discrete components compared to multi-pin ICs. Carefully hold the component in place and properly aligned using needle-nose pliers or tweezers and then solder one end of the component. Then reheat the joint while gently pushing down on the component with the pliers or a Q-tip stick to ensure it is lying flat on the board. Finally, solder the other side of the component.

Fig F—SMT resistors soldered to base board of the Audio Amp in the beginning stages of assembly.

Fig H—Surface mount ICs can be mounted to general-purpose carrier boards, then attached as a submodule with wires to the base board of the homebrew project.

Fig G—The completed homebrew Audio Amp assembly shows simple, effective use of SMT components used together with conventional leaded components when constructed “Manhattan-style.”

leaded components.

Homebrewing with SOIC-packaged integrated circuits is a little trickier and typically requires the use of an “SOIC carrier board” such as the one shown in **Fig H**, onto which you solder your surface mount integrated circuit. You

can then wire the carrier board onto your homebrew project, copper-clad base board or whatever you’re using to hold your other circuit components.

So start melting solder!

The techniques are easy, the SMT components are actually cheaper than conventional through-hole leaded components and you’ll have a smaller, more portable project when you’re done. Go for it!—*George Heron, N2APB.*

Full details on the DDS Daughtercard, the K8IQY Islander Audio Amp, and the Islander Pad Cutter may be found online at www.njqrp.org/dds, www.njqrp.org/islanderamp, and www.njqrp.org/islanderpadcutter, respectively. Also see: www.arri.org/tis/info/surface.html.

tive copper. Copper-clad stock is manufactured with phenolic, FR-4 fiberglass and Teflon base materials in thicknesses up to 1/8 inch. The copper thickness varies. It is usually plated from 1 to 2 oz per square foot of bare stock.

Resists

Resist is a material that is applied to a PC board to prevent the acid etchant from eating away the copper on those areas of the board that are to be used as conductors. There are several different types of resist materials, both commercial and home brew. When resist is applied to those areas of the board that are to remain as copper traces, it “resists” the acid action of the etchant.

The PC board stock must be clean before any resist is applied. This is discussed later in the chapter. After you have applied resist, by whatever means, protect the board by handling it only at its edges. Do not let it get scraped. Etch the board as soon as possible, to minimize the likelihood of oxidation, moisture or oils contaminating the resist or bare board.

Tape

To make a single PC board, Scotch, adhesive or masking tape, securely applied, makes a good resist. (Don’t use drafting tape; its glue may be too weak to hold in the etching bath.) Apply the tape to the entire board, transfer the circuit pattern by means of carbon paper, then cut out and remove the sections of tape where the copper is to be etched away. An X-Acto hobby knife is excellent for this purpose.

Resist Pens

Several electronics suppliers sell resist pens. Use a resist pen to draw PC-board artwork directly onto a bare board. Commercially available resist pens work well. Several types of permanent markers also function as resist, especially the “Sharpie” brand. They come in fine-point and regular sizes; keep two of each on hand.

Paint

Some paints are good resists. Exterior enamel works well. Nail polish is also good, although it tends to dry quickly so you must work fast. Paint the pattern onto the copper surface of the board to be etched. Use an artist’s brush to duplicate the PC board pattern onto bare PC-board stock. Tape a piece of carbon paper to the PC-board stock. Tape the PC-board pattern to the carbon paper. Trace over the original layout with a ballpoint pen. The carbon paper transfers the outline of the pattern onto the bare board. Fill in the outline with the resist paint. After paint

has been applied, allow it to dry thoroughly before etching.

Rub-On Transfer

Several companies (Kepron Circuit Systems, DATAK Corp, GC Electronics) produce rub-on transfer material that can also be used as resist. Patterns are made with various width traces and for most components, including ICs. As the name implies, the pad or trace is positioned on the bare board and rubbed to adhere to the board.

Etchant

Etchant is an acid solution that is designed to remove the unwanted copper areas on PC-board stock, leaving other areas to function as conductors. Almost any strong acid bath can serve as an etchant, but some acids are too strong to be safe for general use. Two different etchants are commonly used to fabricate prototype PC boards: ammonium persulfate and ferric chloride. The latter is the more common of the two.

Ferric chloride etchant is usually sold ready-mixed. It is made from one part ferric chloride crystals and two parts water, by volume. No catalyst is required.

Etchant solutions become exhausted as they are used. Keep a supply on hand. Dispose of the used solution safely; follow the instructions of your local environmental protection authority.

Most etchants work better if they are hot. A board that takes 45 minutes to etch at room temperature will take only a few minutes if the etchant is hot. Use a heat lamp to warm the etchant to the desired temperature. A darkroom thermometer is handy for monitoring the temperature of the bath.

Be careful! Do not heat your etchant above the recommended temperature, typically 160°F. If it gets too hot, it will probably damage the resist. Hot or boiling etchant is also a safety hazard.

Insert the board to be etched into the solution and agitate it continuously to keep fresh chemicals near the board surface. This speeds up the etching process. Normally, the circuit board should be placed in the bath with the copper side facing up.

After the etching process is completed, remove the board from the tray and wash it thoroughly with water. Use medium-grade steel wool to rub off the resist.

WARNING: Use a glass or other non-reactive container to hold etching chemicals. Most etchants will react with a metal container. Etchant is caustic and can burn eyes or skin easily. Use rubber gloves and wear old clothing, or a lab smock, when working with any chemicals. If you get

some on your skin, wash it with soap and cold water. Wear safety goggles (the kind that fit snugly on your face) when working with any dangerous chemicals. Read the safety labels and follow them carefully. If you get etchant in your eyes, wash immediately with large amounts of cool water and seek immediate medical help. Even a small chemical burn on your eye can develop into a serious problem.

Planning and Layout

A PC board can be a real convenience. If you want to build a project and a ready-made PC board is available, you can assemble the project quickly and expect it to work. This is true because someone else has done most of the real work involved—designing the PC board layout and fixing any “bugs” caused by intertrace capacitive coupling, ground loops and similar problems. In most cases, if a ready-made board is not available, ground-plane construction is a lot less work than designing, debugging and then making a PC board.

A later section of this chapter explains how to turn a schematic into a working circuit. It is not as simple as laying out the PC board just like the circuit is drawn on the schematic. Read that section before you design a PC board.

Rough Layout

Start by drawing a rough scale pictorial diagram of the layout. Draw the interconnecting leads to represent the traces that are needed on the board. Rearrange the layout as necessary to find an arrangement that completes all of the circuit traces with a minimum number of jumper-wire connections. In some cases, however, it is not possible to complete a design without at least a few jumpers.

Layout

After you have completed a rough layout, redraw the physical layout on a grid. Graph paper works well for this. Most IC pins are on 0.1-inch centers. Use graph paper that has 10 lines per inch to draw artwork at 1:1 and estimate the distance halfway between lines for 0.05-inch spacing. Drafting templates are helpful in the layout stage. Local drafting-supply stores should be able to supply them. The templates usually come in either full-scale or twice normal size.

To lay out a double-sided board, ensure that the lines on both sides of the paper line up (hold the paper up to the light). You can then use each side of the paper for each side of the board.

When using graph paper for a PC-board layout, include bolt holes, notches for wires and other mechanical consider-

ations. Fit the circuit into and around these, maintaining clearance between parts.

Most modern components have leads on 0.1-inch centers. The rows of dual-inline-package (DIP) IC pins are spaced 0.3 or 0.4 inch. Measure the spacing for other components. Transfer the dimensions to the graph paper. It is useful to draw a schematic symbol of the component onto the layout.

Most IC specification sheets show a top view of the pin locations. If you are designing the “foil” side of a PC board, be sure to invert the pin out.

Draw the traces and pads the way they will look. Using dots and lines is confusing. It’s okay to connect more than one lead per pad, or run a lead through a pad, although using more than two creates a complicated layout. In that case, there may be problems with solder bridges that form short circuits. Traces can run under some components; it is possible to put two or three traces between 0.4-inch centers for a $\frac{1}{4}$ -W resistor, for example.

Leave power-supply and other dc paths for last. These can usually run just about anywhere, and jumper wires are fine for these noncritical paths.

Do not use traces less than 0.010 inch (10 mil) wide. If 1-oz stock is used, a 10-mil trace can safely carry up to 500 mA. To carry higher current, increase the width of the traces in proportion. (A trace should be 0.200 inch to carry 10 A, for example.) Allow 0.1 inch between traces for each kilovolt in the circuit.

When doing a double-sided board, use pads on both sides of the board to connect traces through the board. Home-brew PC boards do not use plated-through holes (a manufacturing technique that has copper and tin plating inside all of the holes to form electrical connections). Use a through hole and solder the associated component to both sides of the board. Make other through-hole connections with a small piece of bus wire providing the connection through the board; solder it on both sides. This serves the same purpose as the plated-through holes found in commercially manufactured boards.

After you have planned the physical design of the board, decide the best way to complete the design. For one or two simple boards, draw the design directly onto the board, using a resist pen, paint or rub-on resist materials. To transfer the design to the PC board, draw light, accurate pencil lines at 0.1- or 0.05-inch centers on the PC board. Draw both horizontal and vertical lines, forming a grid. You only need lines on one side. For single-sided boards, use this grid to transfer the layout directly onto

the board surface. To make drilling easier, use a center punch to punch the centers of holes accurately. Do this before applying the resist so the grid is visible.

When drawing a pad with plenty of room around it, use a pad about 0.05 to 0.1 inch in diameter. For ICs, or other close quarters, make the pad as small as 0.03 inch or so. A “ring” that is too narrow invites soldering problems; the copper may delaminate from the heat. Pads need not be round. It’s okay to shave one or more edges if necessary, to allow a trace to pass nearby.

Draw the traces next. A drafting triangle can help. It should be spaced about 0.1 inch above the table, to avoid smudging the artwork. Use a 9-inch or larger triangle, with a rubber grommet taped to each corner (to hold it off the table). Select a sturdy triangle that doesn’t bend easily.

Align the triangle with the grid lines by eye and make straight, even traces similar to the layout drawing. The triangle can help with angled lines, too. Practice on a few pieces of scrap board.

Make sure that the resist adheres well to the PC board. Most problems can be seen by eye; there can be weak areas or bare spots. If necessary, touch up problems with additional resist. If the board is not clean the resist will not adhere properly. If necessary, remove the resist, clean the board and start from the beginning.

Discard troublesome pens. Resist pens dry out quickly. Keep a few on hand, switch back and forth and put the cap back on each for a bit to give the pen a chance to recover.

Once all of the artwork on the board is drawn, check it against the original artwork. It is easy to leave out a trace. It is not easy to put copper back after a board is etched. In a pinch, replace the missing trace with a small wire.

Applied resist takes about an hour to dry at room temperature. Fifteen minutes in a 200°F oven is also adequate.

Special techniques are used to make double-sided PC boards. See the section on double-sided boards for a description.

Making a PC Board

Several techniques can be used to make PC boards. They usually start with a PC-board “pattern” or artwork. All of the techniques have one thing in common: this pattern needs to be transferred to the copper surface of the PC board. Unwanted copper is then removed by chemical or mechanical means.

Most variations in PC-board manufacturing technique involve differences in resist or etchant materials or techniques.

Cut the Board to Size

No matter what technique you use, you should determine the required size of the PC board, and then cut the board to size. Trimming off excess PC-board material can be difficult after the components are installed.

Board Preparation

The bare (unetched) PC-board stock should be clean and dry before any resist is applied. (This is not necessary if you are using stock that has been treated with presensitized photoresist.) Wear rubber gloves when working with the stock to avoid getting fingerprints on the copper surface. Clean the board with soap and water, and then scrub the board with #000 steel wool. Rinse the board thoroughly then dry it with a clean, lint-free cloth. Keep the board clean and free of fingerprints or foreign substances throughout the entire manufacturing process.

No-Etch PC Boards

The simplest way to make PC boards is to mechanically remove the unwanted copper. Use a grinding tool, such as the Moto-Tool manufactured by the Dremel Company (available at most hardware or hobby stores). Another technique is to score the copper with a strong, sharp knife, then remove unwanted copper by heating it with a soldering iron and lifting it off with a knife while it is still hot. This technique requires some practice and is not very accurate. It often fails with thin traces, so use it only for simple designs.

Photographic Process

Many magazine articles feature printed-circuit layouts. Some of these patterns are difficult to duplicate accurately by hand. A photographic process is the most efficient way to transfer a layout from a magazine page to a circuit board.

The resist ink, tape or dry-transfer processes can be time consuming and tedious for very complex circuit boards. As an alternative, consider the photo process. Not only does the accuracy improve, you need not trace the circuit pattern yourself!

A copper board coated with a light-sensitive chemical is at the heart of the photographic process. In a sense, this board becomes your photographic film.

Make a contact print of the desired pattern by transferring the printed-circuit artwork to special copy film. This film is attached to the copper side of the board and both are exposed to intense light. The areas of the board that are exposed to the light—those areas not shielded by the black portions of the artwork—undergo a chemical

Fig 8.20—PC-board materials are available from several sources. This kit is from RadioShack.

change. This creates a transparent image of the artwork on the copper surface.

Develop the PC board, using techniques and chemicals specified by the manufacturer. After the board is developed, etch it to remove the copper from all areas of the board that were exposed to the light. The result is a PC board that looks like it was made in a factory.

Kepro sells materials and supplies for all types of PC-board manufacturing. RadioShack also sells PC-board materials. See **Fig 8.20**. If you're looking for printed-circuit board kits, chemicals, tools and other materials, contact Ocean State Electronics. They carry products by Kepro and the Meadowlake Corporation.

Iron-On Resist

One company that makes an iron-on resist is the Meadowlake Corporation. Their products make an artwork positive using a standard photocopier. A clothes iron transfers the printed resist pattern to the bare PC board.

Some experimenters have reported satisfactory results using standard photocopier paper or the output from a laser printer. Apparently the toner makes a reasonable resist. Note that the artwork for this method must be reversed with respect to a normal etching pattern because the print must be placed with the toner against the copper.

To transfer the resist pattern onto the board, place the pattern on the board (image side toward the copper), and then firmly press a hot iron onto the entire surface. Use plenty of heat and even pressure. This melts the resist, which then sticks to the bare PC board. This is not a perfect process; there will probably be bad areas on the resist. The amount of heat, the cleanliness of the bare board and the "skill" of the operator may affect the outcome.

The key to making high quality boards with the photocopy techniques is to be good at retouching the transferred resist.

Double-Sided PC Boards—by Hand!

Forget those nightmares about expensive photoresists that didn't work; forget that business of fifty bucks a board! You don't need computer-aided design to make a double-sided PC board; just improve on the basics, and keep it simple. Anyone can make low-cost double-sided boards with traces down to 0.020 inch, with perfect front-to-back hole registration.

To make a double-sided board, drill the holes before applying the resist artwork; that is the only way to assure good front-to-back registration. The artwork on both sides can then be properly positioned to the holes. PC-board drilling was discussed earlier in the text.

After you have drilled the board, clean its surface thoroughly. After that, wear clean rubber or cotton gloves to keep it clean. One fingerprint can really mess up the application of resist or the etchant.

Tape the board to your work surface, making sure it can't move around. Transfer the artwork from your layout grid to the PC board, drawing by hand with a resist pen.

Allot enough time to finish at least one side of the artwork in one sitting. Start with the pads. To make a handy pad-drawing tool, press the tip of a regular-size Sharpie into one of the drilled PC-board holes. This "smoothes" the tip into the shape of the hole, leaving a flat shoulder to draw the pad. See **Fig A**. The diameter of the pad is determined by how hard the pen is pressed; pressing too hard forms a pad that is way too large for most applications. Practice on scrap board first. Use this modified pen to fill in all the holes and draw the pads at the same time. Use an unmodified resist pen to draw all of the traces and to touch up any voids or weak areas in the pads. For the rest of the drawing, the procedure described for single-sided boards applies to double-sided boards, too.

After the resist is applied to the first side, carefully draw the second side. Inspect the board thoroughly; you may have scratched or smudged the first side while you were drawing the second.

Etching a double-sided board is not much different than etching a single-sided board, except that you must ensure that the etchant is able to reach both sides of the board. If you dunk the board in and out of the etchant solution, both sides are exposed to the etchant. If you use a tray, put some spacers on the bottom and rest the board on the spacers. (The spacers must be put on the board edges, not where you want to actually etch.) This ensures that etchant gets to both sides. If you use this method, turn the board over once or twice during the process.—*Dave Reynolds, KE7QF*

Or Photo-Etched

You can also make double-sided boards at home without drawing the layout by hand. This procedure can't produce results to match the finest professionally made double-sided boards, but it can make boards that are good enough for many moderately complex projects.

Start with the same sort of artwork used for single-sided boards, but leave a margin for taping at one edge. It is critical that the patterns for the two sides are accurately sized. The chief limiting factor in this technique is the requirement that matching pads on the two sides are positioned correctly. Not only must the two sides match each other, but they must also be the correct size for the parts in the project. Slight reproduction errors can accumulate to major problems in the length of a 40-pin DIP IC. One good tool to achieve this requirement is a photocopy machine that can make reductions and enlargements in 1% steps. Perform a few experiments to arrive at settings that yield accurately sized patterns.

Choose two holes at opposite corners of the etching patterns. Tape one of the two patterns to one side of the PC board. Choose some small wire and a drill bit that closely matches the wire diameter. For example, #20 enameled wire is a close match for a #62 or a #65 drill, depending on the thickness of the wire's enamel coating. Drill through the pattern and the board at the two chosen holes. Drill the chosen holes through the second pattern. Place two pieces of the wire through the PC board and slide the second pattern down these wire "pins" to locate the pattern on the board. Tape the second pattern in position and remove the pins. From this point on, expose and process each side of the board as if it were a single-sided board, but take care when exposing each side to keep the reverse side protected from light.—*Bob Schetgen, KU7G*

Fig A—Make a permanent marker into a specialized PC-board drawing tool. Simply press the marker point into a drilled hole to form a modified point as shown. More pressure produces a wider shoulder that makes larger pads on the PC board.

Fortunately, the problems are usually easy to retouch, if you have a bit of patience. A resist pen does a good job of reinforcing any spotty areas in large areas of copper.

Double-Sided PC Boards

All of the examples used to describe the above techniques were single-sided PC boards, with traces on one side of the board and either a bare board or a ground plane on the other side. PC boards can also have patterns etched onto both sides, or even have multiple layers. Most home-construction projects use single-sided boards, although some kit builders supply double-sided boards. Multilayer boards are rare in ham construction. One method for making double-sided boards is described in the sidebar, “Double-Sided PC Boards—by Hand!”

Tin Plating

Most commercial PC boards are tin plated, to make them easier to solder. Commercial tin-plating techniques require electroplating equipment not readily available to the home constructor. Immersion tin plating solutions can deposit a thin layer of tin onto a copper PC board. Using them is easy; put some of the solution into a plastic container and immerse the board in the solution for a few minutes. The chemical action of the tin-plating solution replaces some of the copper on the board with tin. The result looks nearly as good as a commercially made board. Agitate the board or solution from time to time. When the tinning is complete, take the board out of the solution and rinse it for five minutes under running water. If you don't remove all of the residue, solder may not adhere well to the surface. Kepro sells immersion tin plating solution.

Drilling a PC Board

After you make a PC board using one of the above techniques, you need to drill holes in the board for the components. Use a drill press, or at least improvise one. Boards can be drilled entirely “free hand” with a hand-held drill but the potential for error is great. A drill press or a small Moto-Tool in an accessory drill press makes the job a lot easier. A single-sided board should be drilled after it is etched; the easiest way to do a double-sided board is to do it before the resist is applied.

To drill in straight lines, build a small movable guide for the drill press so you can slide one edge of the board against it and line up all of the holes on one grid line at a time. See **Fig 8.21**. This is similar to the “rip fence” set up by most woodworkers to cut accurately and repeatably with a table saw.

The drill-bit sizes available in hardware stores are too big for PC boards. You can use high-speed steel bits, but glass epoxy stock tends to dull these after a few hundred holes. (When your drill bit becomes worn, it makes a little “hill” around each drilled hole, as the worn bit pushes and pulls the copper rather than drilling it.) A PC-board drill bit, available from many electronic suppliers, will last for thousands of holes! If you are doing a lot of boards, it is clearly worth the investment.

Small drill bits are usually ordered by number. Here are some useful numbers and their sizes:

Number	Diameter
68	0.0310"
65	0.0350"
62	0.0380"
60	0.0400"

Use high RPM and light pressure to make good holes. Count the holes on both the board and your layout drawing to ensure that none are missed. Use a larger-size drill bit, lightly spun between your fingers, to remove any burrs. Don't use too much pressure; remove only the burr.

“READY-MADE” PC BOARDS

Utility PC Boards

“Utility” PC boards are an alternative to custom-designed etched PC boards. They offer the flexibility of perforated board construction and the mechanical and electrical advantages of etched circuit connection pads. Utility PC boards can be used to build anything from simple passive filter circuits to computers.

Circuits can be built on boards on which the copper cladding has been divided into connection pads. Power supply voltages can be distributed on bus strips. Boards like those shown in **Fig 8.22** are commercially available.

An audio amplifier constructed on a utility PC board is shown in **Fig 8.23**. Component leads are inserted into the board and soldered to the etched pads. Wire jumpers connect the pads together to complete the circuit.

Utility boards with one or more etched plugs for use in computer-bus, interface and general purpose applications are widely available. Connectors, mounting hardware and other accessories are also available. Check with your parts supplier for details.

PC-Board Assembly Techniques

Once you have etched and drilled a PC board you are ready to use it in a project. Several tools come in handy: needle-nose pliers, diagonal cutters, pocket knife, wire strippers, clip leads and soldering iron.

Fig 8.21—This home-built drill fence makes it easy to drill PC-board holes in straight rows.

Fig 8.22—Utility PC boards like these are available from many suppliers.

Fig 8.23—The audio amplifier built on a multipurpose PC breadboard. Top view at A; bottom view at B.

Cleanliness

Make sure your PC board and component leads are clean. Clean the entire PC board before assembly; clean each component before you install it. Corrosion looks dark instead of bright and shiny. Don't use sandpaper to clean your board. Use a piece of fine steel wool or a Scotchbrite cleaning pad to clean component leads or PC board before you solder them together.

Installing Components

In a construction project that uses a PC board, most of the components are installed on the board. Installing components is easy—stick the components in the right board holes, solder the leads, and cut off the extra lead length. Most construction projects have a parts-placement diagram that shows you where each component is installed.

Getting the components in the right holes is called “stuffing” the circuit board. Inserting and soldering one component at a time takes too long. Some people like to put the components in all at once, and then turn the board over and solder all the leads. If you bend the leads a bit (about 20°) from the bottom side after you push them through the board, the components are not likely to fall out when you turn the board over.

Start with the shortest components—horizontally mounted diodes and resistors. Larger components sometimes cover smaller components, so these smaller parts must be installed first. Use adhesive tape to temporarily hold difficult components in place while you solder.

PC-Board Soldering

To solder components to a PC board, bend the leads at a slight angle; apply the soldering iron to one side of the lead, and flow the solder in from the other side of the lead. See Fig 8.24. Too little heat causes a bad or

Fig 8.24—This is how to solder a component to a PC board. Make sure that the component is flush with the board on the other side.

“cold” solder joint; too much heat can damage the PC board. Practice a bit on some spare copper stock before you tackle your first PC board project. After the connection is soldered properly, clip the lead flush with the solder.

Special Concerns

Make sure you have the components in the right holes before you solder them. Components that have polarity, such as diodes, ICs and some capacitors must be oriented as shown on the parts-placement diagram.

FROM SCHEMATIC TO WORKING CIRCUIT

Some people don't know how to turn a schematic into a working circuit. One thing is usually true—you can't build it the way it looks on the schematic. Many design and layout considerations that apply in the real world of practical electronics don't appear on a schematic.

PC Boards—Always the Best Choice?

PC boards are everywhere—in all kinds of consumer electronics, in most of your Amateur Radio equipment. They are also used in most kits and construction projects. A newcomer to electronics might think that there is some unwritten law against building equipment in any other way!

The misconception that everything needs to be built on a printed-circuit board is often a stumbling block to easy project construction. In fact, a PC board is probably the worst choice for a one-time project. In actuality, a moderately complex project (like a QRP transmitter) can be built in much less time using other techniques. The additional design, layout and manufacturing is usually much more work than it would take to build the project by hand.

So why does everyone use PC boards? The most important reason is that they are reproducible. They allow many units to be mass-produced with exactly the same layout, reducing the time and work of conventional wiring and minimizing the possibilities of wiring errors. If you can buy a ready-made PC board or kit for your project, it can save a lot of construction time.

Using a PC board usually makes project construction easier by minimizing the risk of wiring errors or other construction blunders. Inexperienced constructors usually feel more confident when construction has been simplified to the assembly of components onto a PC board. One of the best ways to get started with home construction (to some the best part of Amateur Radio) is to start by assembling a few kits using PC

boards. Contact information for kit manufacturers can be found on *ARRLWeb* (www.arrl.org/cgi-bin/tisfind?pattern=amateur+radio+kit).

One-Time Projects

Kits are fun, but another facet of electronics construction is building and developing your own circuits, starting from circuit diagrams. For one-time construction, PC boards are really not necessary. It takes time to lay out, drill and etch a PC board. Alterations are difficult to make if you change your ideas or make a mistake. Most important, PC boards aren't always the best technique for building RF circuits.

Layout

A circuit diagram is a poor guide toward a proper layout. Circuit diagrams are drawn to look attractive on paper. They follow drafting conventions that have very little to do with the way the circuit works. On a schematic, ground and supply voltage symbols are scattered all over the place. The first rule of RF layout is—*do not wire RF circuits as they are drawn!* How a circuit works in practice depends on the layout. Poor layout can ruin the performance of even a well-designed circuit.

How to Design a Good Circuit Layout

The easiest way to explain good layout practices is to take you through an example. Fig 8.25 is the circuit diagram of a two-stage receiver IF amplifier using dual-gate MOSFETs. It is only a design example, so the values are only typical. To analyze which things are important to the layout of this circuit, ask these questions:

- Which are the RF components, and which are only involved with LF or dc?
- Which components are in the main RF signal path?
- Which components are in the ground return paths?

Use the answers to these questions to plan the layout. The RF components that are in the main RF signal path are usually the most critical. The AF or dc components can usually be placed anywhere. The components in the ground return path should be positioned so they are easily connected to the circuit ground. Answer the questions, apply the answers to the layout, and then follow these guidelines:

- Avoid laying out circuits so their inputs and outputs are close together. If a stage's output is too near a previous stage's input, the output signal can feed-back into the input and cause problems.
- Keep component leads as short as prac-

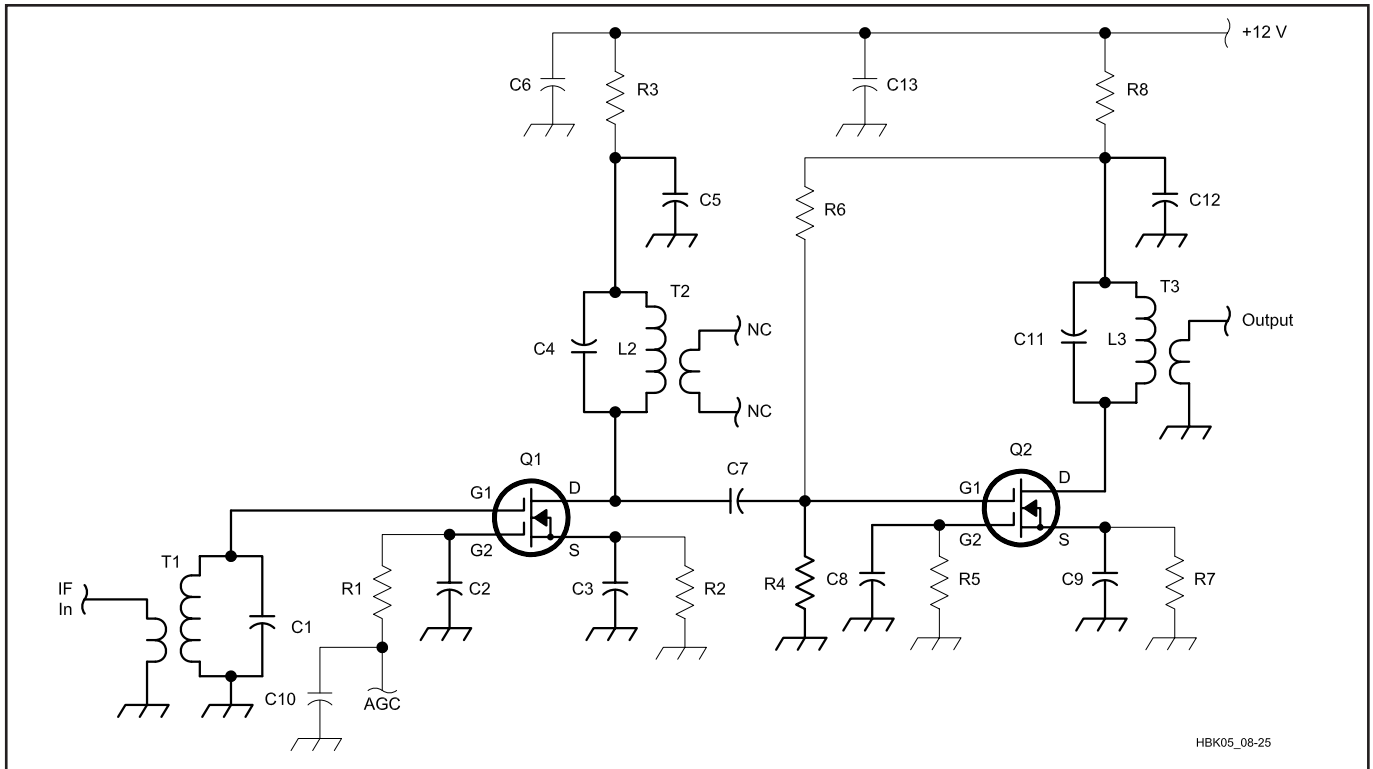

Fig 8.25—The IF amplifier used in the design example. C1, C4 and C11 are not specified because they are internal to the IF transformers.

tical. This doesn't necessarily mean as short as possible—just consider lead length as part of your design.

- Remember that metal transistor cases conduct, and that a transistor's metal case is usually connected to one of its leads. Prevent cases from touching ground or other components, unless called for in the design.

In our design example, the RF components are shown in heavy lines, though not all of these components are in the main RF signal path. The RF signal path consists of T1/C1, Q1, T2/C4, C7, Q2, T3/C11. These need to be positioned in almost a straight line, to avoid feedback from output to input. They form the backbone of the layout, as shown in **Fig 8.26A**.

The question about ground paths requires some further thought—what is really meant by “ground” and “ground-return paths”? Some points in the circuit need to be kept at RF ground potential. The best RF ground potential on a PC board is a copper ground plane covering one entire side. Points in the circuit that cannot be connected directly to ground for dc reasons must be bypassed (“decoupled”) to ground by capacitors that provide ground-return paths for RF.

In Fig 8.26, the components in the ground-return paths are the RF bypass capacitors C2, C3, C5, C8, C9 and C12.

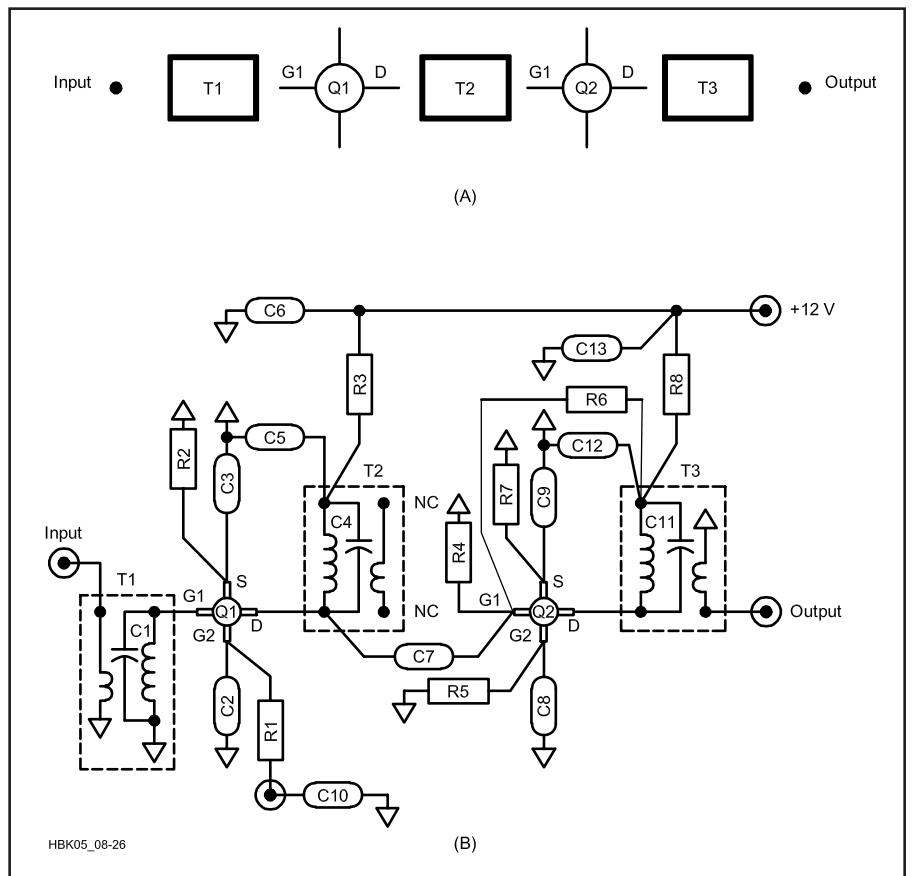

Fig 8.26—Layout sketches. The preliminary line-up is shown in A; the final layout in B.

R4 is primarily a dc biasing component, but it is also a ground return for RF so its location is important. The values of RF bypass capacitors are chosen to have a low reactance at the frequency in use; typical values would be 0.1 μF at LF, 0.01 μF at HF, and 0.001 μF or less at VHF. Not all capacitors are suitable for RF decoupling; the most common are disc ceramic capacitors. RF decoupling capacitors should always have short leads.

Almost every RF circuit has an input, an output and a common ground connection. Many circuits also have additional ground connections, both at the input side and at the output side. Maintain a low-impedance path between input and output ground connections. The input ground connections for Q1 are the grounded ends of C1 and the two windings of T1. (The two ends of an IF transformer winding are generally not interchangeable; one is designated as the “hot” end, and the other must be connected or bypassed to RF ground.) The capacitor that resonates with the adjustable coil is often mounted inside the can of the IF transformer, leaving only two component leads to be grounded as shown in Fig 8.26B.

The RF ground for Q1 is its source connection via C3. Since Q1 is in a plastic package that can be mounted in any orientation, you can make the common ground either above or below the signal path in Fig 8.26B. Although the circuit diagram shows the source at the bottom. The practical circuit works much better with the source at the top, because of the connections to T2.

It’s a good idea to locate the hot end of the main winding close to the drain lead of the transistor package, so the other end is toward the top of Fig 8.26B. If the source of Q1 is also toward the top of the layout, there is a common ground point for C3 (the source bypass capacitor) and the output bypass capacitor C5. Gate 2 of Q1 can safely be bypassed toward the bottom of the layout.

C7 couples the signal from the output of Q1 to the input of Q2. The source of Q2 should be bypassed toward the top of the layout, in exactly the same way as the source of Q1. R4 is not critical, but it should be connected on the same side as the other components. Note how the pinout of T3 has placed the output connection as far as possible from the input. With this layout for the signal path and the critical RF components, the circuit has an excellent chance of working properly.

DC Components

The rest of the components carry dc, so their layout is much less critical. Even so, try to keep everything well separated from

the main RF signal path. One good choice is to put the 12-V connections along the top of the layout, and the AGC connection at the bottom. The source bias resistors R2 and R7 can be placed alongside C3 and C9. The gate-2 bias resistors for Q2, R5 and R6 are not RF components so their locations aren’t too critical. R7 has to cross the signal path in order to reach C12, however, and the best way to avoid signal pickup would be to mount R7 on the opposite side of the copper ground plane from the signal wiring. Generally speaking, $1/8$ -W or $1/4$ -W metal-film or carbon-film resistors are best for low-level RF circuits.

Actually, it is not quite accurate to say that resistors such as R3 and R8 are not “RF” components. They provide a high impedance to RF in the positive supply lead. Because of R8, for example, the RF signal in T2 is conducted to ground through C5 rather than ending up on the 12-V line, possibly causing unwanted RF feedback. Just to be sure, C6 bypasses R3 and C13 serves the same function for R8. Note that the gate-1 bias resistor R6 is connected to C12 rather than directly to the 12-V supply, to take advantage of the extra decoupling provided by R8 and C13.

If you build something, you want it to work the first time, so don’t cut corners! Some commercial PC boards take liberties with layout, bypassing and decoupling. Don’t assume that you can do the same. Don’t try to eliminate “extra” decoupling components such as R3, C6, R8 and C13, even though they might not all be absolutely necessary. If other people’s designs have left them out, put them in again. In the long run it’s far easier to take a little more time and use a few extra components, to build in some insurance that your circuit will work. For a one-time project, the few extra parts won’t hurt your pocket too badly; they may save untold hours in debugging time.

A real capacitor does not work well over a large frequency range. A 10- μF electrolytic capacitor cannot be used to bypass or decouple RF signals. A 0.1- μF capacitor will not bypass UHF or microwave signals. Choose component values to fit the range. The upper frequency limit is limited by the series inductance, L_s . In fact, at frequencies higher than the frequency at which the capacitor and its series inductance form a resonant circuit, the capacitor actually functions as an inductor. This is why it is a common practice to use two capacitors in parallel for bypassing, as shown in Fig 8.27. At first glance, this might appear to be unnecessary. However, the self-resonant frequency of C1 is usually 1 MHz or less; it cannot supply any bypassing above that frequency. How-

ever, C2 is able to bypass signals up into the lower VHF range.

Let’s summarize how we got from Fig 8.24 to Fig 8.26B:

- Lay out the signal path in a straight line.
- By experimenting with the placement and orientation of the components in the RF signal path, group the RF ground connections for each stage close together, without mixing up the input and output grounds.
- Place the non-RF components well clear of the signal path, freely using decoupling components for extra measure.

Practical Construction Hints

Now it’s time to actually construct a project. The layout concepts discussed earlier can be applied to nearly any construction technique. Although you’ll eventually learn from your own experience, the following guidelines give a good start:

- Divide the unit into modules built into separate shielded enclosures—RF, IF, VFO, for example. Modular construction improves RF stability, and makes the individual modules easier to build and test. It also means that you can make major changes without rebuilding the whole unit. RF signals between the modules can usually be connected using small coaxial cable.
- Use a full copper ground plane. This is your largest single assurance of RF stability and good performance.
- Keep inputs and outputs well separated for each stage, and for the whole unit. If possible, lay out all stages in a straight line. If an RF signal path doubles back or recrosses itself it usually results in instability.
- Keep the stages at different frequencies well-separated to minimize interstage coupling and spurious signals.
- Use interstage shields where necessary, but don’t rely on them to cure a bad layout.
- Make all connections to the ground plane short and direct. Locate the common ground for each stage between the input and the output ground. Single-point grounding may work for a single stage, but it is rarely effective in a complex RF system.
- Locate frequency-determining components away from heat sources and mount them so as to maximize mechanical strength.
- Avoid unwanted coupling between tuned circuits. Use shielded inductors or toroids rather than open coils. Keep the RF high-voltage points close to the ground plane. Orient air-wound coils at right angles to minimize mutual coupling.

- Use lots of extra RF bypassing, especially on dc supply lines.
- Try to keep RF and dc wiring on opposite sides of the board, so the dc wiring is well away from RF fields.
- Compact designs are convenient, but don't overdo it! If the guidelines cited above mean that a unit needs to be bigger, make it bigger.

Combination Techniques

You can use a mixture of construction techniques on the same board and in most cases you probably should. Even though you choose one style for most of the wiring, there will probably be places where other techniques would be better. If so, do whatever is best for that part of the circuit. The resulting hybrid may not be pretty (these techniques aren't called "ugly construction" for nothing), but it will work!

Mount dual-in-line package (DIP) ICs in an array of drilled holes, then connect them using wired traces as described earlier. It is okay to mount some of the components using a ground-plane method, push pins or even wire wrap. On any one board, you may use a combination of these techniques, drilling holes for some ICs, or gluing others upside down, then surface mounting some of the pins, and other techniques to connect the rest. These combination techniques are often found in a project that combines audio, RF and digital circuitry.

A Final Check

No matter what construction technique is chosen, do a final check before applying power to the circuit! Things do go wrong, and a careful inspection minimizes the risk of a project beginning and ending its life as a puff of smoke! Check wiring carefully. Make a photocopy of the schematic and mark each lead on the schematic with a red X when you've verified that it's connected to the right spot in the circuit.

Inspect solder connections. A bad solder joint is much easier to find before the PC board is mounted to a chassis. Look for any damage caused to the PC board by soldering. Look for solder "bridges" between adjacent circuit-board traces. Solder bridges (Fig 8.28) occur when solder accidentally connects two or more conductors that are supposed to be isolated. It is often difficult to distinguish a solder bridge from a conductive trace on a tin-plated board. If you find a bridge, remelt it and the adjacent trace or traces to allow the solder's surface tension to absorb it. Double check that each component is installed in the proper holes on the board and that the orientation is correct. Make sure that no component leads or transistor

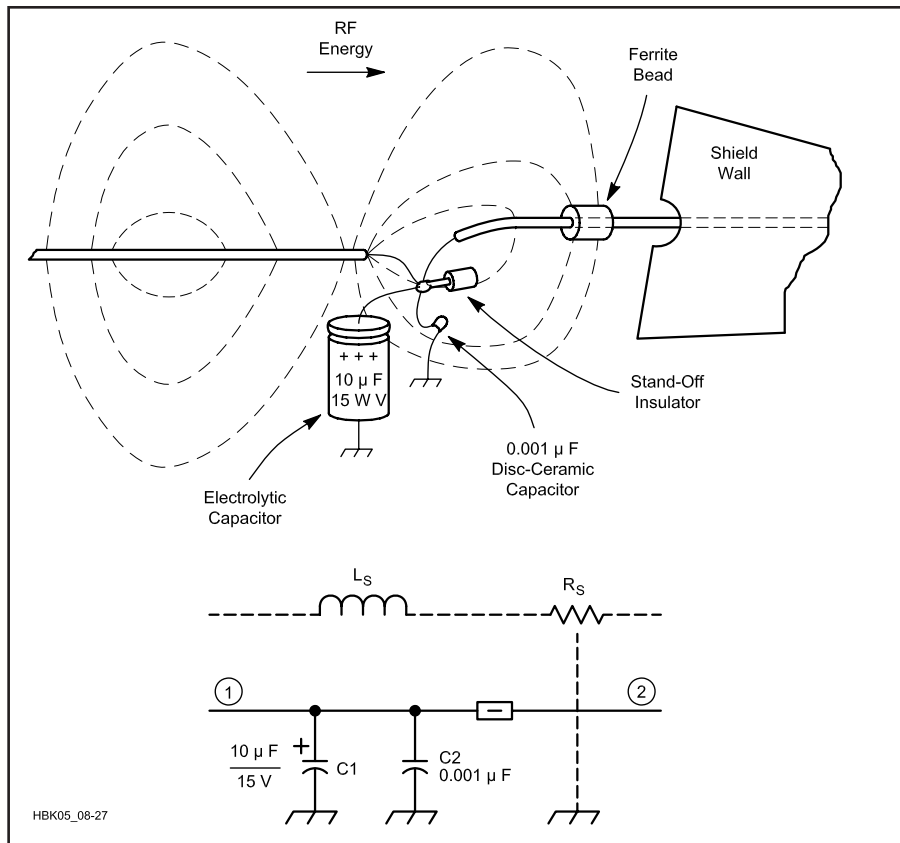

Fig 8.27—Two capacitors in parallel afford better bypassing across a wide frequency range.

Fig 8.28—A solder bridge has formed a short circuit between PC board traces.

tabs are touching other components or PC board connections. Check the circuit voltages before installing ICs in their sockets. Ensure that the ICs are oriented properly and installed in the correct sockets.

OTHER CONSTRUCTION TECHNIQUES

Wiring

Select the wire used in connecting amateur equipment by considering: the maximum current it must carry, the voltage its insulation must withstand and its use.

To minimize EMI, the power wiring of

all transmitters should use shielded wire. Receiver and audio circuits may also require the use of shielded wire at some points for stability or the elimination of hum. Coaxial cable is recommended for all 50-Ω circuits. Use it for short runs of high-impedance audio wiring.

When choosing wire, consider how much current it will carry. Stranded wire is usually preferred over solid wire because stranded wire better withstands the inevitable bending that is part of building and troubleshooting a circuit. Solid wire is more rigid than stranded wire; use it where mechanical rigidity is needed or desired.

Wire with typical plastic insulation is good for voltages up to about 500 V. Use Teflon-insulated or other high-voltage wire for higher voltages. Teflon insulation does not melt when a soldering iron is applied. This makes it particularly helpful in tight places or large wiring harnesses. Although Teflon-insulated wire is more expensive, it is often available from industrial surplus houses. Inexpensive wire strippers make the removal of insulation from hookup wire an easy job. Solid wire is often used to wire HF circuits. Bare soft-drawn tinned wire, #22 to #12 (depending on mechanical requirements) is suitable. Avoid kinks by stretching a piece 10 or

15 ft long and then cutting it into short, convenient lengths. Run RF wiring directly from point to point with a minimum of sharp bends and keep the wire well-spaced from the chassis or other grounded metal surfaces. Where the wiring must pass through the chassis or a partition, cut a clearance hole and line it with a rubber grommet. If insulation is necessary, slip

spaghetti insulation or heat-shrink tubing over the wire. For power-supply leads, bring the wire through the chassis via a feed-through capacitor.

In transmitters where the peak voltage does not exceed 500 V, shielded wire is satisfactory for power circuits. Shielded wire is not readily available for higher voltages—use point-to-point wiring in-

stead. In the case of filament circuits carrying heavy current, it is necessary to use #10 or #12 bare or enameled wire. Slip the bare wire through spaghetti then cover it with copper braid pulled tightly over the spaghetti. Slide the shielding back over the insulation and flow solder into the end of the braid; the braid will stay in place, making it unnecessary to cut it back or

Microwave Construction Techniques

Microwave construction is becoming more popular, but at these frequencies the size of physical component leads and PC-board traces cannot be neglected. Microwave construction techniques either minimize these stray values or make them part of the circuit design.

Microwave construction does not always require tight tolerances and precision construction. A fair amount of error can often be tolerated if you are willing to tune your circuits, as you do at MF/HF. This usually requires the use of variable components that can be expensive and tricky to adjust.

Proper design and construction techniques, using high precision, can result in a “no-tune” microwave design. To build one of these no-tune projects, all you need do is buy the parts and install them on the board. The circuit tuning has been precisely controlled by the board and component dimensions so the project should work.

One tuning technique you can use with a microwave design, if you have the suitable test equipment, is to use bits of copper foil or EMI shielding tape as “stubs” to tune circuits. Solder these small bits of conductor into place at various points in the circuit to make reactances that can actually tune a circuit. After their position has been determined as part of the design, tuning is accomplished by removing or adding small amounts of conductor, or slightly changing the placement of the tuning stub. The size of the foil needed depends on your ability to determine changes in circuit performance, as well as the frequency of operation and the circuit board parameters. A precision setup that lets you see tiny changes allows you to use very small pieces of foil to get the best tuning possible.

From a mechanical accuracy point of view, the most tolerant type of construction is waveguide construction. Tuning is usually accomplished via one or more screws threaded into the waveguide. It becomes unwieldy to use waveguide on the amateur bands below 10 GHz because the dimensions get too large.

At 24 GHz and above, even waveguide becomes small and difficult to work with. At these frequencies, most readily available coax connectors work unreliably, so these higher bands are really a challenge. Special SMA connectors are available for use at 24 GHz.

Modular construction is a useful technique for microwave circuits. Often, circuits are tested by hooking their inputs and output to known 50- Ω sources and loads. Modules are typically kept small to prevent the chassis and PC board from acting as a waveguide, providing a feedback path between the input and output of a circuit, resulting in instability.

At microwave frequencies, the mechanical aspects and physical size of circuits become very much a part of the design. A few millimeters of conductor has significant reactance at these frequencies. This even affects VHF and HF designs! The traces and conductors used in an HF or

VHF design resonate on microwave frequencies. If a high-performance FET has lots of gain in this region, a VHF preamplifier might also function as a 10-GHz oscillator if the circuit stray reactances were just right (or wrong!). You can prevent this by using shields between the input and output or by adding microwave absorptive material to the lid of the shielded module. (SHF Microwave sells absorptive materials.)

It is important to copy microwave circuits exactly, unless you really know what you are doing. “Improvements,” such as better shielding or grounding can sometimes cause poor performance. It isn’t usually attractive to substitute components, particularly with the active devices. It may look possible to substitute different grades of the same wafer, such as the ATF13135 and the ATF13335, but these are really the same transistor with different performance measurements. While two transistors may have exactly the same gain and noise figure at the desired operating frequency, often the impedances needed to maintain stability at other frequencies are be different. Thus, the “substitute” may oscillate, while the proper transistor would work just fine.

You can often substitute MMICs (monolithic microwave integrated circuits) for one another because they are designed to be stable and operate with the same input and output impedances (50 Ω).

The size of components used at microwaves can be critical—in some cases, a chip resistor 80 mils across is not a good substitute for one 60 mils across. Hopefully, the author of a construction project tells you which dimensions are critical, but you can’t always count on this; the author may not know. It’s not unusual for a person to spend years building just one prototype, so it’s not surprising that the author might not have built a dozen different samples to try possible substitutions.

When using glass-epoxy PC board at microwave frequencies, the crucial board parameter is the thickness of the dielectric. It can vary quite a bit, in excess of 10%. This is not surprising; digital and lower-frequency analog circuits work just fine if the board is a little thinner or thicker than usual. Some of the board types used in microwave-circuit construction are a generic Teflon PC board, Duroid 5870 and 5880. These boards are available from Microwave Components of Michigan.

Proper connectors are a necessary expense at microwaves. At 10 GHz, the use of the proper connectors is essential for repeatable performance. Do not hook up microwave circuits with coax and pigtailed. It might work but it probably can’t be duplicated. SMA connectors are common because they are small and work well. SMA jacks are sometimes soldered in place, although 2-56 hardware is more common.—Zack Lau, W1VT, ARRL Laboratory Engineer

secure it in place. Clean the braid first so solder will take with a minimum of heat.

For receivers, RF wiring follows the methods described above. At RF, most of the current flows on the surface of the wire (a phenomenon called “skin effect”). Hollow tubing is just as good a conductor at RF as solid wire.

High-Voltage Techniques

High-voltage wiring requires special care. You need to use wire rated for the voltage it is carrying. Most standard hookup wire is inadequate. High-voltage wire is usually insulated with Teflon or special multilayer plastic. Some coaxial cable is rated at up to 3700 V.

Air is a great insulator, but high voltage can break down its resistance and form an arc. You need to leave ample room between any circuit carrying voltage and any nearby conductors. At dc, leave a gap of at least 0.1 inch per kilovolt. The actual breakdown voltage of air varies with the frequency of the signal, humidity and the shape of the conductors.

High voltage is also prone to corona discharge, a bleeding off of charge, primarily from sharp edges. For this reason, all connections need to be soldered, leaving only rounded surfaces on the soldered connection. It takes a little practice to get a “ball” of solder on each joint, but for voltages above 5 kV it is important.

Be careful working near high-voltage circuits! Most high-voltage power supplies can deliver a lethal shock.

Cable Lacing and Routing

Where power or control leads run together for more than a few inches, they present a better appearance when bound together in a single cable. Both plastic and waxed-linen lacing cords are available. You can also use a variety of plastic devices to bundle wires into cables and to clamp or secure them in place. Check with your local electronic parts supplier for items that are in stock.

To give a commercial look to the wiring of any unit, route any dc leads and shielded signal leads along the edge of the chassis. If this isn't possible, the cabled leads should then run parallel to an edge of the chassis. Further, the generous use of the tie points mounted parallel to an edge of the chassis, for the support of one or both ends of a resistor or fixed capacitor, adds to the appearance of the finished unit. In a similar manner, arrange the small components so that they are parallel to the panel or sides of the chassis.

Tie Points

When power leads have several

branches in the chassis, it is convenient to use fiber-insulated multiple tie points as anchors for junction points. Strips of this kind are also useful as insulated supports for resistors, RF chokes and capacitors. Hold exposed points of high-voltage wiring to a minimum; otherwise, make them inaccessible to accidental contact.

Winding Coils

Winding coils seems so simple, yet many new constructors run into difficulty. Understanding the techniques prevents some of the frustration or construction errors associated with coil winding.

Close-wound coils are readily wound on the specified form by anchoring one end of the length of wire (in a vise or to a doorknob) and the other end to the coil form. Straighten any kinks in the wire and then pull to keep the wire under slight tension. Wind the coil to the required number of turns while walking toward the anchor, always maintaining a slight tension on the wire.

To space-wind the coil, wind the coil simultaneously with a suitable spacing medium (heavy thread, string or wire) in the manner described above. When the winding is complete, secure the end of the coil to the coil-form terminal and then carefully unwind the spacing material. If the coil is wound under suitable tension, the spacing material can be easily removed without disturbing the winding. Finish space-wound coils by judicious applications of Duco cement to hold the turns in place.

The “cold” end of a coil is the end at (or close to) chassis or ground potential. Wind coupling links on the cold end of a coil to minimize capacitive coupling.

Winding Toroidal Inductors

Toroidal inductors and transformers are specified for many projects in this *Handbook*. The advantages of these cores include compactness and a self-shielding property. **Figs 8.29** and **8.30** illustrate the proper way to wind and count turns on a toroidal core.

The task of winding a toroidal core, when more than just a few turns are required, can be greatly simplified by the use of a homemade bobbin upon which the wire is first wound. A simple yet effective bobbin can be fashioned from a wooden popsicle stick. Cut a “V” notch at each end and first wind the wire coil on the popsicle stick lengthwise through the notches. Once this is done, the wound bobbin can be easily passed through the toroid's inside diameter. While firmly grasping one of the wire ends against the toroidal core, the bobbin can be moved up, around, and through the toroidal core repeatedly until the wire has been completely transferred

from the bobbin. The choice of bobbin used is somewhat dependent on the inside diameter of the toroid, the wire size, and the number of turns required.

When you wind a toroid inductor, count each pass of the wire through the toroid center as a turn. You can count the number of turns by counting the number of times the wire passes through the center of the core. See Fig 8.30A.

Multiwire Windings

A bifilar winding is one that has two identical lengths of wire, which when

Fig 8.29—The maximum-Q method for winding a single-layer toroid is shown at A. A 30° gap is best. Methods at B and C have greater distributed capacitance. D shows how to place a tap on a toroidal coil winding.

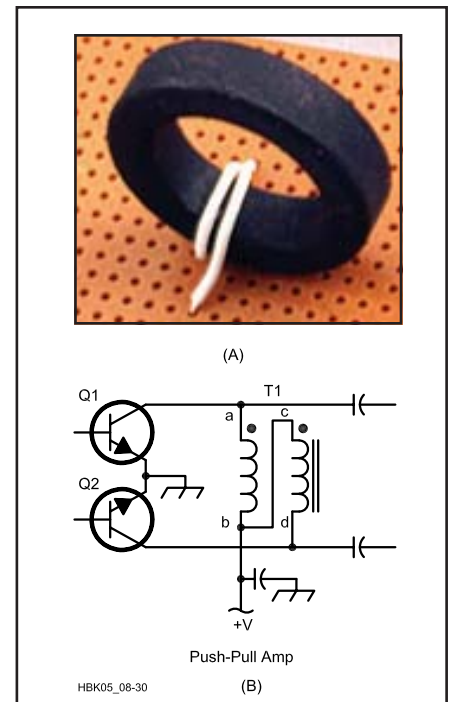

Fig 8.30—A shows a toroidal core with two turns of wire (see text). Large black dots, like those at T1 in B, indicate winding polarity (see text).

placed on the core result in the same number of turns for each wire. The two wires are wound on the core side by side at the same time, just as if a single winding were being applied. An easier and more popular method is to twist the two wires (8 to 15 turns per inch is adequate), then wind the twisted pair on the core. The wires can be twisted handily by placing one end of each in a bench vise. Tighten the remaining

ends in the chuck of a small hand drill and turn the drill to twist the pair.

A trifilar winding has three wires, and a quadrifilar winding has four. The procedure for preparation and winding is otherwise the same as for a bifilar winding. **Fig 8.31** shows a bifilar toroid in schematic and pictorial form. The wires have been twisted together prior to placing them on the core. It is helpful, though by no

means essential, to use wires of different color when multifilar-winding a core. It is more difficult to identify multiple windings on a core after it has been wound. Various colors of enamel insulation are available, but it is not easy for amateurs to find this wire locally or in small-quantity lots. This problem can be solved by taking lengths of wire (enameled magnet wire), cleaning the ends to remove dirt and

How to Buy Parts for Electronics Projects

The number one question received by the ARRL Technical Information Service starts out "Where can I buy..." It seems that one of the most perplexing problems faced by the would-be constructor is where to get parts. Sometimes you are lucky—the circuit author has made a kit available. But not every project has a ready-made kit. If you would like to expand your construction horizons, you can learn to be your own "purchasing manager." That means searching out parts sources and dealing with them in person.

In reality, it is not all that difficult to find most parts. Unfortunately, though, the days of the local electronic parts supplier seem to be gone. This is not surprising. Years ago an electronics supplier had to stock a relatively small number of electronic components—resistors, capacitors, tube sockets, a few relays and variable resistors. Technology has increased the number of components by a few orders of magnitude. Nowadays, the number of integrated circuits alone is enough to fill a multivolume book. No single electronics supplier could possibly stock them all. It has become a mail-order world; the electronics world is no exception.

Although it is no longer always possible to purchase all of your electronic needs from a local electronics supplier, the good news is that you don't have to! For a few dollars, mail-order companies are willing to supply whatever you need. You only need do two things to obtain nearly any electronic component—make a phone call and write a check.

Become an electronic catalog collector. Electronic suppliers also advertise in magazines that cater to ham-radio and electronics enthusiasts. If you are lucky, you may have a local source of electronics parts. Look in the Yellow Pages under "Electronic Equipment Suppliers" to find the local outlets. RadioShack is one local source found nearly everywhere. They carry an assortment of the more common electronic parts. You'll probably need to order from more than one mail-order company. (It's almost a corollary to Murphy's Law: No matter how wide a selection you find in one mail-order catalog, there's always at least one part you must buy somewhere else!)

While you're waiting for your catalogs, look at the parts list for the project you want to build. Unfortunately, you can't just photocopy the list and send it off to a mail-order company with a note that says "please send me these parts." You need to convert the part list into a part-order list that shows the order number and quantity required of each component. This may require a similar list for each parts supplier where one supplier does not have all the parts.

Check the type, tolerance, power rating and other key characteristics of the parts. Group the parts by those parameters before grouping them by value. If all of the circuit's components are already grouped by value on the parts list, you can just count the number of each value. Each time you add parts to the order list, check them off the published parts list. Sometimes the parts list does not

include common components like resistors and capacitors. If this is the case, make a copy of the schematic and check off the parts as you build your shopping list.

Although you'll probably be able to order exactly the right number of each part for a project, buy a few extras of some parts for your junk box. It's always good to have a few extra parts on hand; you may break a component lead during assembly, or damage a solid-state component with too much heat or by wiring it in backwards. If you don't have extras, you'll need to order another part. Even if you don't need the extras for this project, they may come in handy, and you'll be encouraged to build another project! Pick up an extra toroid or two as well.

Now's the time to decide whether you're going to build your project with ground-plane construction or PC board. If you need a PC-board, FAR Circuits and others have them for many ARRL book and *QST* projects. If you're going to use ground-plane construction, buy a good-sized piece of single-sided copper-clad board—glass-epoxy board if you can. Phenolic board is inferior because it is brittle and deteriorates rapidly with soldering heat.

Don't forget an enclosure for your project. This is often overlooked in parts lists for most projects, because different builders like different enclosures. Make sure there's room in the box for all of the components used in your project. Some people like to cram projects in the smallest possible box, but miniaturization can be extremely frustrating if you're not good at it.

There are almost always a few items you can't get from one company and most have minimum orders. You may need to distribute your order between two or more companies to meet minimum-order requirements. Some companies put out beautiful catalogs, but their minimum order is \$25 or they charge \$5 for shipping if you place a small order.

If you order enough parts, you'll soon find out which companies you like to deal with and which have slow service. It is frustrating to receive most of an order, then wait months for the parts that are on back-order. If you don't want the company to back-order your parts, write clearly on the order form, "Do not back-order parts." They will then ship the parts they have and leave you to order the rest from somewhere else.

If you are in a hurry, call the company to inquire about the availability of the parts in your order. Some companies take credit-card orders over the telephone. Some companies hold orders a few weeks to allow personal checks to clear.

If you are familiar with the catalogs and policies of electronic-component suppliers, you will find that getting parts is not difficult. Concentrate on the fun part—building the circuit and getting it working.—Bruce Hale, KB1MW

grease, then spray painting them. Ordinary aerosol-can spray enamel works fine. Spray lacquer is not as satisfactory because it is brittle when dry and tends to flake off the wire.

The winding sense of a multifilar toroidal transformer is important in most circuits. Fig 8.30B illustrates this principle. The black dots (called phasing dots) at the top of the T1 windings indicate polarity. That is, points a and c are both start or finish ends of their respective windings. In this example, points a and d are of opposite phase (180° phase difference) to provide push-pull voltage output from Q1 and Q2.

After you wind a coil, scrape the insulation off the wire before you solder it into the circuit.

MECHANICAL FABRICATION

Buy or Build a Chassis?

Most projects end up in some sort of an enclosure, and most hams choose to purchase a ready-made chassis for small projects, but some projects require a custom enclosure. Even a ready-made chassis may require a fabricated sheet-metal shield or bracket, so it's good to learn something about sheet-metal and metal-fabrication techniques.

Most often, you can buy a suitable enclosure. These are sold by RadioShack and most electronics distributors.

Select an enclosure that has plenty of room. A removable cover or front panel can make any future troubleshooting or modifications easy. A project enclosure should be strong enough to hold all of the components without bending or sagging; it should also be strong enough to stand up to expected use and abuse.

Cutting and Bending Sheet Metal

Enclosures, mounting brackets and shields are usually made of sheet metal. Most sheet metal is sold in large sheets, 4 to 8 ft or larger. It must be cut to the size needed.

Most sheet metal is thin enough to cut with metal shears or a hacksaw. A jigsaw or bandsaw makes the task easier. If you use any kind of saw, select a blade that has teeth fine enough so that at least two teeth are in contact with the metal at all times.

If a metal sheet is too large to cut conveniently with a hacksaw, it can be scored and broken. Make scratches as deep as possible along the line of the cut on both sides of the sheet. Then, clamp it in a vise and work it back and forth until the sheet breaks at the line. Do not bend it too far before the break begins to weaken, or the edge of the sheet might bend. A pair of flat bars, slightly longer than the sheet being

Fig 8.31—Schematic and pictorial presentation of a bifilar-wound toroidal transformer.

bent, make it easier to hold a sheet firmly in a vise. Use "C" clamps to keep the bars from spreading at the ends.

Smooth rough edges with a file or by sanding with a large piece of emery cloth or sandpaper wrapped around a flat block.

Finishing Aluminum

Give aluminum chassis, panels and parts a sheen finish by treating them in a caustic bath. Use a plastic container to hold the solution. Ordinary household lye can be dissolved in water to make a bath solution. Follow the directions on the container. A strong solution will do the job more rapidly.

Stir the solution with a stick of wood until the lye crystals are completely dissolved. If the lye solution gets on your skin, wash with plenty of water. If you get any in your eyes, immediately rinse with plenty of clean, room-temperature water and seek medical help. It can also damage your clothing, so wear something old. Prepare sufficient solution to cover the piece completely. When the aluminum is immersed, a very pronounced bubbling takes place. Provide ventilation to disperse the escaping gas. A half hour to two hours in the bath is sufficient, depending on the strength of the solution and the desired surface characteristics.

Chassis Working

With a few essential tools and proper procedure, building radio gear on a metal chassis is a relatively simple matter. Aluminum is better than steel, not only because it is a superior shielding material, but also because it is much easier to work and provides good chassis contact when used with secure fasteners.

Spend sufficient time planning a project to save trouble and energy later. The actual construction is much simpler when all details are worked out beforehand. Here we discuss a large chassis-and-cabinet

project, such as a high-power amplifier. The techniques are applicable to small projects as well.

Cover the top of the chassis with a piece of wrapping paper or graph paper. Fold the edges down over the sides of the chassis and fasten them with adhesive tape. Place the front panel against the chassis front and draw a line there to indicate the chassis top edge.

Assemble the parts to be mounted on the chassis top and move them about to find a satisfactory arrangement. Consider that some will be mounted underneath the chassis and ensure that the two groups of components won't interfere with each other.

Place controls with shafts that extend through the cabinet first, and arrange them so that the knobs will form the desired pattern on the panel. Position the shafts perpendicular to the front chassis edge. Locate any partition shields and panel brackets next, then sockets and any other parts. Mark the mounting-hole centers of each part accurately on the paper. Watch out for capacitors with off-center shafts that do not line up with the mounting holes. Do not forget to mark the centers of socket holes and holes for wiring leads. Make the large center hole for a socket *before* the small mounting holes. Then use the socket itself as a template to mark the centers of the mounting holes. With all chassis holes marked, center-punch and drill each hole.

Next, mount on the chassis the capacitors and any other parts with shafts extending to the panel. Fasten the front panel to the chassis temporarily. Use a machinist's square to extend the line (vertical axis) of any control shaft to the chassis front and mark the location on the front panel at the chassis line. If the layout is complex, label each mark with an identifier. Also mark the back of the front panel with the locations of any holes in the chassis front that must go through the front panel. Remove the front panel.

PC-Board Materials

Much tedious sheet-metal work can be eliminated by fabricating chassis and enclosures from copper-clad printed-circuit board material. While it is manufactured in large sheets for industrial use, some hobby electronics stores and surplus outlets market usable scraps at reasonable prices. PC-board stock cuts easily with a small hacksaw. The nonmetallic base material isn't malleable, so it can't be bent. Corners are easily formed by holding two pieces at right angles and soldering the seam. This technique makes excellent RF-tight enclosures. If mechanical rigidity is required of a large copper-clad surface,

solder stiffening ribs at right angles to the sheet.

Fig 8.32 shows the use of PC-board stock to make a project enclosure. This enclosure was made by cutting the pieces to size, then soldering them together. Start by laying the bottom piece on a workbench, then placing one of the sides in place at right angles. Tack-solder the second piece in two or three places, then start at one end and run a bead of solder down the entire seam. Use plenty of solder and plenty of heat. Continue with the rest of the pieces until all but the top cover is in place.

In most cases, it is better to drill all needed holes in advance. It can sometimes be difficult to drill holes after the enclosure is soldered together.

You can use this technique to build enclosures, subassemblies or shields. This technique is easy with practice; hone your skills on a few scrap pieces of PC-board stock.

Drilling Techniques

Before drilling holes in metal with a hand drill, indent the hole centers with a center punch. This prevents the drill bit from “walking” away from the center when starting the hole. Pre-drill holes greater than 1/2-inch in diameter with a smaller bit that is large enough to contain the flat spot at the large bit’s tip. When the metal being drilled is thinner than the depth of the drill-bit tip, back up the metal with a wood block to smooth the drilling process.

The chuck on the common hand drill is limited to 3/8-inch bits. Some bits are much larger, with a 3/8-inch shank. If necessary, enlarge holes with a reamer or round file. For very large or odd-shaped holes, drill a series of closely spaced small holes just inside of the desired opening. Cut the metal remaining between the holes with a cold chisel and file or grind the hole to its finished shape. A nibbling tool also works well for such holes.

Use socket-hole punches to make socket holes and other large holes in an aluminum chassis. Drill a guide hole for the punch center bolt, assemble the punch with the bolt through the guide hole and

Fig 8.32—A box made entirely from PC-board stock.

tighten the bolt to cut the desired hole. Oil the threads of the bolt occasionally.

Cut large circular holes in steel panels or chassis with an adjustable circle cutter (“flycutter”). Occasionally apply machine oil to the cutting groove to speed the job. Test the cutter’s diameter setting by cutting a block of wood or scrap material first.

Remove burrs or rough edges that result from drilling or cutting with a burr-remover, round or half-round file, a sharp knife or chisel. Keep an old chisel sharpened and available for this purpose.

Rectangular Holes

Square or rectangular holes can be cut with a nibbling tool or a row of small holes as previously described. Large openings can be cut easily using socket-hole punches.

Construction Notes

If a control shaft must be extended or insulated, a flexible shaft coupling with adequate insulation should be used. Satisfactory support for the shaft extension, as well as electrical contact for safety, can be provided by means of a metal panel bushing made for the purpose. These can be obtained singly for use with existing shafts, or they can be bought with a captive extension shaft included. In either case the panel bushing gives a solid feel to the control. The use of fiber washers between ceramic insulation and metal brackets, screws or nuts will prevent the ceramic parts from breaking.

Painting

Painting is an art, but, like most arts, successful techniques are based on skills that can be learned. The surfaces to be painted must be clean to ensure that the paint will adhere properly. In most cases, you can wash the item to be painted with soap, water and a mild scrub brush, then rinse thoroughly. When it is dry, it is ready for painting. Avoid touching it with your bare hands after it has been cleaned. Your skin oils will interfere with paint adhesion. Wear rubber or clean cotton gloves.

Sheet metal can be prepared for painting by abrading the surface with medium-grade sandpaper, making certain the strokes are applied in the same direction (not circular or random). This process will create tiny grooves on the otherwise smooth surface. As a result, paint or lacquer will adhere well. On aluminum, one or two coats of zinc chromate primer applied before the finish paint will ensure good adhesion.

Keep work areas clean and the air free of dust. Any loose dirt or dust particles will probably find their way onto a freshly painted project. Even water-based paints produce some fumes, so properly ventilate work areas.

Select a paint suitable to the task. Some paints are best for metal, others for wood and so on. Some dry quickly, with no fumes; others dry slowly and need to be thoroughly ventilated. You may want to select a rust-preventative paint for metal surfaces that might be subjected to high moisture or salts.

Most metal surfaces are painted with some sort of spray, either from a spray gun or from spray cans of paint. Either way, follow the manufacturer’s instructions for a high-quality job.

SUMMARY

If you’re like most amateurs, once you’ve got the building bug, you won’t let your soldering iron stay cold for long. Starting is the hardest part. Now, the next time you think about adding another project to your station, you’ll know where to start.

Chapter 9

Modes and Systems

The various modes, modulation types and protocols we use partly reflect the different types of information we might wish to transmit, such as data, voice, image or even multimedia communications. Other considerations are the behavior of the radio link including fading, delay, Doppler frequency shift and distortion. We are also limited by regulatory restrictions such as bandwidth and following certain conventions or protocols. Some of the bands used by amateurs are wide and well behaved, such as VHF links over short paths. Others may be narrow, unstable and hostile to our signals, such as a long HF path through the auroral zones. Such conditions dictate which mode will be most successful.

ISSUES COMMON TO ALL TRANSMISSION MODES

Bandwidth is the amount of frequency spectrum that a signal occupies. There are narrow-band modes, such as CW and PSK31, and wideband modes, such as TV and spread spectrum. Not all modes are permitted on all amateur bands. Wideband modes can be used only where the total width of the amateur allocation is sufficient to contain the wide signal. In addition, voluntary agreements and regulatory restrictions keep some wideband modes out of certain bands or subbands so that one station's signal does not preclude operation by a large number of others using the narrower modes.

All users of the radio spectrum must comply with FCC bandwidth rules. The occupied bandwidth is determined not only by the mode being used, but by proper opera-

tion of that mode. Many of the permitted modes can become too wide when improperly adjusted. Perhaps the greatest source of conflict between ham operators is “splatter” or “key clicks” caused by overmodulated or otherwise improperly operated equipment, regardless of the mode being used. An amateur signal must be no wider than is necessary for good communication, and as clean as the “state of the art” will allow. Section 97.3 (a)(8) of the FCC rules defines occupied bandwidth as the point where spurious energy drops to 26 dB below the mean power of the transmitted signal.

Sensitivity refers to the relative ability of a mode to decode weak signals. Some modes are favored by DXers in that they have a greater ability to “get through” when the signals are very weak. For local communications, sensitivity may not be the major concern. *Fidelity* is not a major issue for most amateurs, although they rightly take pride in the clarity of their transmissions and some amateurs take audio quality quite seriously. *Intelligibility* is related to fidelity in a complex way and, sometimes, voice signals are modified in such a way as to make them more understandable, perhaps under difficult conditions, even though not as natural as they might otherwise be.

Quality is the corresponding term for images, and *accuracy* describes the degree to which a text mode reproduces the original message. *Robustness* or *reliability* refers to the ability of a mode to maintain continuous communication under difficult conditions. For example, a very robust signal is desired when controlling a model airplane. DXers are not overly concerned with reliability in that continuous contact is not needed. How-

ever, they do want a signal that gets through when needed to work a rare station.

Efficiency is the ability of a mode to get the signal through with minimum energy expended. Within the regulatory power limit, energy cost is not a major concern for most home stations. Thus, efficiency is a concern mainly to those on battery power—using handheld or portable stations. Emergency operators also need to consider using efficient modes. For radio services that use high power, such as shortwave broadcasters, efficiency is very important. QRP is a popular activity, where operators take pride in making contact with a very small amount of transmitter power (maximum miles per milliwatt!).

Stability is the ability to maintain the frequency of the transmission very precisely. Some modes require precise frequency control. Most modern equipment is very stable, but some vintage or homemade gear may be limited in frequency stability. Higher frequency work can put tight limits on frequency stability. Channel stability refers to both frequency, amplitude and phase variations of the transmission medium itself. The inherent instability of a radio channel may permit some modes but preclude others.

Noise immunity is the ability of a radio system to reject noise of various types that could otherwise destroy the meaning or impair the quality of the message. This is all-important in HF mobile operations and for those living in densely populated areas. Man-made electrical noise is an increasingly serious threat to ham operations and requires both regulatory and technical solutions.

Emission Classifications

Emissions are designated according to their classification and their necessary bandwidth. A minimum of three symbols is used to describe the basic characteristics of radio waves. Emissions are classified and symbolized according to the following characteristics:

- I. First symbol—Type of modulation of the main carrier
- II. Second symbol—Nature of signal(s) modulating the main carrier
- III. Third symbol—Type of information to be transmitted
- Note: A fourth and fifth symbol are provided for in the ITU Radio Regulations. Use of the fourth and fifth symbol is optional.
- IV. Details of signal(s)
- V. Nature of multiplexing

- First symbol**—type of modulation of the main carrier
- (1) Emission of an unmodulated carrier N
 - (2) Emission in which the main carrier is amplitude-modulated (including cases where subcarriers are angle-modulated):
 - Double sideband A
 - Single sideband, full carrier H
 - Single sideband, reduced or variable level carrier R
 - Single sideband, suppressed carrier J
 - Independent sidebands B
 - Vestigial sideband C
 - (3) Emission in which the main carrier is angle-modulated:
 - Frequency modulation F
 - Phase modulation G

Note: Whenever frequency modulation (F) is indicated, phase modulation (G) is also acceptable.
 - (4) Emission in which the main carrier is amplitude and angle-modulated either simultaneously or in a pre-established sequence D
 - (5) Emission of pulses¹
 - Sequence of unmodulated pulses P
 - A sequence of pulses:
 - Modulated in amplitude K
 - Modulated in width/duration L
 - Modulated in position/phase M
 - In which the carrier is angle-modulated during the period of the pulse Q
 - Which is a combination of the foregoing or in produced by other means V
 - (6) Cases not covered above, in which an emission consists of the main carrier modulated, either simultaneously or in a pre-established sequence in a combination of two or more of the following modes: amplitude, angle, pulse W
 - (7) Cases not otherwise covered X

- Second symbol**—nature of signal(s) modulating the main carrier
- (1) No modulating signal 0
 - (2) A single channel containing quantized or digital information without the use of a modulating subcarrier, excluding time-division multiplex 1
 - (3) A single channel containing quantized or digital information with the use of a modulating subcarrier, excluding time-division multiplex 2
 - (4) A single channel containing analog information 3
 - (5) Two or more channels containing quantized or digital information 7

- (6) Two or more channels containing analog information 8
- (7) Composite system with one or more channel containing quantized or digital information, together with one or more channels containing analog information 9
- (8) Cases not otherwise covered X

- Third symbol**—type of information to be transmitted²
- (1) No information transmitted N
 - (2) Telegraphy, for aural reception A
 - (3) Telegraphy, for automatic reception B
 - (4) Facsimile C
 - (5) Data transmission, telemetry, telecommand D
 - (6) Telephony (including sound broadcasting) E
 - (7) Television (video) F
 - (8) Combination of the above W
 - (9) Cases not otherwise covered X

Where the fourth or fifth symbol is used it shall be used as indicated below. Where the fourth or the fifth symbol is not used this should be indicated by a dash where each symbol would otherwise appear.

- Fourth symbol**—Details of signal(s)
- (1) Two-condition code with elements of differing numbers and/or durations A
 - (2) Two-condition code with elements of the same number and duration without error-correction B
 - (3) Two-condition code with elements of the same number and duration with error-correction C
 - (4) Four-condition code in which each condition represents a signal element (of one or more bits) D
 - (5) Multi-condition code in which each condition represents a signal element (of one or more bits) E
 - (6) Multi-condition code in which each condition or combination of conditions represents a character F
 - (7) Sound of broadcasting quality (monophonic) G
 - (8) Sound of broadcasting quality (stereophonic or quadraphonic) H
 - (9) Sound of commercial quality (excluding categories given in (10) and (11) below J
 - (10) Sound of commercial quality with frequency inversion or band-splitting K
 - (11) Sound of commercial quality with separate frequency-modulated signals to control the level of demodulated signal L
 - (12) Monochrome M
 - (13) Color N
 - (14) Combination of the above W
 - (15) Cases not otherwise covered X

- Fifth symbol**—Nature of multiplexing
- (1) None N
 - (2) Code-division multiplex³ C
 - (3) Frequency-division multiplex F
 - (4) Time-division multiplex T
 - (5) Combination of frequency-division and time-division multiplex W
 - (6) Other types of multiplexing X

¹ Emissions where the main carrier is directly modulated by a signal which has been coded into quantized form (eg, pulse code modulation) should be designated under (2) or (3).

² In this context the word “information” does not include information of a constant unvarying nature such as is provided by standard frequency emissions, continuous wave and pulse radars, etc.

³ This includes bandwidth expansion techniques.

Emission, Modulation and Transmission Characteristics

Emission designators are generally expressed as characters representing the necessary bandwidth and emission classification symbols. *Necessary bandwidth* is expressed as a maximum of five numerals and one letter. The letter occupies the position of the decimal point and represents the unit of bandwidth, as follows: H = hertz, K = kilohertz, M = megahertz and G = gigahertz. For example, a bandwidth of 2.8 kHz is expressed as 2K8 or 2K80 and a bandwidth of 150 Hz is noted as 150H.

Emission classification symbols are (1) type of modulation of the main carrier, (2) nature of the signal(s) modulating the main carrier and (3) the information to be transmitted. They may be supplemented by (4) details of signal(s) and (5) nature of multiplexing, but the FCC does not require these. These designators are found in Appendix 1 of the ITU Radio Regulations, ITU-R Recommendation SM.1138 and in the FCC rules §2.201.

TRANSMISSION IMPAIRMENTS

In addition to attenuation of a signal from a transmitting station to a receiving station, the signal is subject to a variety of impairments. These include flat fading, frequency-selective fading, wave polarization rotation fading, Doppler shift, interference from other signals, atmospheric noise, galactic noise and manmade noise. Receiver thermal noise is not usually an issue at HF because external noise often dominates but can be a limiting factor at VHF and above.

Effect of the HF Path on Pulses

Digital signals, including Morse signals copied by ear, are transmissions in which the wave abruptly changes state. That means that something about them is varied in order to carry the digital information. Understanding what happens to pulses of all types when they travel via the ionosphere is important for knowing how to design a workable HF digital system. VHF and UHF signals generally use more benign paths but some of the same principles important in HF will also apply to them.

Since Morse CW using OOK (on-off keying) is the oldest as well as the simplest digital mode, it is useful to analyze the propagation effects on a simple Morse character, namely the letter “E.” This consists of a single pulse, which can be distinguished from the letter “T” by its length, provided the keying speed is known beforehand. Using the ARRL-recommended values for shaping to prevent excessive key clicks, a single Morse “E” will appear as shown on the left in Fig 9.1 as it leaves the transmitter. A ham living nearby would observe the

Fig 9.1—Morse “E” as transmitted (left) and received (right).

pulse essentially unchanged and could comment usefully on the shape of the keying.

However, a receiver far enough removed so that sky wave was the dominant mode would see a much different picture. If both ground wave and sky wave were present, as could occur on 80 meters at a distance of 20 miles, the received dit might appear as shown on the right in Fig 9.1. Several things, however, distort the pulse. One is multipath, meaning that the signal arrives by more than one route. One route might be the ground wave, another the single-hop sky wave, and others, very likely considerably weaker, multiple-hop sky waves.

In addition, if the ionosphere is moving up or down, Doppler shifts will change the received frequency slightly. If operation is near the MUF, some energy may be greatly delayed by reflections from varying heights, further smearing the pulse. Noise of various types will be added to the pulse. Finally, fading effects may be noticed even on such a short time frame as a single Morse letter.

The successful decoding of a Morse signal consists of simply deciding whether a pulse was sent or not, and its length. Humans have been given a brain and sense organs that, when properly trained, can cope with all these problems to a high degree. Our brain’s ability to filter out extraneous noise and signals is remarkable. The dynamic range and sensitivity of both vision and hearing are close to the theoretical limits. Human AGC (automatic gain control) operates to provide a continually variable “decision threshold.” If all else fails during on-air contacts, repeats can be requested.

A satisfactory non-human Morse decoder would have to replicate all of the above human functions. As it turns out, Morse, using OOK, is one of the hardest digital systems to copy error free, although by using fixed speed, and with reasonably good propagation, it is possible. Those who have worked with software or hardware schemes for decoding Morse will point out that narrow filtering will clean up the above pulse considerably. This is really a form of averaging or integration, which smoothes out the abrupt changes in amplitude. A phase-locked loop detector provides averaging and

threshold detection in one circuit. Even with these improvements, OOK signals are difficult to decode reliably.

The second oldest method of transmitting pulses is with frequency shift keying (FSK) where, instead of turning a signal on and off, it is made to jump between different frequencies to correspond to the “key-up” and “key-down” conditions. RTTY (radio teletype) does not *require* the use of FSK and some have used OOK for RTTY. However, because of long use, most of us associate FSK transmissions with RTTY, the mechanical or computer decoding of text (plus crude images) using the Baudot code. Digital text modes have used AM (of which OOK is an example, but not the only one), FSK or PSK (phase shift keying).

As with FM analog transmissions, FSK and PSK tend to discriminate against amplitude noise, which is common on HF. Thus, amplitude changes resulting from fading and/or static can be reduced. However, as discussed in this *Handbook’s AC/RF Sources* chapter, AM noise can change into phase noise, so this is not a complete solution. Modes based on phase modulation, such as the PSK modes, are not noise free. You need only observe the little phase “compass” included in some PSK31 software to be aware that even when transmitting an idle tone, the received signal’s phase will jump around.

Doppler shifts introduce noise into phase- and frequency-shift systems. If we are counting on seeing a certain frequency shift as a signal, you don’t want the path adding any shifts that will show up as noise. Thus, Doppler shift places a lower limit on the amount of frequency or phase shift needed to distinguish between the various data bits. On HF, ionospheric Doppler, which can be up to 5 Hz, places a lower limit on the carrier spacing of multi carrier modes. Lengthening of pulses of up to several milliseconds is common on HF paths. The general solution for channel-produced lengthening of pulses is simply to use a slower rate of transmission. Thus, the pulse has time to settle before being interpreted.

The fastest CW operators slow down when unusual multipath propagation conditions smear the characters together. A machine can operate at speeds where even normal multipath can smear the characters, not just in extreme cases. This factor puts an upper limit on the *symbol rate*. If a bit rate is to be increased beyond this point, each pulse must carry more than one bit. This calls for the use of complex modulation schemes involving multiple states per pulse. These can be represented by a number of different frequencies in an FSK mode, many phases

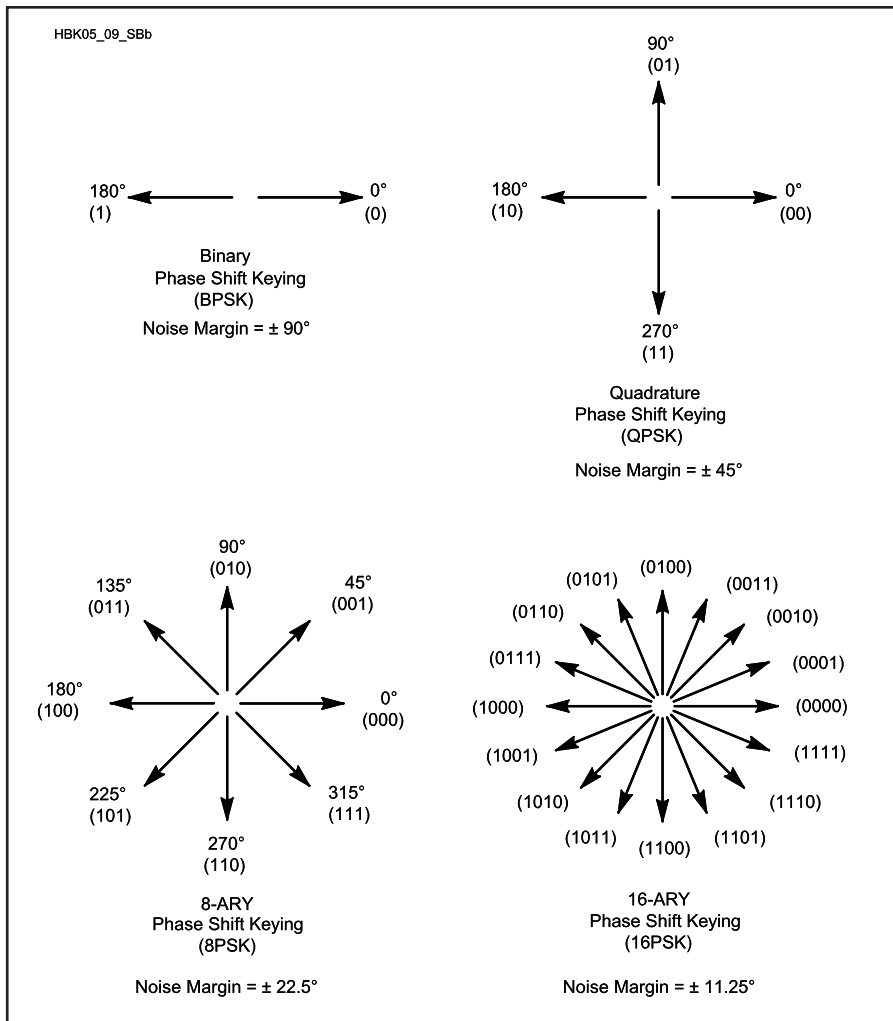

Fig 9.2—An example of multilevel phase modulation.

in a PSK mode, many levels in an AM mode or a combination of several or even all of the above. An example of multi-level phase modulation is illustrated in Fig 9.2. One type of a complex system would be QAM (quadrature amplitude modulation), which requires special equipment to observe.

With complex modulation forms, noise-induced changes in both amplitude and phase will cause some pulses to fall into oblivion, where you simply cannot say what was sent. Thus, a higher signal to noise ratio is needed for complex types of modulation such as 64QAM, whereas binary modes may work closer to the noise.

For high bit rates on HF, many carriers may be used, each one carrying multiple amplitude and phase levels. There are, however, regulatory and practical limits. Thus, while it is feasible to transmit digital speech in a 3-kHz bandwidth, full-motion, high-resolution full-motion TV signals would be very difficult to transmit on HF, even if an entire amateur band were used.

Schemes that use more than one frequency, such as FSK and multicarrier systems, must cope with *selective fading*, where not all frequencies fade at the same time. Users of RTTY FSK systems have long observed that either the mark or space frequency may momentarily fade away leaving only the other. A good decoder will work with only one of the two tones present.

All present and future digital modes must address these problems, and the development of new text modes has seen a steady progression from the original and hallowed CW and RTTY modes. As digital voice, image, text and control modes develop, they will all cope with the above channel limitations in various ways and with varying degrees of success. Some will be very resistant to QRM; others will be efficient in use of spectrum or in *throughput*—the amount of data that can be sent in a given time.

Modes that are optimum for a QRM-free VHF channel may work poorly on HF. Optimum HF modes will be too slow for some

VHF applications. Error-correction schemes will always be useful for the more difficult channels, since on HF there is no such thing as a 100% reliable channel. On all frequencies, hams have a habit of “pushing the limits” so that marginal paths are often used. The design of digital communications systems will always be an exercise in trade-offs.

EFFECT OF THE HF PATH ON ANALOG SIGNALS

Analog signals undergo the same impairments as digital signals along an ionospheric transmission path. However, the signals are normally decoded by the combination of the human ear and brain, which overcome problems, often without much notice. Frequency-selective fading of double-sideband AM signals manifests itself as distortion or mushiness at the receiver audio that may be ignored by the human operator. Even if the signal becomes temporarily unreadable, often the operator can fill in the blanks because the information is familiar or expected. Single-sideband AM (SSB) usually suffers less mushiness in the receiver due to frequency selective fading because the signal occupies a narrower bandwidth, in which low and high-frequency audio tend to fade together. The human operator can usually cope with such temporary fadeouts or can request a retransmission for any part missed.

MULTIPLE ACCESS AND MULTIPLEXING TECHNOLOGIES

To appreciate some of the more complex communications systems, you need an understanding of the different methods of sharing a carrier or accessing the frequency spectrum. *Multiple access* refers to more than one originating source having use of the media. *Multiplexing* means combining of two or more information streams into one carrier or transmission path.

Frequency Division Multiple Access (FDMA)

FDMA is probably the oldest and most familiar method of accessing the frequency spectrum, since individual signals are on different frequency channels. It is also the least efficient, since each frequency occupies a slot that is reserved for one user at a time.

Frequency Division Multiplexing (FDM)

FDM uses more than one subcarrier, imposed on a carrier, to convey different information. It traditionally was used for multiplexed telephone systems but is rarely used in the Amateur Radio Service.

Fig 9.3—Spectrum of an individual OFDM carrier.

Time Division Multiple Access (TDMA)

TDMA is simply time-sharing a frequency. In a general sense, this occurs naturally as stations in a QSO take turns transmitting. TDMA is also used in digital systems that reverse the direction of a circuit automatically to send information and acknowledgements.

Time Division Multiplex (TDM)

TDM is transmission of two or more signals over a common channel by interleaving so that the signals occur in different time slots. Some cellular telephone systems, such as Global System for Mobile Communications (GSM) use TDM. In the Amateur Radio Service it is used mostly for telemetry, such as from amateur satellites and remote repeaters.

Orthogonal Frequency Division Multiplexing (OFDM)

The term *orthogonal* is derived from the

Fig 9.4—Overall OFDM spectrum.

fact that multiple carriers are closely spaced in frequency, but positioned such that they do not interfere with one another. The center frequency of one carrier's signal falls within the nulls of the signals on either side of it. Figs 9.3 and 9.4, illustrate how the carriers are interleaved to prevent intercarrier interference.

Because each carrier is modulated at a relatively low rate, OFDM links suffer less intersymbol interference (ISI) on HF ionospheric paths than single-carrier modulation

at a higher rate. See Smith, Doug, KF6DX, "Distortion and Noise in OFDM Systems," *QEX* Mar/Apr 2005.

Code Division Multiple Access (CDMA)

CDMA is a form of *spread spectrum* and is generated by modulating a carrier with a spreading code sequence known to both the sender and receiver. Unlike FDMA and TDMA, there is no fixed limit on the number of users but the number is not infinite.

Major Modulation Systems

The broadest category of modulation is how the *main carrier* is modulated. The major types are amplitude modulation, angle modulation and pulse modulation.

AMPLITUDE MODULATION

Amplitude modulation (AM) covers a class of modulation systems in which the amplitude of the *main carrier* is the characteristic that is varied. AM is sometimes simplistically described as varying the amplitude of the carrier from zero power to a peak power level. In fact, the carrier itself stays at the same amplitude when modulated by an analog (such as voice) baseband signal. The modulation itself produces sidebands, which are bands of frequencies on both sides of the carrier frequency. AM is basically a process of heterodyning or non-

linear mixing. As in any mixer, when a carrier and baseband modulation are combined, there are three products in the frequency range of interest: (1) the carrier, (2) the lower sideband (LSB), and (3) the upper sideband (USB). Thus, if a carrier of 10 MHz were modulated by a 1-kHz sine wave, the outputs would be as shown in Fig 9.5.

The bandwidth of the modulated signal in this example would be 2 kHz, the difference between the lowest and highest frequencies. In AM, the difference between the carrier and farthest-away component of the sideband is determined by the highest frequency component contained in the baseband-modulating signal.

ANGLE MODULATION

Two particular forms of angle modula-

Fig. 9.5—A 10-MHz carrier AM-modulated by a 1-kHz sine wave.

tion are *frequency modulation (FM)* and *phase modulation (PM)*. Frequency and phase modulation are not independent, since the frequency cannot be varied without also varying the phase, and vice versa.

The communications effectiveness of FM and PM depends almost entirely on the receiving methods. If the receiver can respond to frequency and phase changes but is insensitive to amplitude changes, it will discriminate against most forms of noise, particularly impulse noise, such as that from ignition systems.

Frequency Modulation

Fig 9.6 is a representation of frequency modulation. When a modulating signal is applied, the carrier frequency is increased during one half cycle of the modulating signal and decreased during the half cycle of the opposite polarity. This is indicated in the drawing by the fact that the RF cycles occupy less time (higher frequency) when the modulating signal is negative.

The change in the carrier frequency (*frequency deviation*) is proportional to the instantaneous amplitude of the modulating signal. Thus, the deviation is small when the instantaneous amplitude of the modulating signal is small and is greatest when the modulating signal reaches its peak, either positive or negative. The drawing shows that the amplitude of the RF signal does not

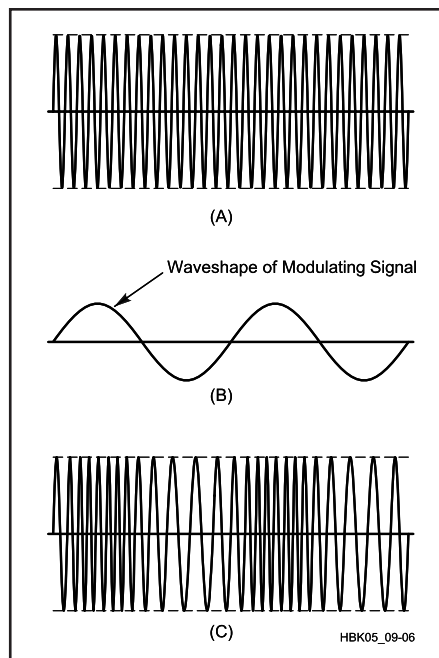

Fig 9.6—Graphical representation of frequency modulation. In the unmodulated carrier (A) each RF cycle occupies the same amount of time. When the modulating signal (B) is applied, the radio frequency is increased and decreased according to the amplitude and polarity of the modulating signal (C).

Fig 9.7—Amplitude of the FM carrier and sidebands with modulation index. This is a graphical representation of mathematical functions developed by F. W. Bessel. Note that the carrier completely disappears at modulation indexes of 2.405 and 5.52.

change during modulation. This is an oversimplification and is true only in the overall sense, as the amplitude of both the carrier and sidebands do vary with frequency modulation. FM is capable of conveying dc levels, as it can maintain a specific frequency.

Phase Modulation

In phase modulation, the characteristic varied is the carrier phase from a reference value. In PM systems, the demodulator responds only to instantaneous changes in frequency. PM cannot convey dc levels unless special phase-reference techniques are used. The amount of frequency change, or deviation, is directly proportion to how rapidly the phase is changing and the total amount of the phase change.

Bessel Functions

Bessel functions are employed—using the carrier null method—to set deviation. Some version of the chart shown in **Fig 9.7** has appeared in the *ARRL Handbook* for 50 years. This chart is unlike previous ones in that the values are plotted here in dB, which is more familiar to anyone who uses an S meter or a spectrum analyzer to observe the various FM sidebands. This version also plots all values as positive because receiv-

ers, including spectrum analyzers, do not distinguish between positive and negative phase values. Thus, this plot will give values directly in dB below the unmodulated carrier of each component of a frequency-modulated wave, based on the modulation index.

Since the carrier and each sideband of a frequency-modulated signal change amplitude according to fixed rules as the deviation and modulating frequency change, we can use those rules to set deviation, provided we have a way to observe the FM spectrum. Based on a set of mathematical functions named after F.W. Bessel, who developed them, we know that a modulation index of 2.405 will produce what is called the “first carrier null.” Thus, if we wish to set our deviation to 5 kHz, we can use an audio tone of $5000/2.405$ or 2079 Hz. While observing the spectrum, we can then increase the deviation from zero until the carrier is in a null. This guarantees that the deviation is now 5000 Hz. If we use a frequency counter to set the audio tone accurately, the exactness of the deviation setting should be very high. Similarly, for setting the deviation to 3 kHz, we could use the audio frequency of 1247 kHz and adjust for the first carrier null. If a spectrum analyzer is not available, an all-mode receiver using a narrow CW filter

could be used to detect the carrier null, using the S meter and carefully tuning to the carrier. Additional carrier nulls occur with modulation indices of 5.52 and 8.654. These would be useful for wideband FM or when using low audio frequencies for setting the deviation with narrow-band FM.

Other methods of setting deviation include observing the bandwidth on a spectrum analyzer using a very low frequency audio tone and using a deviation meter—an FM receiver whose audio output is metered on a scale calibrated directly in kHz of deviation. An FM service monitor may include both a deviation meter and a spectrum dis-

play. The carrier-null method is the most accurate of the three methods and can even be used to calibrate a deviation meter.

You can also use the plot in Fig 9.7 to predict the bandwidth of any given audio frequency and deviation combination. Consider this example. We wish to keep our bandwidth narrow enough to pass through a 15-kHz receive filter and we are transmitting a tone of 3 kHz. Since the third set of sidebands will be 18 kHz apart, we would do well to keep them, and all higher sidebands, below -40 dB. A quick look at the chart shows that this means the modulation index must be no more than about 0.7, mean-

ing the deviation should be $0.7 \times 3 = 2.1$ kHz. If we are willing to allow the third set of sidebands to be only 34 dB down, we can use a modulation index of 1, meaning the deviation will be 3 kHz—close to the recommended value for 9600 bits/s digital signals on FM. The above calculations strictly apply only when the highest audio frequency (3 kHz) is present. If there is little chance of 100% modulation at the highest audio frequency as, for example, with a normal voice signal, higher deviation could be used. When new digital modems and modes are used on FM, the above procedures should be part of the design.

Operating Modes

This chapter examines various *operating modes* used in the Amateur Radio Service, including text modes, data, telemetry and telecommand, voice, image, spread spectrum and multimedia. While modes once fit into neat categories, there is now a blurring of the definitions. For example, data transmissions could include images.

TELEGRAPHY MODES

These are basically text modes; that is, transmission of letters, figures and punctuation, in a format suitable for printing at the receiving station. Morse telegraphy and radioteletype (Baudot and ASCII) are described, but you should be aware that the term “telegraphy” includes facsimile transmission as well.

Morse Telegraphy (CW)

Text messages sent by on-off keying (OOK, also known as amplitude-shift keying, or ASK) is the original mode for both amateur and commercial radio. It is alive and well today and is not expected to fade away. For many amateurs, it is the principal, or even the only, mode they use and many take great and justifiable pride in their proficiency with it. The complete international Morse (including the new @ character) code itself is defined in ITU-R Recommendation M.1677, *International Morse code*.

CW continues in use, however, not just for reasons of nostalgia. When used by an experienced operator, it can rival most any mode for “getting the message through” under marginal conditions and is absolutely unrivaled in terms of the simplicity of the equipment needed. Methods of generating the code characters, and even of decoding them, have used the latest technology, but the straight key and “copy by ear” are still in

use. Of all modes, CW is the most versatile in terms of signaling speed. It is used at speeds—measured in words per minute (WPM)—of less than one, and up to several hundred. Depending on ability of the operator, direct human copy works well between about 5 and 60 WPM, but for very slow or very fast speeds, the signals may be recorded and the speed adjusted to allow human decoding. Very slow speeds and extremely narrow filters make possible communication using signals below the noise, while very fast speeds are useful for meteor scatter communication where bandwidth is large, but the reflection path lasts only a second or less.

The bandwidth occupied by a CW signal

depends on the keying rate (See the **Mixers, Modulators and Demodulators** chapter of this *Handbook*), with higher speeds requiring a wider filter to pass the sidebands. In addition, occupied bandwidth depends on the rise and fall time and the shape of the keyed RF envelope. That shape should be somewhat rounded (no abrupt transitions) in order to prevent “key clicks”—harmonics of the keying pulse. These can extend over several kHz and cause unnecessary interference. The ideal RF envelope of a code element would rise and fall in the shape of a sine wave. See **Figs 9.8 and 9.9**. ARRL has long recommended a 5-ms rise time for CW, up to 60 WPM, which keeps the signal within a 150-Hz bandwidth. Use of a nar-

Fig 9.8—Optimum CW keying waveforms. The on-off transitions of the RF envelope should be smooth, ideally following a sine-wave curve. See text.

Fig 9.9—Keying speed vs rise and fall times vs bandwidth for fading and non-fading communications circuits. For example, to optimize transmitter timing for 25 WPM on a non-fading circuit, draw a vertical line from the WPM axis to the $K = 3$ line. From there draw a horizontal line to the rise/fall time axis (approximately 15 ms). Draw a vertical line from where the horizontal line crosses the bandwidth line and see that the bandwidth will be about 60 Hz.

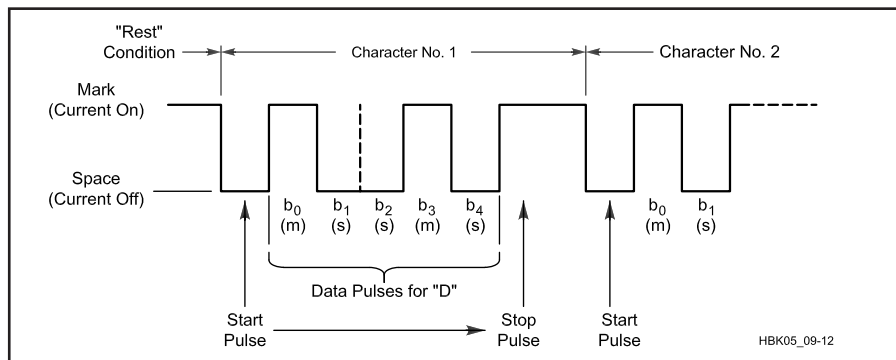

Fig 9.10—A typical Baudot timing sequence for the letter “D.”

rower filter than this on receive end is uncommon for ear-copied CW; therefore, narrower bandwidth is unnecessary and would make the signal sound “mushy.” Very fast pulses, such as would be used for High-Speed CW (HSCW) meteor scatter work, are computer generated and can occupy a normal SSB filter bandwidth.

Morse code is one of the most efficient modes in terms of information sent per baud. The commonly accepted ratio for bauds to WPM is $WPM = 1.2 \times B$. Thus, a keying

speed of 25 dots per second or 50 bauds is equal to 60 WPM. The efficiency of Morse text messages is based on the use of the shortest code combinations to represent the most commonly used letters and symbols. Efficiency is further achieved by extensive use of abbreviations and “Q signals.” By making use of these multiple levels of universally recognized coding schemes, CW can get essential information across quickly. CW abbreviations are universal so that simple contacts can be made without the

need of a shared language. In skilled hands, CW can achieve a QSO or traffic rate approaching that of phone operation while using a fraction of the bandwidth.

Baudot Radioteletype (RTTY)

One of the first data communications codes to receive widespread use had five bits (also called “levels”) to present the alphabet, numerals, symbols and machine functions. In the US, we use International Telegraph Alphabet No. 2 (ITA2), commonly called *Baudot*, as specified in FCC §97.309(a)(1). The code is defined in the ITA2 Codes table on the CD-ROM included with this book. In the United Kingdom, the almost-identical code is called *Murray* code. There are many variations in five-bit coded character sets, principally to accommodate foreign-language alphabets.

Five-bit codes can directly encode only $2^5 = 32$ different symbols. This is insufficient to encode 26 letters, 10 numerals and punctuation. This problem can be solved by using one or more of the codes to select from multiple code-translation tables. ITA2 uses a LTRS code to select a table of upper-case letters and a FIGS code to select a table of numbers, punctuation and special symbols. Certain symbols, such as carriage return, occur in both tables. Unassigned ITA2 FIGS codes may be used for the remote control of receiving printers and other functions.

FCC rules provide that ITA2 transmissions must be sent using start-stop pulses, as illustrated in Fig 9.10. The bits in the figure are arranged as they would appear on an oscilloscope.

Speeds and Signaling Rates

The signaling speeds for RTTY are those used by the old TTYs, primarily 60 WPM or 45.45 bauds. The *baud* (Bd) is a unit of signaling speed equal to one pulse (event) per second. The signaling rate, in bauds, is the reciprocal of the shortest pulse length.

Transmitter Keying

When TTYs and TUs (terminal units) roamed the airwaves, frequency-shift keying (FSK) was the order of the day. DC signals from the TU controlled some form of reactance (usually a capacitor or varactor) in a transmitter oscillator stage that shifted the transmitter frequency. Such direct FSK is still an option with some new radios.

AFSK

Multimode communications processors (MCPs), however, generally connect to the radio AF input and output, often through the speaker and microphone connectors, and sometimes through auxiliary connectors. They simply feed AF tones to the microphone input of an SSB transmitter or trans-

ceiver. This is called AFSK for “audio frequency-shift keying.”

When using AFSK, make certain that audio distortion, carrier and unwanted sidebands do not cause interference. Particularly when using the low tones discussed later, the harmonic distortion of the tones should be kept to a few percent. Most modern AFSK generators are of the continuous-phase (CPFSK) type. Also remember that equipment is operating at a 100% duty cycle for the duration of a transmission. For safe operation, it is often necessary to reduce the transmitter power output (25 to 50% of normal) from the level that is safe for CW operation.

What are High and Low Tones?

US amateurs customarily use the same modems (2125 Hz mark, 2295 Hz space) for both VHF AFSK and HF via an SSB transmitter. Because of past problems (when 850-Hz shift was used), some amateurs use “low tones” (1275 Hz mark, 1445 Hz space). Both high and low tones can be used interchangeably on the HF bands because only the *amount* of shift is important. The frequency difference is unnoticed on the air because each operator tunes for best results. On VHF AFSK, however, the high and low tone pairs are not compatible.

Transmit Frequency

It is normal to use the lower sideband mode for RTTY on SSB radio equipment. In order to tune to an exact RTTY frequency, remember that most SSB radio equipment displays the frequency of its (suppressed) carrier, not the frequency of the mark signal. Review your MCP’s manual to determine the tones used and calculate an appropriate display frequency. For example, to operate on 14,083 kHz with a 2125-Hz AFSK mark frequency, the SSB radio display (suppressed-carrier) frequency should be $14,083 \text{ kHz} + 2.125 \text{ kHz} = 14,085.125 \text{ kHz}$.

Receiving Baudot

TUs (Terminal Units) have been replaced by multi-mode communications processors (MCPs), which accept AF signals from a radio and translate them into common ASCII text or graphics file formats (see Fig 9.11). Because the basic interface is via ASCII, MCPs are compatible with virtually any PC running a simple terminal program. Many MCPs handle CW, RTTY, ASCII, packet, fax, SSTV and new digital modes as they come into amateur use. To an increasing extent, personal computer sound cards with appropriate software are a viable and low-cost alternative to MCPs. However, sound cards have their limitations and dedicated hardware can

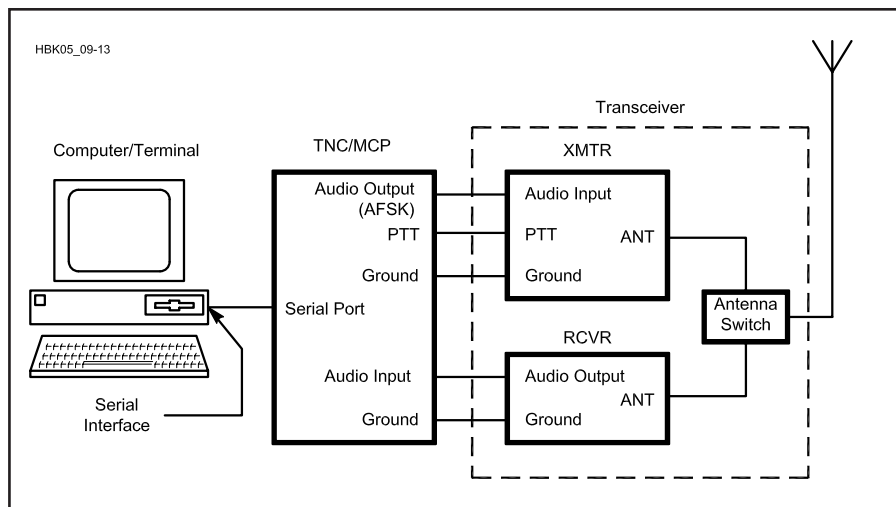

Fig 9.11—A typical multimode communications processor (MCP) station. MCPs can do numerous data modes as well as SSTV and fax.

more efficiently perform some operations.

AFSK Demodulators

An AFSK demodulator takes the shifting tones from the audio output of a receiver and produces TTY keying pulses. FM is a common AFSK demodulation method. The signal is first bandpass filtered to remove out-of-band interference and noise. It is then limited to remove amplitude variations. The signal is demodulated in a discriminator or a PLL. The detector output is low pass filtered to remove noise at frequencies above the keying rate. The result is fed to a circuit that determines whether it is a mark or a space.

AM (limiterless) detectors, when properly designed, permit continuous copy even when the mark or space frequency fades out completely. At 170-Hz shift, however, the mark and space frequencies tend to fade at the same time. For this reason, FM and AM demodulators are comparable at 170-Hz shift.

Diversity Reception

Although not restricted to RTTY, *diversity reception* can be achieved by using two antennas, two receivers and a dual demodulator. Some amateurs are using it with good results. One of the antennas would be the normal station antenna for that band. The second antenna could be either another antenna of the same polarization located at least $\frac{3}{8}$ -wavelength away, or an antenna of the opposite polarization located near the first antenna. A problem is to get both receivers on the same frequency without carefully tuning each one manually. Two demodulators are needed for this type of diversity. Also, some type of diversity combiner, selector or processor is needed. Many commercial or military RTTY demodulators are equipped for diversity reception.

The payoff for using diversity is a worthwhile improvement in copy. Depending on fading conditions, adding diversity may be equivalent to raising transmitter power severalfold.

ASCII (IA5) RADIOTELETYPE

The American National Standard Code for Information Interchange (ASCII) is a coded character set used for information-processing systems, communications systems and related equipment. Current FCC regulations provide that amateur use of ASCII shall conform to ASCII as defined in ANSI Standard X3.4-1977. Its international counterparts are ISO 646-1983 and International Alphabet No. 5 (IA5) as specified in ITU-T Recommendation V.3.

ASCII uses 7 bits to represent letters, figures, symbols and control characters. Unlike ITA2 (Baudot), ASCII has both upper- and lower-case letters. A table of ASCII characters is presented as “ASCII Character Set” on the CD-ROM that accompanies this book.

Parity

While not strictly a part of the ASCII standard, an eighth bit may be added for parity (P) checking. FCC rules permit optional use of the parity bit. The applicable US and in-

Glossary of Digital Communications Terminology

- ACK**—Acknowledgment, the control signal sent to indicate the correct receipt of a transmission block.
- Address**—A character or group of characters that identifies a source or destination.
- AFSK**—Audio frequency-shift keying.
- ALE**—Automatic link establishment.
- AMRAD**—Amateur Radio Research and Development Corporation, a nonprofit organization dedicated to experimentation.
- AMSAT**—Radio Amateur Satellite Corporation.
- AMTOR**—Amateur teleprinting over radio, an amateur radioteletype transmission technique employing error correction as specified in several ITU-R Recommendations M.476-2 through M.476-4 and M.625.
- ANSI**—American National Standards Institute.
- Answer**—The station intended to receive a call. In modem usage, the called station or modem tones associated therewith.
- APCO**—Association of Public Safety Communications Officials.
- ARQ**—Automatic Repeat reQuest, an error-sending station, after transmitting a data block, awaits a reply (ACK or NAK) to determine whether to repeat the last block or proceed to the next.
- ASCII**—American National Standard Code for Information Interchange, a code consisting of seven information bits.
- AX.25**—Amateur packet-radio link-layer protocol. Copies of protocol specification are available from ARRL HQ.
- Backwave**—An unwanted signal emitted between the pulses of an on/off-keyed signal.
- Balanced**—A relationship in which two stations communicate with one another as equals; that is, neither is a primary (master) or secondary (slave).
- Baud**—A unit of signaling speed equal to the number of discrete conditions or events per second. (If the duration of a pulse is 20 ms, the signaling rate is 50 bauds or the reciprocal of 0.02, abbreviated Bd).
- Baudot code**—A coded character set in which five bits represent one character. Used in the US to refer to ITA2.
- Bell 103**—A 300-baud full-duplex modem using 200-Hz-shift FSK of tones centered at 1170 and 2125 Hz.
- Bell 202**—A 1200-baud modem standard with 1200-Hz mark, 2200-Hz space, used for VHF FM packet radio.
- BER**—Bit error rate.
- BERT**—Bit-error-rate test.
- Bit stuffing**—Insertion and deletion of 0s in a frame to preclude accidental occurrences of flags other than at the beginning and end of frames.
- Bit**—Binary digit, a single symbol, in binary terms either a one or zero.
- Bit/s**—Bits per second.
- BLER**—Block error rate.
- BLERT**—Block-error-rate test.
- Break-in**—The ability to hear between elements or words of a keyed signal.
- Byte**—A group of bits, usually eight.
- Carrier detect (CD)**—Formally, received line signal detector, a physical-level interface signal that indicates that the receiver section of the modem is receiving tones from the distant modem.
- CDMA**—Code division multiple access.
- Chirp**—Incidental frequency modulation of a carrier as a result of oscillator instability during keying.
- CLOVER**—Trade name of digital communications system developed by Hal Communications.
- COFDM**—Coded Orthogonal Frequency Division Multiplex, OFDM plus coding to provide error correction and noise immunity.
- Collision**—A condition that occurs when two or more transmissions occur at the same time and cause interference to the intended receivers.
- Constellation**—A set of points in the complex plane which represent the various combinations of phase and amplitude in a QAM or other complex modulation scheme.
- Contention**—A condition on a communications channel that occurs when two or more stations try to transmit at the same time.
- Control field**—An 8-bit pattern in an HDLC frame containing commands or responses, and sequence numbers.
- CRC**—Cyclic redundancy check, a mathematical operation. The result of the CRC is sent with a transmission block. The receiving station uses the received CRC to check transmitted data integrity.
- CSMA**—Carrier sense multiple access, a channel access arbitration scheme in which packet-radio stations listen on a channel for the presence of a carrier before transmitting a frame.
- CTS**—clear to send, a physical-level interface circuit generated by the DCE that, when on, indicates the DCE is ready to receive transmitted data (abbreviated CTS).
- DARPA**—Defense Advanced Research Projects Agency.
- DBPSK**—Differential binary phase-shift keying.
- DQPSK**—Differential quadrature phase-shift keying.
- DCE**—Data circuit-terminating equipment, the equipment (for example, a modem) that provides communication between the DTE and the line radio equipment.
- Domino**—A conversational HF digital mode similar in some respects to MFSK16.
- DRM**—Digital Radio Mondiale. A consortium of broadcasters, manufacturers, research and governmental organizations which developed a system for digital sound broadcasting in bands between 100 kHz and 30 MHz.
- EIA**—Electronic Industries Alliance.
- EIA-232**—An EIA standard physical-level interface between DTE (terminal) and DCE (modem), using 25-pin connectors. Formerly RS-232, a popular serial line standard, equivalent of ITU-T V.24 and V.28.
- Envelope-delay distortion**—In a complex waveform, unequal propagation delay for different frequency components.
- Equalization**—Correction for amplitude-frequency and/or phase-frequency distortion.
- Eye pattern**—An oscilloscope display in the shape of one or more eyes for observing the shape of a serial digital stream and any impairments.
- Facsimile (fax)**—A form of *telegraphy* for the transmission of fixed images, with or without half-tones, with a view to their reproduction in a permanent form.
- FCS**—Frame check sequence. (See CRC.)
- FDM**—Frequency division multiplexing
- FDMA**—Frequency division multiple access
- FEC**—Forward error correction, an error-control technique in which the transmitted data is sufficiently redundant to permit the receiving station to correct some errors.
- FSK**—Frequency-shift keying.
- GNU**—A project to develop a free UNIX style operating system.
- G-TOR**—A digital communications system developed by Kantronics.
- HDLC**—High-level data link control procedures as specified in ISO 3309.
- Hellschreiber**—A facsimile system for transmitting text.
- Host**—As used in packet radio, a computer with applications programs accessible by remote stations.
- IA5**—International Alphabet No. 5, a 7-bit coded character set, ITU-T version of ASCII.
- IBOC**—In Band On Channel. A method of using the same channel on the AM or FM broadcast bands to transmit simultaneous digital and analog modulation.
- Information field**—Any sequence of bits containing the intelligence to be conveyed.
- ISI**—Intersymbol interference; slurring of one symbol into the next as a result of multipath propagation.
- ISO**—International Organization for Standardization.
- ITA2**—International Telegraph Alphabet No. 2, a ITU-T 5-bit coded character set commonly called the Baudot or Murray code.

ITU—International Telecommunication Union, a specialized agency of the United Nations. (See www.itu.int.)

ITU-R—Radiocommunication Sector of the ITU, formerly CCIR.

ITU-T—Telecommunication Standardization Sector of the ITU, formerly CCITT.

Jitter—Unwanted variations in amplitude or phase in a digital signal.

Key clicks—Unwanted transients beyond the necessary bandwidth of a keyed radio signal.

LAP—Link access procedure, ITU-T Recommendation X.25 unbalanced-mode communications.

LAPB—Link access procedure, balanced, ITU-T Recommendation X.25 balanced-mode communications.

Layer—In communications protocols, one of the strata or levels in a reference model.

Level 1—Physical layer of the OSI reference model.

Level 2—Link layer of the OSI reference model.

Level 3—Network layer of the OSI reference model.

Level 4—Transport layer of the OSI reference model.

Level 5—Session layer of the OSI reference model.

Level 6—Presentation layer of the OSI reference model.

Level 7—Application layer of the OSI reference model.

Linux—A free Unix-type operating system originated by Linus Torvalds, et al. Developed under the GNU General Public License.

Loopback—A test performed by connecting the output of a modulator to the input of a demodulator.

LSB—Least-significant bit.

MFSK16—A multi-frequency shift communications system

Modem—Modulator-demodulator, a device that connects between a data terminal and communication line (or radio). Also called data set.

MSB—Most-significant bit.

MSK—Frequency-shift keying where the shift in Hz is equal to half the signaling rate in bits per second.

MT-63—A keyboard-to-keyboard mode similar to PSK31 and RTTY.

NAK—Negative acknowledge (opposite of ACK).

Node—A point within a network, usually where two or more links come together, performing switching, routine and concentrating functions.

NRZI—Nonreturn to zero. A binary baseband code in which output transitions result from data 0s but not from 1s. Formal designation is NRZ-S (nonreturn-to-zero-space).

Null modem—A device to interconnect two devices both wired as DCEs or DTEs; in EIA-232 interfacing, back-to-back DB25 connectors with pin-for-pin connections except that Received Data (pin 3) on one connector is wired to Transmitted Data (pin 3) on the other.

Octet—A group of eight bits.

OFDM—Orthogonal Frequency Division Multiplex. A method of using spaced subcarriers that are phased in such a way as to reduce the interference between them.

Originate—The station initiating a call. In modem usage, the calling station or modem tones associated therewith.

OSI-RM—Open Systems Interconnection Reference Model specified in ISO 7498 and ITU-T Recommendation X.200.

Packet radio—A digital communications technique involving radio transmission of short bursts (frames) of data containing addressing, control and error-checking information in each transmission.

FACTOR®—Trade name of digital communications protocols offered by Special Communications Systems GmbH & Co KG (SCS).

Parity check—Addition of non-information bits to data, making the number of ones in a group of bits always either even or odd.

PID—Protocol identifier. Used in AX.25 to specify the network-layer protocol used.

Primary—The master station in a master-slave relationship; the master maintains control and is able to perform actions that the slave cannot. (Compare secondary.)

Project 25—Digital voice system developed for APCO, also known as P25.

Protocol—A formal set of rules and procedures for the exchange of information within a network.

PSK—Phase-shift keying.

PSK31—A narrow-band digital communications system developed by Peter Martinez, G3PLX.

Q15X25—A DSP-intensive mode intended as an error-free mode more reliable on HF than packet.

QAM—Quadrature Amplitude Modulation. A method of simultaneous phase and amplitude modulation. The number that precedes it, eg, 64QAM, indicates the number of discrete stages in each pulse.

QPSK—Quadrature phase-shift keying.

RAM—Random access memory.

Router—A network packet switch. In packet radio, a network-level relay station capable of routing packets.

RTS—Request to send, physical-level signal used to control the direction of data transmission of the local DCE.

RTTY—Radioteletype.

RxD—Received data, physical-level signals generated by the DCE are sent to the DTE on this circuit.

SCAMP—Sound Card Automated Message Protocol, an inexpensive alternative to hardware for passing e-mail traffic on narrow-bandwidth channels.

Secondary—The slave in a master-slave relationship. Compare primary.

Source—In packet radio, the station transmitting the frame over a direct radio link or via a repeater.

SSID—Secondary station identifier. In AX.25 link-layer protocol, a multipurpose octet to identify several packet-radio stations operating under the same call sign.

TAPR—Tucson Amateur Packet Radio Corporation, a nonprofit organization involved in packet-radio development.

TDM—Time division multiplexing

TDMA—Time division multiple access

Telecommand—The use of telecommunication for the transmission of signals to initiate, modify or terminate functions of equipment at a distance.

Telemetry—The use of telecommunication for automatically indicating or recording measurements at a distance from the measuring instrument.

Telephony—A form of telecommunication primarily intended for the exchange of information in the form of speech.

Telegraphy—A form of telecommunication in which the transmitted information is intended to be recorded on arrival as a graphic document; the transmitted information may sometimes be presented in an alternative form or may be stored for subsequent use.

Teleport—A radio station that acts as a relay between terrestrial radio stations and a communications satellite.

Television—A form of telecommunication for the transmission of transient images of fixed or moving objects.

Throb—A multi-frequency shift mode like MFSK16.

TNC—Terminal node controller, a device that assembles and disassembles packets (frames); sometimes called a PAD.

TR switch—Transmit-receive switch to allow automatic selection between receive and transmitter for one antenna.

TTY—Teletypewriter.

Turnaround time—The time required to reverse the direction of a half-duplex circuit, required by propagation, modem reversal and transmit-receive switching time of transceiver.

TxD—Transmitted data, physical-level data signals transferred on a circuit from the DTE to the DCE.

UI—Unnumbered information frame.

V.24—An ITU-T Recommendation defining physical-level interface circuits between a DTE (terminal) and DCE (modem), equivalent to EIA-232.

V.28—An ITU-T Recommendation defining electrical characteristics for V.24 interface.

Virtual circuit—A mode of packet networking in which a logical connection that emulates a point-to-point circuit is established (compare Datagram).

Window—In packet radio at the link layer, the range of frame numbers within the control field used to set the maximum number of frames that the sender may transmit before it receives an acknowledgment from the receiver.

X.25—An ITU-T packet-switching protocol Recommendation.

ternational standards (ANSI X3.16-1976; ITU-T Recommendation V.4) recommend an even parity sense for asynchronous and odd parity sense for synchronous data communications. The standards, however, generally are not observed by hams. By sacrificing parity, the eighth bit can be used to extend the ASCII 128-character code to 256 characters.

ASCII Serial Transmission

Serial transmission standards for ASCII (ANSI X3.15 and X3.16; ITU-T Recommendation V.4 and X.4) specify that the bit sequence shall be least-significant bit (LSB) first to most-significant bit (MSB); that is, b0 through b6 (plus the parity bit, P, if used).

Serial transmission may be either *synchronous* or *asynchronous*. In synchronous transmissions, only the information bits (and optional parity bit) are sent, as shown in Fig 9.12A.

Asynchronous serial transmission adds a start pulse and a stop pulse to each character. The start pulse length equals that of an information pulse. The stop pulse may be one or two bits long. There is some variation, but one stop bit is the convention.

ASCII Data Rates

Data-communication signaling rates depend largely on the medium and the state of the art when the equipment was selected. The most-used rates tend to progress in 2:1 steps from 300 to 9600 bits/s and in 8 kbits/s increments from 16 kbits/s upward.

The “baud” (Bd) is a unit of signaling speed equal to one discrete condition or event per second. In single-channel transmission, such as the FCC prescribes for Baudot transmissions, the signaling rate in bauds equals the data rate in bits per second. However, the FCC does not limit ASCII to single-channel transmission. Some digital modulation systems have more than two (mark and space) states. In *dibit* (pronounced “die-bit”) modulation, two ASCII bits are sampled at a time. The four possible states for a dibit are 00, 01, 10 and 11. In four-phase modulation, each state is assigned an individual phase of 0°, 90°, 180° and 270° respectively. For dibit phase modulation, the signaling speed in bauds is half the information-transfer rate in bits/s. Since the FCC specifies the digital sending speed in bauds, amateurs may transmit ASCII at higher information rates by using digital modulation systems that encode more bits per signaling element.

Amateur ASCII RTTY Operations

On April 17, 1980, the FCC first permitted ASCII in the Amateur Radio Service. Amateurs have been slow to abandon Baudot in favor of asynchronous serial

ASCII. Rather than transmitting start-stop ASCII, this code has become embedded in more sophisticated data transmission modes, which are described later in this chapter.

AMTOR

AMTOR is derived from ITU-R Recommendation M.476, and is known “narrowband direct printing” (NBPD) and commercially as “SITOR.” It has been largely overtaken by newer protocols.

AMTOR uses two forms of time diversity in either Mode A (ARQ, Automatic Repeat reQuest) or Mode B (FEC, Forward Error Correction). In Mode A, a repeat is sent only when requested by the receiving station. In Mode B, each character is sent twice. In Mode A or Mode B, the second type of time diversity is supplied by the redundancy of the code itself.

Mode B (FEC)

When transmitting to no particular station

(for example calling CQ, in a net operation or during bulletin transmissions) there is no (one) receiving station to request repeats. Mode B uses a simple forward-error-control (FEC) technique: It sends each character twice. Burst errors are virtually eliminated by delaying the repetition for a period thought to exceed the duration of most noise bursts. In AMTOR, groups of five characters are sent (DX) and then repeated (RX). At 70 ms per character, there is 280 ms between the first and second transmissions of a character.

The Information Sending Station (ISS) transmitter must be capable of 100% duty-cycle operation for Mode B. Thus, it may be necessary to reduce power level to 25% to 50% of full rating.

Mode A (ARQ)

This synchronous system transmits blocks of three characters from the Information Sending Station (ISS) to the Information Receiving Station (IRS). After each block, the IRS either acknowledges correct receipt (based on the 4/3 mark/space ratio) or requests a repeat. The station that initiates the ARQ protocol is known as the Master Station (MS). The MS first sends the selective call of the called station in blocks of three characters, listening between blocks. Four-letter AMTOR calls are normally derived from the first character and the last three letters of the station call sign. For example, W1AW’s AMTOR call would be WVAW. The Slave Station (SS) recognizes its selective call and answers that it is ready. The MS now becomes the ISS and will send traffic as soon as the IRS says it is ready.

On the air, AMTOR Mode A signals have a characteristic “chirp-chirp” sound. Because of the 210/240-ms on/off timing, Mode A can be used with some transmitters at full power levels.

PSK31

Peter Martinez, G3PLX, who was instrumental in bringing us AMTOR, also developed PSK31 for real time keyboard-to-keyboard QSOs. This section was adapted from an article in *RadCom*, Jan 1999. The name derives from the modulation type (phase-shift keying) and the data rate, which is actually 31.25 bauds. PSK31 is a robust mode for HF communications that features the 128 ASCII (Internet) characters and the full 256 ANSI character set. This mode works well for two-way QSOs and for nets. Time will tell if PSK31 will replace Baudot RTTY on the amateur HF bands.

Morse code uses a single carrier frequency keyed on and off as dits and dahs to form characters. RTTY code shifts between two frequencies, one for *mark* (1) the other for *space* (0). Sequences of marks and spaces comprise the various characters.

Martinez devised a new variable-length code for PSK31 that combines the best of Morse and RTTY. He calls it *Varicode* because a varying number of bits are used for each character (see Fig 9.13). Much like Morse code, the more commonly used letters in PSK31 have shorter codes.

As with RTTY, there is a need to signal the gaps between characters. The Varicode does this by using “00” to represent a gap. The Varicode is structured so that two zeros never appear together in any of the combinations of 1s and 0s that make up the characters. In on-the-air tests, Martinez has verified that the unique “00” sequence works significantly better than RTTY’s stop code for keeping the receiver synchronized.

With Varicode, a typing speed of about 50 words per minute requires a 32 bit/s transmission rate. Martinez chose 31.25 bit/s because it can be easily derived from the 8-kHz sample rate used in many DSP systems.

The shifting carrier phase generates sidebands 31.25 Hz from the carrier. These are used to synchronize the receiver with the transmitter. The bandwidth of a PSK31 signal is shown in Fig 9.14.

PSK31 Error Correction

Martinez added error correction to PSK31 by using QPSK (quaternary phase shift keying) and a *convolutional encoder* to generate one of four different phase shifts that correspond to patterns of five successive data bits. At the receiving end, a Viterbi decoder is used to correct errors.

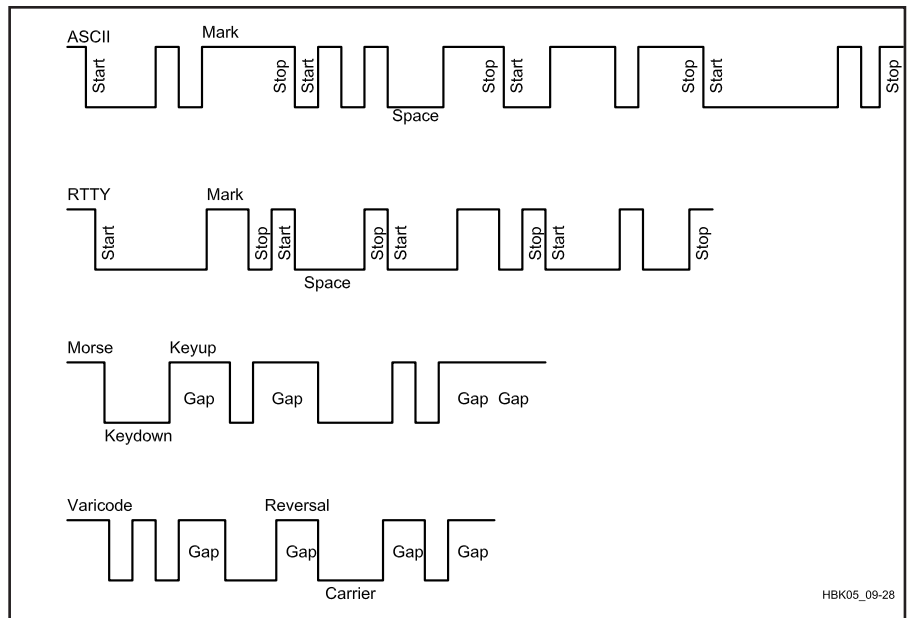

Fig 9.13—Codes for the word “ten” in ASCII, Baudot, Morse and Varicode.

Fig 9.14—The spectrum of a PSK31 signal.

There are 32 possible sequences for five bits. The Viterbi decoder tracks these possibilities while discarding the least likely and retaining the most likely sequences. Retained sequences are given a score that is based on the running total. The most accurate sequence is reported, and thus errors are corrected.

Operating PSK31 in the QPSK mode should result in 100% copy under most conditions, but at a price. Tuning is twice as critical as it is with BPSK. An accuracy of less than 4 Hz is required for the Viterbi decoder to function properly.

Getting Started

In addition to a transceiver and antenna, you only need a computer with a Windows operating system and a 16-bit sound card to receive and transmit PSK31. Additional information and software is available for free

download over the Web. Use a search engine to find PSK31 information and links to downloads.

An interesting wrinkle is to generate text, transmit it via PSK31 or some other RTTY or data mode, receive it and use a speech synthesizer to read the message. An example of this technique was described by W3NRG in the October 2004 issue of *CQ Magazine* (p 48). Synthesized speech takes some getting used to, as everybody sounds pretty much alike, and the personality of the speaker does not come through.

DATA MODES

The difference between text and data modes is not abrupt but a blur. *Data* could be

used to mean text, numbers, telecommand, telemetry and in some cases images. The third letter of the emission symbol “D” is used in common for data, telecommand and telemetry.

Packet Radio

Data communications is telecommunication between computers. *Packet switching* is a form of data communications that transfers data by subdividing it into “packets,” and *packet radio* is packet switching using the medium of radio. This description was written by Steve Ford, WB8IMY.

Packet radio has its roots in the Hawaiian Islands, where the University of Hawaii began using the mode in 1970 to transfer data to its remote sites dispersed throughout the islands. Amateur packet radio began in Canada after the Canadian Department of Communications permitted amateurs to use the mode in 1978. (The FCC permitted amateur packet radio in the US in 1980.)

In the first half of the 1980s, packet radio was the habitat of a small group of experimenters who did not mind communicating with a limited number of potential fellow packet communicators. In the second half of the decade, packet radio “took off” as the experimenters built a network that increased the potential number of packet stations that could intercommunicate and thus attracted tens of thousands of communicators who wanted to take advantage of this potential.

Packet radio provides error-free data transfer. The receiving station receives information exactly as the transmitting station sends it, so you do not waste time deciphering communication errors caused by interference or changes in propagation.

Packet uses time efficiently, since packet bulletin-board systems (PBBs) permit packet operators to store information for later retrieval by other amateurs. And it uses the radio spectrum efficiently, since one radio channel may be used for multiple communications simultaneously, or one radio channel may be used to interconnect a number of packet stations to form a “cluster” that provides for the distribution of information to all of the clustered stations. The popular *DX PacketClusters* are typical examples (see Fig 9.15).

Each local channel may be connected to other local channels to form a network that affords interstate and international data communications. This network can be used by interlinked packet bulletin-board systems to transfer information, messages and third-party traffic via HF, VHF, UHF and satellite links. Primary node-to-node links are also active on the Internet.

It uses other stations efficiently, since any packet-radio station can use one or more other packet-radio stations to relay data to

its intended destination. It uses current station transmitting and receiving equipment efficiently, since the same equipment used for voice communications may be used for packet communications. The outlay for the additional equipment necessary to make your voice station a packet-radio station may be as little as \$100. It also allows you to use that same equipment as an alternative to costly landline data communications links for transferring data between computers.

The TNC

The terminal node controller—or *TNC*—is at the heart of every packet station. A TNC

is actually a computer unto itself. It contains the AX.25 packet protocol firmware, along with other enhancements depending on the manufacturer. The TNC communicates with you through your computer or data terminal. It also allows you to communicate with other hams by feeding packet data to your transceiver.

The TNC accepts data from a computer or data terminal and assembles it into packets (see Fig 9.16). In addition, it translates the digital packet data into audio tones that can be fed to a transceiver. The TNC also functions as a receiving device, translating the audio tones into digital data a com-

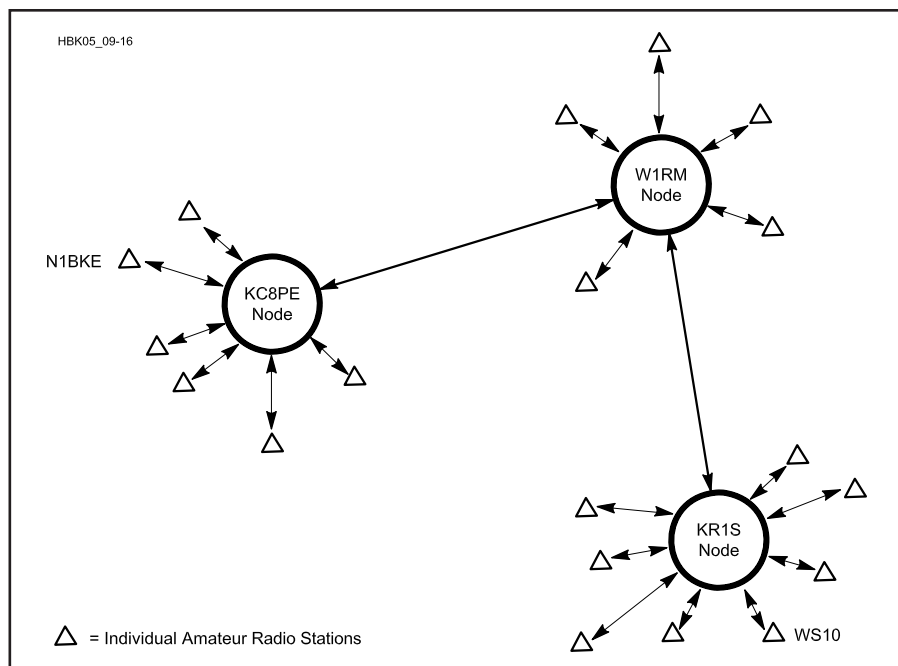

Fig 9.15—DX PacketClusters are networks comprised of individual nodes and stations with an interest in DXing and contesting. In this example, N1BKE is connected to the KC8PE node. If he finds a DX station on the air, he’ll post a notice—otherwise known as a *spot*—which the KC8PE node distributes to all its local stations. In addition, KC8PE passes the information along to the W1RM node. W1RM distributes the information and then passes it to the KR1S node, which does the same. Eventually, WS10—who is connected to the KR1S node—sees the spot on his screen. Depending on the size of the network, WS10 will receive the information within minutes after it was posted by N1BKE.

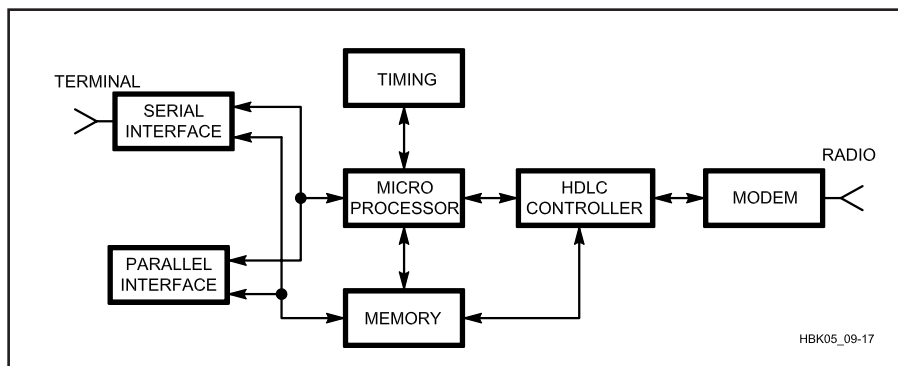

Fig 9.16—The functional block diagram of a typical TNC.

puter or terminal can understand. The part of the TNC that performs this tone-translating function is known as a *modem* (see Fig 9.17).

If you're saying to yourself, "These TNCs sound a lot like telephone modems," you're pretty close to the truth! The first TNCs were based on telephone modem designs. If you're familiar with so-called *smart* modems, you'd find that TNCs are very similar.

You have plenty of TNCs to choose from. The amount of money you'll spend depends directly on what you want to accomplish. Most TNCs are designed to operate at 300 and 1200 bit/s, or 1200 bit/s exclusively (see Fig 9.18). There are also TNCs dedicated to 1200 and 9600 bit/s operation, or 9600 bit/s exclusively. Many of these TNCs include convenient features such as personal packet mailboxes, where friends can leave messages when you're not at home. Some TNCs also include the ability to easily disconnect the existing modem and substitute another. This feature is very important if you wish to experiment at different data rates. For example, a 1200 bit/s TNC with a *modem disconnect header* can be converted to a 9600 bit/s TNC by disconnecting the 1200 bit/s modem and adding a 9600 bit/s modem.

If you're willing to spend more money, you can buy a complete *multimode communications processor*, or *MCP*. These devices not only offer packet, they also provide the capability to operate RTTY, CW, AMTOR, PACTOR, FAX and other modes. In other words, an MCP gives you just about every digital mode in one box.

TNC Emulation and Internal TNCs

TNC-emulation systems exist for IBM PCs and compatibles. One is known as *BayCom*, which uses the PC to emulate the functions of a TNC/terminal while a small external modem handles the interfacing. BayCom packages are available in kit form for roughly half the price of a basic TNC.

PC owners also have the option of buying full-featured TNCs that mount *inside* their computers. TNC *cards* are available on the market. They are complete TNCs that plug into card slots inside the computer cabinet. No TNC-to-computer cables are necessary. Connectors are provided for cables that attach to your transceiver. In many cases, specialized software is also provided for efficient operation.

Transceiver Requirements

Packet activity on the HF bands typically takes place at 300 bit/s using common SSB transceivers. The transmit audio is fed from the TNC to the microphone jack or auxiliary audio input. Receive audio is obtained from the radio's external speaker jack or auxil-

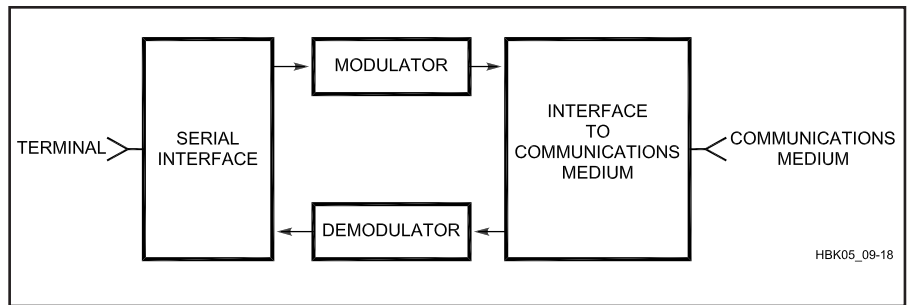

Fig 9.17—A block diagram of a typical modem.

Fig 9.18—Four popular 1200 bit/s packet TNCs: (clockwise, from bottom left) the MFJ-1270C, AEA PK-88, Kantronics KPC-3 and the DRSI DPK-2.

ary audio output. Tuning is critical for proper reception; a visual tuning indicator—available on some TNCs and all MCPs—is recommended.

These simple connections also work for 1200 bit/s packet, which is common on the VHF bands (2 m in particular). Almost any FM transceiver can be made to work with 1200 bit/s packet by connecting the transmit audio to the microphone jack and taking the receive audio from the external speaker (or earphone) jack.

At data rates beyond 1200 bit/s, transceiver requirements become more rigid. At 9600 bit/s (the most popular data rate above 1200 bit/s), the transmit audio must be injected at the modulator stage of the FM transceiver. Receive audio must be tapped at the discriminator. Most 9600 bit/s operators use modified Amateur Radio transceivers or commercial radios.

In the mid 1990s amateur transceiver manufacturers began incorporating data ports on some FM voice rigs. The new "data-ready" radios are not without problems, however. Their IF filter and discriminator characteristics leave little room for error. If you're off frequency by a small amount, you may not be able to pass data. In addition, the ceramic discriminator coils

used in some transceivers have poor group delay, making it impossible to tune them for wider bandwidths. With this in mind, some amateurs prefer to make the leap to 9600 bit/s and beyond using dedicated amateur data radios.

Regardless of the transceiver used, setting the proper deviation level is extremely critical. At 9600 bit/s, for example, optimum performance occurs when the maximum deviation is maintained at 3 kHz. Deviation adjustments involve monitoring the transmitted signal with a deviation meter or service monitor. The output level of the TNC is adjusted until the proper deviation is achieved.

PACKET NETWORKING

Digipeaters

A *digipeater* is a packet-radio station capable of recognizing and selectively repeating packet frames. An equivalent term used in industry is *bridge*. Virtually any TNC can be used as a single-port digipeater, because the digipeater function is included in the AX.25 Level 2 protocol firmware. Although the use of digipeaters is waning today as network nodes take their place, the digipeater function is handy when you

need a relay and no node is available, or for on-the-air testing.

TCP/IP

If you're an active packeteer, sooner or later someone will bring up the subject of TCP/IP—Transmission Control Protocol/Internet Protocol. Despite its name, TCP/IP is more than two protocols; it's actually a set of several protocols. Together they provide a high level of flexible, "intelligent" packet networking. TCP/IP enthusiasts see a future when the entire nation, and perhaps the world, will be linked by high-speed TCP/IP systems using terrestrial microwave and satellites.

TCP/IP has a unique solution for busy networks. Rather than transmitting packets at randomly determined intervals, TCP/IP stations automatically *adapt* to network delays as they occur. As network throughput slows down, active TCP/IP stations sense the change and lengthen their transmission delays accordingly. As the network speeds up, the TCP/IP stations shorten their delays to match the pace. This kind of intelligent network sharing virtually guarantees that all packets will reach their destinations with the greatest efficiency the network can provide.

With TCP/IP's adaptive networking scheme, you can chat using the *telnet* protocol with a ham in a distant city and rest assured that you're not overburdening the system. Your packets simply join the constantly moving "freeway" of data. They might slow down in heavy traffic, but they *will* reach their destination eventually. (This adaptive system is used for all TCP/IP packets, no matter what they contain.)

TCP/IP excels when it comes to transferring files from one station to another. By using the TCP/IP *file transfer protocol* (ftp), you can connect to another station and transfer computer files—including software. As you can probably guess, transferring large files can take time. With TCP/IP, however, you can still send and receive mail (using the *SMTP* protocol) or talk to another ham while the transfer is taking place.

When you attempt to contact another station using TCP/IP, all network routing is performed automatically according to the TCP/IP address of the station you're trying to reach. In fact, TCP/IP networks are transparent to the average user.

To operate TCP/IP, all you need is a computer (it must be a computer, not a terminal), a 2-m FM transceiver and a TNC with *KISS* capability. As you might guess, the heart of your TCP/IP setup is software. The TCP/IP software set was written by Phil Karn, KA9Q, and is called *NOSNET* or just *NOS* for short.

There are dozens of *NOS* derivatives available today. All are based on the origi-

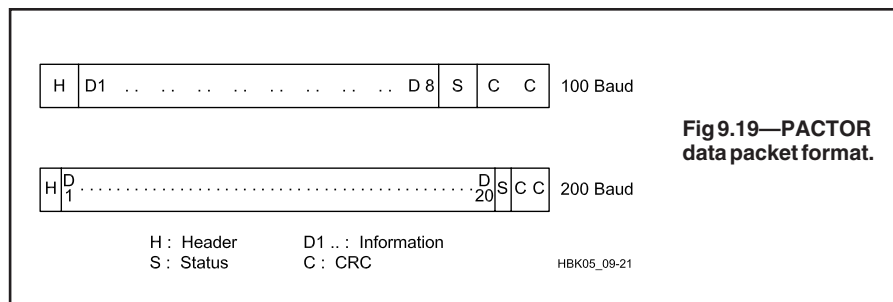

Fig 9.19—PACTOR data packet format.

nal *NOSNET*. The programs are available primarily for IBM-PC compatibles and Macintoshes. You can obtain *NOS* software from on-line sources such as the CompuServe *HAMNET* forum libraries, Internet ftp sites, Amateur Radio-oriented BBSs and elsewhere. *NOS* takes care of all TCP/IP functions, using your "KISSable" TNC to communicate with the outside world. The only other item you need is your own IP address. Individual IP Address Coordinators assign addresses to new TCP/IP users.

PACTOR

PACTOR (PT), now often referred to as PACTOR-I, is an HF radio transmission system developed by German amateurs Hans-Peter Helfert, DL6MAA, and Ulrich Strate, DF4KV. It was designed to overcome the shortcomings of AMTOR and packet radio. It performs well under both weak-signal and high-noise conditions. PACTOR-I has been overtaken by PACTOR-II and PACTOR-III but remains in use.

TRANSMISSION FORMATS

Information Blocks

All packets have the basic structure shown in **Fig 9.19**, and their timing is as shown in **Table 9.1**:

- **Header:** Contains a fixed bit pattern to simplify repeat requests, synchronization and monitoring. The header is also important for the Memory ARQ function. In each packet carrying new information, the

Table 9.1

PACTOR Timing

Object	Length (seconds)
Packet	0.96 (200 bd: 192 bits; 100 bd: 96 bits)
CS receive time	0.29
Control signals	0.12 (12 bits at 10 ms each)
Propagation delay	0.17
Cycle	1.25

Table 9.2

PACTOR Status Word

Bit	Meaning
0	Packet count (LSB)
1	Packet count (MSB)
2	Data format (LSB)
3	Data format (MSB)
4	Not defined
5	Not defined
6	Break-in request
7	QRT request

Data Format Bits

Format	bit 3	bit 2
ASCII 8 bit	0	0
Huffman code	0	1
Not defined	1	0
Not defined	1	1

Bits 0 and 1 are used as a packet count; successive packets with the same value are identified by the receiver as repeat packets. A modulus-4 count helps with unrecognized control signals, which are unlikely in practice.

bit pattern is inverted.

- **Data:** Any binary information. The format is specified in the status word. Current choices are 8-bit ASCII or 7-bit ASCII (with Huffman encoding). Characters are not broken across packets. ASCII RS (hex 1E) is used as an IDLE character in both formats.
- **Status word:** See **Table 9.2**
- **CRC:** The CRC is calculated according to the CCITT standard, for the data, status and CRC.

Acknowledgment Signals

The PACTOR acknowledgment signals are shown in **Table 9.3**. Each of the signals is 12 bits long. The characters differ in pairs in 8 bits (Hamming offset) so that the chance of confusion is reduced. If the CS is not correctly received, the TX reacts by repeating the last packet. The request status can be uniquely recognized by the 2-bit packet number so that wasteful transmissions of pure RQ blocks are unnecessary.

Timing

The receiver pause between two blocks is 0.29 s. After deducting the CS lengths, 0.17 s remain for switching and propagation delays so that there is adequate reserve for DX operation.

CONTACT FLOW

Listening

In the listen mode, the receiver scans any received packets for a CRC match. This method uses a lot of computer processing resources, but it's flexible.

CQ

A station seeking contacts transmits CQ packets in an FEC mode, without pauses for acknowledgment between packets. The transmit time length, number of repetitions and speed are the transmit operator's choice. (This mode is also suitable for bulletins and other group traffic.) Once a listening station has copied the call, the listener assumes the TX station role and initiates a contact. Thus, the station sending CQ initially takes the RX station role. The contact begins as shown in **Table 9.4**

Speed Changes

With good conditions, PACTOR's normal signaling rate is 200 bauds, but the system automatically changes from 200 to 100 bauds and back, as conditions demand. In addition, Huffman coding can further increase the throughput by a factor of 1.7. There is no loss of synchronization speed changes; only one packet is repeated.

When the RX receives a bad 200-baud packet, it can acknowledge with CS4. TX immediately assembles the previous packet in 100-baud format and sends it. Thus, one packet is repeated in a change from 200 to 100 bauds.

The RX can acknowledge a good 100-baud packet with CS4. TX immediately switches to 200 bauds and sends the next packet. There is no packet repeat in an upward speed change.

Change of Direction

The RX station can become the TX station by sending a special change-over

packet in response to a valid packet. RX sends CS3 as the first section of the changeover packet. This immediately changes the TX station to RX mode to read the data in that packet and responds with CS1 and CS3 (acknowledge) or CS2 (reject).

End of Contact

PACTOR provides a sure end-of-contact procedure. TX initiates the end of contact by sending a special packet with the QRT bit set in the status word and the call of the RX station in byte-reverse order at 100 bauds. The RX station responds with a final CS.

PACTOR-II

This is a significant improvement over PACTOR-I, yet it is fully compatible with the older mode. Also invented in Germany, PACTOR uses 16PSK to transfer up to 800 bit/s at a 100-baud rate. This keeps the bandwidth less than 500 Hz.

PACTOR-II uses digital signal processing (DSP) with Nyquist waveforms, Huffman and Markov compression, and powerful Viterbi decoding to increase transfer rate and sensitivity into the noise level. The effective transfer rate of text is over 1200 bit/s. Features of PACTOR II include:

- Frequency agility—It can automatically adjust or lock two signals together over a ± 100 -Hz window.
- Powerful data reconstruction based upon computer power—With over 2 MB of available memory.
- Cross correlation—Applies analog Memory ARQ to acknowledgment frames and headers.
- Soft decision making—Uses artificial intelligence (AI), as well as digital information received to determine frame validity.
- Extended data block length—When transferring large files under good conditions, the data length is doubled to increase the transfer rate.
- Automatic recognition of PACTOR-I, PACTOR-II and so on, with automatic mode switching.
- Intermodulation products are canceled by the coding system.
- Two long-path modes extend frame tim-

Table 9.3

PACTOR Control Signals

Code	Chars(hex)	Function
CS1	4D5	Normal acknowledge
CS2	AB2	Normal acknowledge
CS3	34B	Break-in (forms header of first packet from RX to TX)
CS4	D2C	Speed change request

All control signals are sent only from RX to TX.

ing for long-path terrestrial and satellite propagation paths.

This is a fast, robust mode, possibly the most powerful in the ham bands. It has excellent coding gain as well. It can also communicate with all earlier PACTOR-I systems. PACTOR-II stations acknowledge each received transmission block. PACTOR-II employs computer logic as well as received data to reassemble defective data blocks into good frames. This reduces the number of transmissions and increases the throughput of the data.

PACTOR-III

PACTOR-III is a software upgrade for existing PACTOR-II modems that provides a data transmission mode for improved speed and robustness. PACTOR-III is not a new modem or hardware device. Most current PACTOR-II modems are upgradeable to use PACTOR-III via a software update, since PACTOR-II firmware accommodates the new PACTOR-III software. Both the transmitting and receiving stations must support PACTOR-III for end-to-end communications using this mode.

PACTOR-III's maximum uncompressed speed is 2722 bit/s. Using online compression, up to 5.2 kbit/s is achievable. This requires an audio passband from 400 Hz to 2600 Hz (for PACTOR-III speed level 6).

On an average channel, PACTOR-III is more than three times faster than PACTOR-II. On good channels, the effective throughput ratio between PACTOR-III and PACTOR-II can exceed five. PACTOR-III is also slightly more robust than PACTOR-II at their lower SNR edges.

The ITU emission designator for PACTOR-III is 2K20J2D. Because PACTOR-III builds on PACTOR-II, most specifications like frame length and frame structure are adopted from PACTOR-II. The only significant difference is PACTOR III's multi-tone waveform that uses up to 18 carriers while PACTOR-II uses only two carriers. PACTOR-III's carriers are located in a 120-Hz grid and modulated with 100 symbols per second DBPSK or DQPSK. Channel coding is also adopted from PACTOR-II's Punctured Convolutional Coding.

PACTOR-III Link Establishment

The calling modem uses the PACTOR-I FSK connect frame for compatibility. When the called modem answers, the modems negotiate to the highest level of which both modems are capable. If one modem is only capable of PACTOR-II, then the 500 Hz PACTOR-II mode is used for the session. With the *MYLevel* (MYL) command a user may limit a modem's highest mode. For example, a user may set MYL to "1" and

Table 9.4**PACTOR Initial Contact****Master Initiating Contact**

Size (bytes)	1	8	6
Content	/Header	/SLAVECAL	/SLAVECAL/
Speed (bauds)	100	100	200

Slave Response

The receiving station detects a call, determines mark/space polarity, decodes 100-bd and 200-bd call signs. It uses the two call signs to determine if it is being called and the quality of the communication path. The possible responses are:

First call sign does not match slave's (Master not calling this slave)	none
Only first call sign matches slave's (Master calling this slave, poor communications)	CS1
First and second call signs both match the slaves (good circuit, request speed change to 200 bd)	CS4

Table 9.5**CLOVER-II Modulation Modes**

As presently implemented, CLOVER-II supports a total of 7 different modulation formats: 5 using PSM and 2 using a combination of PSM and ASM (Amplitude Shift Modulation).

Name	Description	In-Block Data Rate
16P4A	16 PSM, 4-ASM	750 bps
16PSM	16 PSM	500 bps
8P2A	8 PSM, 2-ASM	500 bps
8PSM	8 PSM	375 bps
QPSM	4 PSM	250 bps
BPSM	Binary PSM	125 bps
2DPSM	2-Channel Diversity BPSM	62.5 bps

only a PACTOR-I connection will be made, set to "2" and PACTOR-I and II connections are available, set to "3" and PACTOR-I through III connections are enabled. The default MYL is set to "2" with the current firmware and with PACTOR-III firmware it will be set to "3". If a user is only allowed to occupy a 500 Hz channel, MYL can be set to "2" and the modem will stay in its PACTOR-II mode. The PACTOR-III Protocol Specification is available on the Web at www.scs-ptc.com/pactor.html.

Ford, Steve, WB8IMY, ARRL's *HF Digital Handbook*, Third Ed., ARRL, 2004.

G-TOR

This brief description has been adapted from "A Hybrid ARQ Protocol for Narrow Bandwidth HF Data Communication" by Glenn Prescott, WBØSKX, Phil Anderson, WØXI, Mike Huslig, KBØNYK, and Karl Medcalf, WK5M (May 1994 *QEX*).

G-TOR is short for *Golay-TOR*, an innovation of Kantronics, Inc. It was inspired by

HF Automatic Link Establishment (ALE) concepts and is structured to be compatible with ALE.

The purpose of the G-TOR protocol is to provide an improved digital radio communication capability for the HF bands. The key features of G-TOR are:

- Standard FSK tone pairs (mark and space)
- Link-quality-based signaling rate: 300, 200 or 100 bauds
- 2.4-second transmission cycle
- Low overhead within data frames
- Huffman data compression—two types, on demand
- Embedded run-length data compression
- Golay forward-error-correction coding
- Full-frame data interleaving
- CRC error detection with hybrid ARQ
- Error-tolerant "Fuzzy" acknowledgments.

The G-TOR Protocol

Since one of the objectives of this protocol is ease of implementation in existing TNCs, the modulation format consists of standard tone pairs (FSK), operating at 300, 200 or 100 bauds, depending upon channel conditions. (G-TOR initiates contacts and sends ACKs only at 100 bauds.) The G-TOR

waveform consists of two phase-continuous tones (BFSK), spaced 200 Hz apart (mark = 1600 Hz, space = 1800 Hz); however, the system can still operate at the familiar 170-Hz shift (mark = 2125 Hz, space = 2295 Hz), or with any other convenient tone pairs. The optimum spacing for 300-baud transmission is 300 Hz, but you trade some performance for a narrower bandwidth.

Each transmission consists of a synchronous ARQ 1.92-s frame and a 0.48-s interval for propagation and ACK transmissions (2.4 s cycle). All advanced protocol features are implemented in the signal-processing software.

Data Compression

Data compression is used to remove redundancy from source data. Therefore, fewer bits are needed to convey any given message. This increases data throughput and decreases transmission time—valuable features for HF. G-TOR uses run-length coding and two types of Huffman coding during normal text transmissions. Run-length coding is used when more than two repetitions of an 8-bit character are sent. It provides an especially large savings in total transmission time when repeated characters are being transferred.

The Huffman code works best when the statistics of the data are known. G-TOR applies Huffman A coding with the upper- and lower-case character set, and Huffman B coding with upper-case-only text. Either type of Huffman code reduces the average number of bits sent per character. In some situations, however, there is no benefit from Huffman coding. The encoding process is then disabled. This decision is made on a frame-by-frame basis by the information-sending station.

Golay Coding

The real power of G-TOR resides in the properties of the (24,12) extended Golay error-correcting code, which permits correction of up to three random errors in three received bytes. The (24,12) extended Golay code is a half-rate error-correcting code: Each 12 data bits are translated into an additional 12 parity bits (24 bits total). Further, the code can be implemented to produce separate input-data and parity-bit frames.

The extended Golay code is used for G-TOR because the encoder and decoder are simple to implement in software. Also, Golay code has mathematical properties that make it an ideal choice for short-cycle synchronous communication.

CLOVER-II

The desire to send data via HF radio at high data rates and the problems encountered when using AX.25 packet radio on HF radio led Ray Petit, W7GHM, to develop a unique modulation waveform and data transfer protocol that is now called "CLOVER-II." Bill Henry, K9GWT, supplied this description of the Clover-II system. CLOVER modulation is characterized by the following key parameters:

- Very low base symbol rate: 31.25 symbols/second (all modes).
- Time-sequence of amplitude-shaped pulses in a very narrow frequency spectrum. Occupied bandwidth = 500 Hz at 50 dB below peak output level.
- Differential modulation between pulses.
- Multilevel modulation.

The low base symbol rate is very resistant to multipath distortion because the time between modulation transitions is much longer than even the worst-case time-smearing caused by summing of multipath signals. By using a time-sequence of tone pulses, Dolph-Chebyshev "windowing" of the modulating signal and differential modulation, the total occupied bandwidth of a CLOVER-II signal is held to 500 Hz.

The CLOVER Waveform

Multilevel tone, phase and amplitude modulation give CLOVER a large selection of data modes that may be used (see **Table 9.5**). The adaptive ARQ mode of CLOVER senses current ionospheric conditions and automatically adjusts the modulation mode to produce maximum data throughput. When using the "Fast" bias setting, ARQ throughput automatically varies from 11.6 byte/s to 70 byte/s.

The CLOVER-II waveform uses four tone pulses that are spaced in frequency by 125 Hz. The time and frequency domain characteristics of CLOVER modulation are shown in **Figs 9.20, 9.21 and 9.22**. The time-domain shape of each tone pulse is intentionally shaped to produce a very compact frequency spectrum. The four tone pulses are spaced in time and then combined to produce the composite output shown. Unlike other modulation schemes, the CLOVER modulation spectra is the same for all modulation modes.

Modulation

Data is modulated on a CLOVER-II signal by varying the phase and/or amplitude of the tone pulses. Further, all data modulation is differential on the same tone pulse—

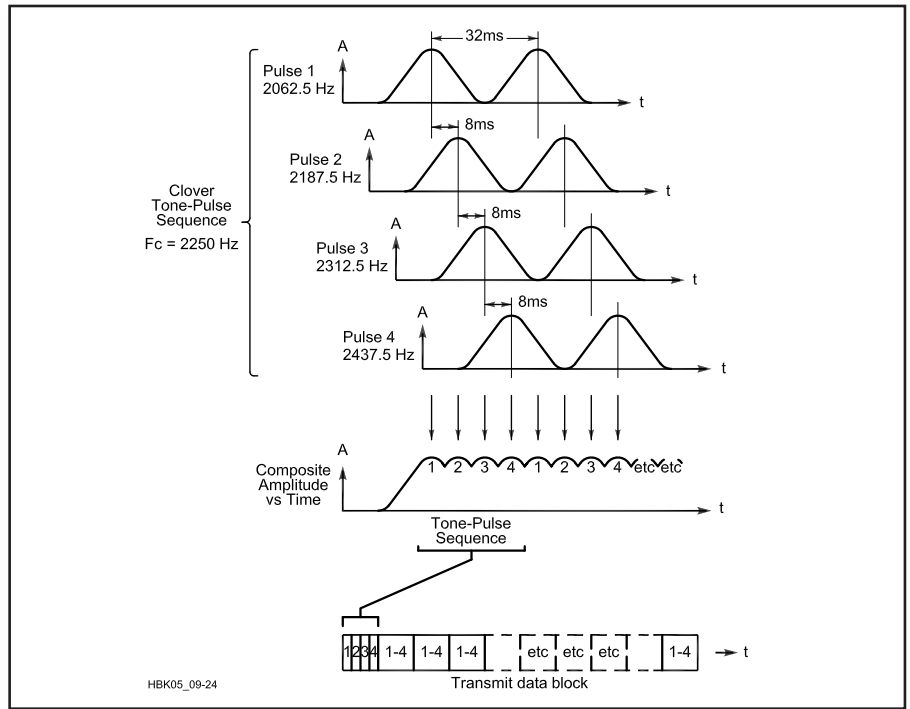

Fig 9.20—Amplitude vs time plots for CLOVER-II's four-tone waveform.

Fig 9.21—A frequency-domain plot of a CLOVER-II waveform.

data is represented by the phase (or amplitude) difference from one pulse to the next. For example, when binary phase modulation is used, a data change from "0" to "1" may be represented by a change in the phase of tone pulse 1 by 180° between the first and second occurrence of that pulse. Further, the phase state is changed only while the pulse amplitude is zero. Therefore, the wide frequency spectra normally associated with

PSK of a continuous carrier is avoided. This is true for all CLOVER-II modulation formats. The term "phase-shift modulation" (PSM) is used when describing CLOVER modes to emphasize this distinction.

Coder Efficiency Choices

CLOVER-II has four "coder efficiency" options: 60%, 75%, 90% and 100% ("efficiency" being the approximate ratio of real data bytes to total bytes sent). "60% efficiency" corrects the most errors but has the lowest net data throughput. "100% efficiency" turns the encoder off and has the highest throughput but fixes no errors. There is therefore a tradeoff between raw data throughput versus the number of errors that can be corrected without resorting to retransmission of the entire data block.

Note that while the "In Block Data Rate" numbers listed in the table go as high as 750 bit/s, overhead reduces the net throughput or overall efficiency of a CLOVER transmission. The FEC coder efficiency setting and protocol requirements of FEC and ARQ modes add overhead and reduce the net efficiency. **Table 9.6** and **Table 9.7** detail the relationships between block size, coder efficiency, data bytes per block and correctable byte errors per block.

CLOVER FEC

All modes of CLOVER-II use Reed-Solomon forward error correction (FEC) data encoding, which allows the receiving station to correct errors without requiring a

Table 9.6**Data Bytes Transmitted Per Block**

Block Size	Reed-Solomon Encoder Efficiency			
	60%	75%	90%	100%
17	8	10	12	14
51	28	36	42	48
85	48	60	74	82
255	150	188	226	252

Table 9.7**Correctable Byte Errors Per Block**

Block Size	Reed-Solomon Encoder Efficiency			
	60%	75%	90%	100%
17	1	1	0	0
51	9	5	2	0
85	16	10	3	0
255	50	31	12	0

repeat transmission. This is a very powerful error-correction technique that is not available in some other common HF data modes.

CLOVER ARQ

Reed-Solomon data coding is the primary means by which errors are corrected in CLOVER “FEC” mode. In ARQ mode, CLOVER-II employs a three-step strategy to combat errors. First, channel parameters are measured and the modulation format is adjusted to minimize errors and maximize data throughput. This is called the “Adaptive ARQ Mode” of CLOVER-II. Second, Reed-Solomon encoding is used to correct a limited number of byte errors per transmitted block. Finally, only those data blocks in which errors exceed the capacity of the Reed-Solomon decoder are repeated (selective block repeat).

With seven different modulation formats, four data-block lengths (17, 51, 85 or 255 bytes) and four Reed-Solomon coder efficiencies (60%, 75%, 90% and 100%), there are 112 ($7 \times 4 \times 4$) different waveform modes that could be used to send data via CLOVER. Once all of the determining factors are considered, however, there are eight different waveform combinations that are actually used for FEC and/or ARQ modes.

CLOVER-2000

CLOVER-2000 is a faster version of CLOVER (about four times faster) that uses eight tone pulses, each of which is 250 Hz wide, spaced at 250-Hz centers, contained within the 2-kHz bandwidth between 500 and 2500 Hz. The eight tone pulses are sequential, with only one tone being present at any instant and each tone lasting 2 ms. Each frame consists of eight tone pulses lasting a total of 16 ms, so the base modu-

**Fig 9.22—Spectra plots of AMTOR, HF packet-radio and CLOVER-II signals.**

lation rate of a CLOVER-2000 signal is always 62.5 symbols per second (regardless of the type of modulation being used). CLOVER-2000’s maximum raw data rate is 3000 bit/s.

Allowing for overhead, CLOVER-2000 can deliver error-corrected data over a standard HF SSB radio channel at up to 1994 bit/s, or 249 characters (8-bit bytes) per second. These are the uncompressed data rates; the maximum throughput is typically doubled for plain text if compression is used. The effective data throughput rate of CLOVER-2000 can be even higher when binary file transfer mode is used with data compression.

The binary file transfer protocol used by HAL Communications operates with a terminal program explained in the HAL E2004 engineering document listed under references. Data compression algorithms tend to be context sensitive—compression that works well for one mode (eg, text), may not work well for other data forms (graphics, etc). The HAL terminal program uses the PK-WARE compression algorithm, which has proved to be a good general-purpose compressor for most computer files and programs. Other algorithms may be more efficient for some data formats, particularly for compression of graphic image files and digitized voice data. The HAL Communications CLOVER-2000 modems can be operated with other data compression algorithms in the users’ computers.

CLOVER-2000 is similar to the previous version of CLOVER, including the transmission protocols and Reed-Solomon error detection and correction algorithm. The

original descriptions of the CLOVER Control Block (CCB) and Error Correction Block (ECB) still apply for CLOVER-2000, except for the higher data rates inherent to CLOVER-2000. Just like CLOVER, all data sent via CLOVER-2000 is encoded as 8-bit data bytes and the error-correction coding and modulation formatting processes are transparent to the data stream—every bit of source data is delivered to the receiving terminal without modification.

Control characters and special “escape sequences” are not required or used by CLOVER-2000. Compressed or encrypted data may therefore be sent without the need to insert (and filter) additional control characters and without concern for data integrity. Five different types of modulation may be used in the ARQ mode—BPSM (Binary Phase Shift Modulation), QPSM (Quadrature PSM), 8PSM (8-level PSM), 8P2A (8PSM + 2-level Amplitude-Shift Modulation), and 16P4A (16 PSM plus 4 ASM).

The same five types of modulation used in ARQ mode are also available in Broadcast (FEC) mode, with the addition of 2-Channel Diversity BPSM (2DPSM). Each CCB is sent using 2DPSM modulation, 17-byte block size and 60% bias. The maximum ARQ data throughput varies from 336 bit/s for BPSM to 1992 bit/s for 16P4A modulation. BPSM is most useful for weak and badly distorted data signals, while the highest format (16P4A) needs extremely good channels, with high SNRs and almost no multipath.

Most ARQ protocols designed for use with HF radio systems can send data in only one direction at a time. CLOVER-2000

does not need an “OVER” command; data may flow in either direction at any time. The CLOVER ARQ time frame automatically adjusts to match the data volume sent in either or both directions. When first linked, both sides of the ARQ link exchange information using six bytes of the CCB. When one station has a large volume of data buffered and ready to send, ARQ mode automatically shifts to an expanded time frame during which one or more 255 byte data blocks are sent.

If the second station also has a large volume of data buffered and ready to send, its half of the ARQ frame is also expanded. Either or both stations will shift back to CCB level when all buffered data has been sent. This feature provides the benefit of full-duplex data transfer but requires use of only simplex frequencies and half-duplex radio equipment. This two-way feature of CLOVER can also provide a back-channel order-wire capability. Communications may be maintained in this “chat” mode at 55 words per minute, which is more than adequate for real-time keyboard-to-keyboard communications.

SCAMP AND RDFT

SCAMP (Sound Card Amateur Message Protocol) is intended as a low-cost alternative to commercial modems (TNCs). A paper describing SCAMP was presented by Rick Muething, KN6KB, at the 2004 ARRL/TAPR Digital Communications Conference. It is a new digital sound card protocol suitable for both HF and VHF for transmission of text messages with binary attachments. It is compatible with Winlink 2000 and is designed for manually initiated message forwarding. SCAMP is not a keyboard (chat) mode.

SCAMP incorporates the work by Barry Sanderson, KB9VAK, on Redundant Digital File Transfer (RDFT) and adds an ARQ wrapper around RDFT to ensure error-free

transmission. There are four redundancy levels: 10%, 20%, 40% and 70%, the latter being the most robust and requires the most transmission time. Audio data is sent at a standard rate of 11.025 kHz, with 16-bit samples using a PC sound card. SCAMP occupies a bandwidth of about 2 kHz and a net throughput of 2 to 4 kbytes/minute, depending on conditions. It employs an automated “channel-busy” detector for reduction of QRM and to protect against QRM from “hidden transmitters.” For more details, please see the SCAMP Bibliography, below.

On-the-air peer-to-peer testing began in November 2004 and the first transcontinental transmission was made in December 2004 between N6KZB in Temecula, CA, and W3QA in West Chester, PA. Beta testing began of SCAMP with WinLink 2000 in March 2005.

AUTOMATIC LINK ESTABLISHMENT

The US military services have found it difficult to maintain a sufficient number of qualified radio operators to operate MF/HF radios. So the Defense Department contracted with MITRE Corporation for the development of a method of operating MF/HF radios without skilled operators. MITRE studied what skilled operators do and developed Automatic Link Establishment (ALE) to operate radios and make contact with another station without human intervention and under computer control. ALE automatically finds the best frequency among a pre-arranged list using techniques such as selective calling, handshaking, link quality analysis, polling, sounding, etc.

ALE is used by the Military Affiliate Ra-

dio Service (MARS). It has also been adopted by some radio amateurs.

ALE Waveform

The ALE waveform is designed to be compatible with the audio passband of a standard SSB radio. It has a robust waveform for reliability during poor path conditions. It consists of 8-ary frequency-shift keying (FSK) modulation with eight orthogonal tones, a single tone for a symbol. These tones represent 3 bits of data, with least significant bit to the right, as follows:

Frequency	Data
750 Hz	000
1000 Hz	001
1250 Hz	011
1500 Hz	010
1750 Hz	110
2000 Hz	111
2250 Hz	101
2500 Hz	100

The tones are transmitted at a rate of 125 tones per second, 8 ms per tone. The resultant transmitted bit rate is 375 bit/s. The basic ALE word consists of 24 bits of information. Details can be found in Federal Standard 1045, Detailed Requirements, www.its.bldrdoc.gov/fs-1054a/45-detr.htm.

IRLP

Created by David Cameron, W7LTD, the Internet Radio Linking Project (IRLP) uses Voice over Internet Protocol (VoIP) to form a voice communications network

Internetworking

Although it has been a goal of some radio amateurs to develop a digital communications network independent of the Internet, interconnection with the Internet provides a good bridge between isolated amateur radio nets. Several methods of transferring data, e-mail or linking repeaters have been developed.

WINLINK 2000

WinLink 2000 is a *Windows* application that permits messages to be transferred automatically between the Internet and remote amateur stations, which may be on recreational vehicles or at sea. The Internet is used as a backbone to allow WinLink mailbox operation (MBO) stations to share their data-

of servers and nodes between amateur repeaters and/or simplex stations. See: www.irlp.net/.

EchoLink

EchoLink was developed by Jonathan Taylor, K1RFD, to link a personal computer to communicate by VoIP with several thousand repeaters having *EchoLink* capabilities. Or, it can be used to permit amateur stations within range of your station to connect with the Internet. See: www.echolink.org/.

eQSO

eQSO, created by Paul Davies, MØZPD, was designed to operate like a worldwide amateur radio net. See: www.eqso.net/.

TELEMETRY, TRACKING AND TELECOMMAND

According to FCC Part 97 rules, *telemetry* is a one-way transmission of measurements at a distance from the measuring instrument, whereas *telecommand* is a one-way transmission to initiate, modify or terminate functions of a device at a distance. Actually, the two go hand in hand, since it is important to have telemetry first, then modify the remote device, then look once again in the telemetry to see if the desired action took place.

Telemetry, tracking and telecommand (often seen as TT&C) are attracting increasing attention because Amateur Radio rules permit higher power transmitters than allowed under Part 15 of the FCC rules. TT&C is distinct from traditional forms of Amateur Radio (telegraphy, voice and image intended to be heard or seen by human operators), since it receives information from an

object and commands the object to take an action. Although pulse modulation systems are common, TT&C also uses familiar communications modes, such as television (in this case used as a form of telemetry), packet radio (such as ASCII used for telemetry coding, commands or uploading programs).

This section provides only a sampling of telemetry, tracking and telecommand systems involving Amateur Radio. *APRS* (Automatic Position Reporting System) is a marriage of an application of the Global Positioning System and Amateur Radio to relay position and tracking information. Telemetry and telecommand are also used to manage remote terrestrial stations, as well as amateur satellites. Radio Control (R/C) of remote objects has long been a part of Amateur Radio because of the versatility offered by Part 97 rules to licensed operators. R/C is not limited to model cars, boats and airplanes but is vital for the growing field of robotics.

APRS

Bob Bruninga, WB4APR, developed Automatic Position Reporting System (APRS) as a result of trying to use packet radio for real-time communications for public service events. Packet radio is not well suited for those real-time events, where information has a very short lifetime. APRS avoids the complexity and limitations of trying to maintain a connected network. It uses UI (unconnected) frames to permit any number of stations to participate and exchange data, just like voice users would on a voice net. Stations that have information to contribute simply transmit it, and all stations monitor and collect all data on frequency. APRS also recognizes that one of the greatest real-time needs at any special event or emergency is the knowledge of where all stations and other key assets are located. APRS accomplishes the real-time display of operational traffic via a split screen and map displays.

Since the object of APRS is the rapid dissemination of real-time information using packet UI frames, a fundamental precept is that old information is less important than new information. All beacons, position reports, messages and display graphics are redundantly transmitted, but at longer and

longer repetition rates. Each new beacon is transmitted immediately, then again 20 seconds later. After every transmission, the period is doubled. After ten minutes only six packets have been transmitted. After an hour this results in only three more beacons; and only three more for the rest of the day! Using this redundant UI broadcast protocol, APRS is actually much more efficient than if a fully connected link had to be maintained between all stations.

The standard configuration for packet radio hardware (radio-to-TNC-to-computer) also applies to APRS until you add a GPS (Global Positioning System) receiver to the mix. You don't need a GPS receiver for a stationary APRS installation (nor do you need a computer for a mobile or tracker APRS installation). In these cases, an extra port or special cable is not necessary. It is necessary, however, when you desire both a computer and a GPS receiver in the same installation.

One way of accomplishing this is by using a TNC or computer that has an extra serial port for a GPS receiver connection. Alternatively, you can use a hardware single port switch (HSP) cable to connect a TNC and GPS receiver to the same serial port of your computer. The HSP cable is available from a number of sources including TNC manufacturers Kantronics, MFJ and PacComm.

Whichever GPS connection you use, make sure that you configure the APRS software so it is aware that a GPS receiver is part of the hardware configuration and how the GPS receiver connection is accomplished.

APRS also supports an optional weather station interface. The wind speed, direction, temperature and rainfall are inserted into the station's periodic position report. The station shows up on all APRS maps as a large blue dot, with a white line showing the wind speed and direction. Several automatic APRS weather reporting stations, supported with additional manual reporting stations, can form a real-time reporting network in support of SKYWARN activities. For additional information see the book, *APRS Tracks, Maps and Mobiles* by Stan Horzempa, WA1LOU, published by ARRL.

Radio Control (R/C)

Amateur Radio gave birth to the radio control (R/C) hobby as we know it today. FCC §97.215 rules specifically permit "remote control of model craft" as a licensed amateur station activity. Station identification is not required for R/C, and the transmitter power is limited to 1 W. FCC §97.215 states:

"Telemetry transmitted by an amateur station on or within 50 km of the Earth's surface is not considered to be codes or ciphers intended to obscure the meaning of communications."

This section was contributed by H. Warren Plohr, W8IAH. The simplest electronic control systems are currently used in low-cost toy R/C models. These toys often use simple on/off switching control that can be transmitted by on/off RF carrier or tone modulation. More expensive toys and R/C hobby models use more sophisticated con-

Fig 9.23—Photo of three R/C model electric cars.

trol techniques. Several simultaneous proportional and switching controls are available, using either analog or digital coding on a single RF carrier.

R/C hobby sales records show that control of model cars is the most popular segment of the hobby. Battery powered cars like that shown in Fig 9.23 are the most popular. Other popular types include models powered by small internal combustion gas engines.

R/C model aircraft are next in the line of popularity and include a wide range of styles and sizes. Fixed-wing models like those shown in Fig 9.24 are the most popular. They can be unpowered (gliders) or powered by either electric or gas engines. The basic challenge for a new model pilot is to operate the model in flight without crashing. Once this is achieved, the challenge extends to operating detailed scaled models in realistic flight, performing precision aerobatics, racing other models or engaging in model-to-model combat.

The challenge for the R/C glider pilot is to keep the model aloft in rising air currents. The most popular rotary-wing aircraft models are helicopters. The sophistication of model helicopters and their control systems can only be appreciated when one sees a skilled pilot perform a schedule of precision flight maneuvers. The most exotic maneuver is sustained inverted flight, a maneuver not attainable by a full-scale helicopter.

R/C boats are another facet of the hobby. R/C water craft models can imitate full-scale ships and boats, from electric motor powered scale warships that engage in scale battles, to gas powered racing hydroplanes, model racing yachts and even submarines.

Most R/C operation is no longer on Amateur Radio frequencies. The FCC currently authorizes 91 R/C frequencies between 27 MHz and 76 MHz. Some frequencies are for all models, some are only for aircraft and others for surface (cars, boats) models only. Some frequencies are used primarily for toys and others for hobbyist models. Amateur Radio R/C

Fig 9.24—Photo of two R/C aircraft models.

operators use the 6-m band almost exclusively. Spot frequencies in the upper part of the band are used in geographical areas where R/C operation is compatible with 6-m repeater operation and TV Channel-2 signals that can interfere with control. Eight spot frequencies, 53.1 to 53.8 MHz, spaced 100 kHz apart, are used. There is also a newer 200 kHz R/C band from 50.8 to 51.0 MHz providing ten channels spaced 20 kHz apart. The close channel spacing in this band requires more selective receivers than do the 53-MHz channels. The Academy of Model Aeronautics (www.modelaircraft.org) *Membership Manual* provides a detailed list of all R/C frequencies in current use as well as other useful information. The *ARRL Repeater Directory* lists current Amateur Radio R/C frequencies.

Fig 9.25 shows a typical commercial R/C system, consisting of a hand-held aircraft transmitter (A), a multiple-control receiver, four control servos and a battery (B). This particular equipment is available for any of the ten R/C frequencies in the 50.8-51.0 MHz band. Other commercially available control devices include relays (solid-state and mechanical) and electric motor speed controllers.

Some transmitters are tailored to specific kinds of models. A helicopter, for example, requires simultaneous control of both collective pitch and engine throttle. A model helicopter pilot commands this response with a linear motion of a single transmitter control stick. The linear control stick signal

(A)

(B)

Fig 9.25—A, photo of Futaba's Conquest R/C aircraft transmitter. B shows the matching airborne system.

Fig 9.26—Photo of Airtronics Infinity 660 R/C aircraft transmitter.

is conditioned within the transmitter to provide the encoder with a desired combination of nonlinear signals. These signals then command the two servos that control the vertical motion of the helicopter.

Transmitter control-signal conditioning is provided by either analog or digital circuitry. The signal conditioning circuitry is often designed to suit a specific type of model, and it is user adjustable to meet an individual model's control need. (Low-cost transmitters use analog circuitry.) They are available for helicopters, sailplanes and pattern (aerobatic) aircraft.

More expensive transmitters use digital microprocessor circuitry for signal conditioning. Fig 9.26 shows a transmitter that uses a programmable microprocessor. It is available on any 6-m Amateur Radio R/C frequency with switch-selectable PPM or PCM coding. It can be programmed to suit the needs of a helicopter, sailplane or pattern aircraft. Nonvolatile memory retains up to four user-programmed model configurations.

Many R/C operators use the Amateur Radio channels to avoid crowding on the non-ham channels. Others do so because they can operate home-built or modified R/C transmitters without obtaining FCC type acceptance. Still others use commercial R/C hardware for remote control purposes around the shack.

R/C RF MODULATION

The coded PPM or PCM information for R/C can modulate an RF carrier via either amplitude- or frequency-modulation techniques. Commercial R/C systems use both AM and FM modulation for PPM, but use FM exclusively for PCM.

The AM technique used by R/C is 100% "down modulation." This technique switches the RF carrier off for the duration of the PPM pulse, usually 250 to 350 μ s. A typical transmitter design consists of a third-overtone transistor oscillator, a buffer amplifier and a power amplifier of about $\frac{1}{2}$ W output. AM is achieved by keying the 9.6-V supply to the buffer and final amplifier.

The FM technique used by R/C is frequency shift keying (FSK). The modulation is applied to the crystal-oscillator stage, shifting the frequency about 2.5 or 3.0 kHz. The direction of frequency shift, up or down with a PPM pulse or PCM code, can be in either direction, as long as the receiver detector is matched to the transmitter. R/C manufacturers do not standardize, so FM receivers from different manufacturers may not be compatible.

SIGNALING TECHNIQUES

Radio control (R/C) of models has used many different control techniques in the

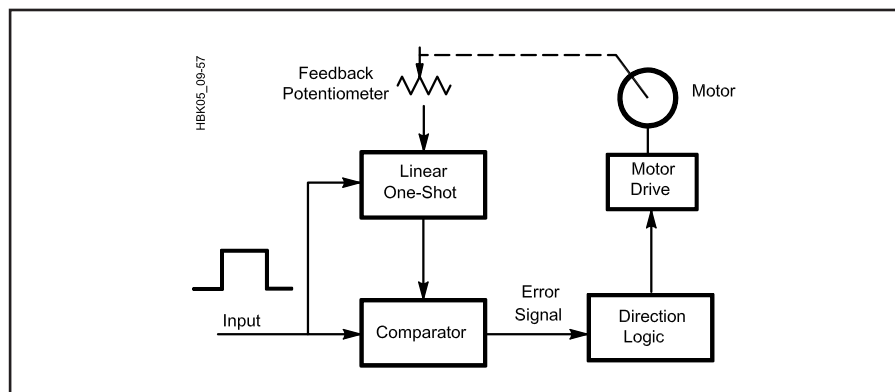

Fig 9.27—Diagram of a pulse-feedback servo.

past. Experimental techniques have included both frequency- and time-division multiplexing, using both electronic and mechanical devices. Most current systems use time-division multiplexing of pulse-width information. This signaling technique, used by hobbyist R/C systems, sends pulse-width information to a remotely located pulse-feedback servomechanism. Servos were initially developed for R/C in the 1950s and are still used today in all but low-cost R/C toys.

Fig 9.27 is a block diagram of a pulse-feedback servo. The leading edge of the input pulse triggers a linear one-shot multivibrator. The width of the one-shot output pulse is compared to the input pulse. Any pulse width difference is an error signal that is amplified to drive the motor. The motor drives a feedback potentiometer that controls the one-shot timing. When this feedback loop reduces the error signal to a few microseconds, the drive motor stops. The servo position is a linear function of the input pulse width. The motor-drive electronics are usually timed for pulse repetition rates of 50 Hz or greater and a pulse width range of 1 to 2 ms. A significantly slower repetition rate reduces the servomechanism slew rate but not the position accuracy.

In addition to motor driven servos, the concept of pulse-width comparison can be used to operate solid-state or mechanical relay switches. The same concept is used in solid-state proportional electric motor speed controllers. These speed controllers are used to operate the motors powering model cars, boats and aircraft. Currently available model speed controllers can handle tens of amperes of direct current at voltages up to 40 V dc using MOSFET semiconductor switches.

Requirements

The signaling technique required by R/C is the transmission of 1- to 2-ms-wide pulses with an accuracy of ± 1 μ s at repetition rates

Fig 9.28—Diagram of a four-channel PPM RF envelope.

of about 50 Hz. A single positive-going dc pulse of 3 to 5 V amplitude can be hard wired to operate a single control servomechanism. If such a pulse is used to modulate an RF carrier, however, distortion of the pulse width in the modulation/demodulation process is often unacceptable. Consequently, the pulse-width information is usually coded for RF transmission. In addition, most R/C systems require pulse-width information for more than one control. Time-division multiplexing of each control provides this multichannel capability. Two coding techniques are used to transfer the pulse-width information for multiple control channels: pulse-position modulation (PPM) and pulse-code modulation (PCM).

Pulse-Position Modulation

PPM is analog in nature. The timing between transmitted pulses is an analog of the encoded pulse width. A train of pulses encodes multiple channels of pulse-width information as the relative position or timing between pulses. Therefore the name, pulse-position modulation. The transmitted pulse is about 300 μ s in width and uses slow rise and fall times to minimize the transmitter RF bandwidth. The shape of the received waveform is unimportant because the desired information is in the timing between pulses. Fig 9.28 diagrams a frame of five pulses that transmits four control channels of pulse-width information. The frame of

modulation pulses is clocked at 50 Hz for a frame duration of 20 ms. Four multiplexed pulse widths are encoded as the times between five 300- μ s pulses. The long period between the first and the last pulse is used by the decoder for control-channel synchronization.

PPM is often incorrectly called *digital control* because it can use digital logic circuits to encode and decode the control pulses. A block diagram of a typical encoder is shown in Fig 9.29. The 50-Hz clock frame generator produces the first 300- μ s modulation pulse and simultaneously triggers the first one-shot in a chain of multivibrators. The trailing edge of each one-shot generates a 300- μ s modulation pulse while simultaneously triggering the succeeding multivibrator one-shot. In a four-channel system the fifth modulation pulse, which indicates control of the fourth channel, is followed by a modulation pause that is dependent on the frame rate. The train of 300- μ s pulses are used to modulate the RF carrier.

Received pulse decoding can also use digital logic semiconductors. Fig 9.30 shows a simple four-control-channel decoder circuit using a 74C95 CMOS logic IC. The IC is a 4-bit shift register operated in the right-shift mode. Five data pulses spaced 1 to 2 ms apart, followed by a synchronization pause, contain the encoded pulse-width information in one frame. During the sync pause, the RC circuit discharges and sends a logic-one signal to the 74C95 serial input terminal. Subsequent negative going data pulses remove the logic-one signal from the serial input and sequentially clock the logic one through the four D-flip-flops. The output of each flip-flop is a positive going pulse, with a width corresponding to the time between the clocking pulses. The output of each flip-flop is a demultiplexed signal that is used to control the corresponding servo.

Pulse Code Modulation

PCM uses true digital code to transfer R/C signals. The pulse width data of each control channel is converted to a binary word. The digital word information of each control channel is coded and multiplexed to permit transmission of multiple channels of control on a single RF carrier. On the receiving end, the process is reversed to yield the servo control signals.

There is no standard for how the digital word is coded for transmission. Therefore PCM R/C transmitters and receivers from different makers are not interchangeable. Some older PCM systems provide only 256 discrete positions for 90° of servo motion, thereby limiting servo resolution. Newer systems use more digital bits for each word and provide smooth servo motion with 512 and 1024 discrete positions. All PCM and

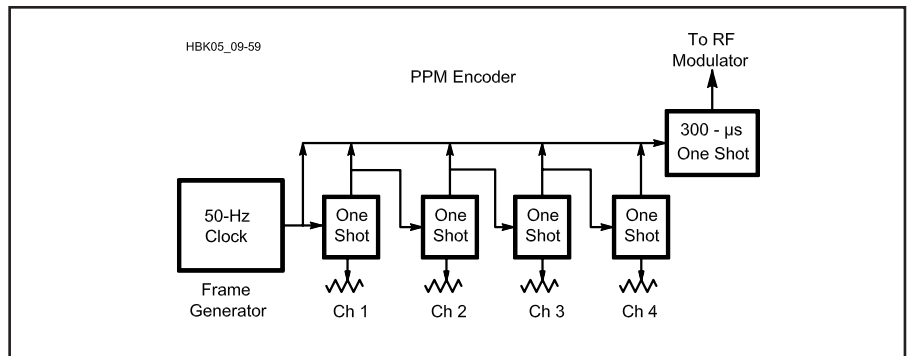

Fig 9.29—Diagram of a PPM encoder.

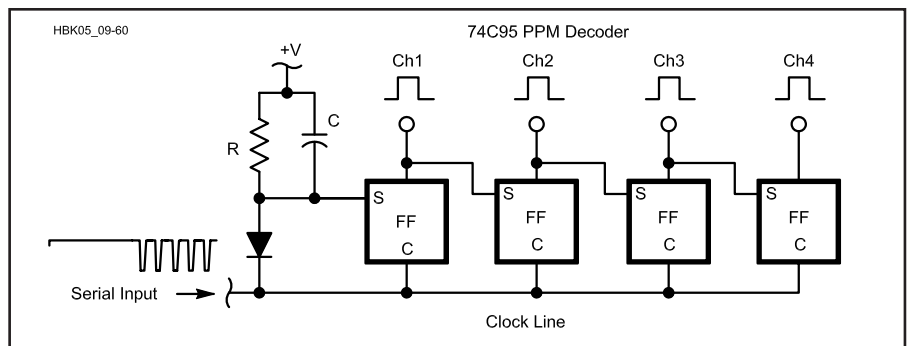

Fig 9.30—Diagram of a 74C95 PPM decoder.

PPM systems use the same servo input-signal and supply voltages. Therefore the servos of different manufacture are interchangeable once compatible wiring connectors have been installed.

AMATEUR SATELLITE TT&C

TT&C plays a vital part of the launching and management of amateur satellites. Satellites have onboard intelligence and are increasing able to make their own decisions but Article 25 of the international Radio Regulations requires the following:

“Administrations authorizing space stations in the amateur-satellite service shall ensure that sufficient earth command stations are established before launch to ensure that any harmful interference caused by emissions from a station in the amateur-satellite service can be terminated immediately.”

The U.S. implementation of the Radio Regulations in Part 15 of the FCC rules has these provisions:

*“§97.211 Space telecommand station.
(a) Any amateur station desig-*

nated by the licensee of a space station is eligible to transmit as a telecommand station for that space station, subject to the privileges of the class of operator license held by the control operator.

(b) A telecommand station may transmit special codes intended to obscure the meaning of telecommand messages to the station in space operation.

.....

(d) A telecommand station may transmit one-way communications.”

Telemetry from amateur satellites, such as from “engineering beacons” is available to all amateurs. Computer programs are available from AMSAT for decoding the telemetry to monitor the health of the spacecraft and other measurements. However, telecommand of amateur satellites is closely held in order to maintain effective control.

Voice Modes

AMPLITUDE MODULATION (AM)

This material was written by John O. Stanley, K4ERO. The first AM broadcast of speech and music occurred nearly a century ago, when on Christmas eve of 1906, Fessenden, using a modulated high frequency alternator, surprised ship operators with a program of music, Bible readings and poetry. The development of a continuous wave transmitter, one that produced a constant sine wave output, rather than the rough spark signal, made AM practical. Thus, CW, as this pure wave was called, not only greatly enhanced Morse communications, but allowed voice transmissions as well. By changing the strength or amplitude of this smooth continuous wave, a voice could be superimposed on the radio frequency carrier.

The decade of the 1920s saw not only the rapid development of the broadcast industry, but also enabled many hams to try the new voice mode. Indeed, in those early years, there was sometimes little difference between a ham who used voice and a broadcaster. The situation was a mess, and QRM was king! By 1929 it was permissible to use AM voice in limited portions of our amateur spectrum and, on some bands, only the most qualified licensees had the privilege.

Users of AM had to learn that an RF wave could have only a certain amount of audio imposed upon it before overmodulation occurred. Trying to go above 100% modulation produced severe distortion and splatter. AM remained the dominant voice mode for ham operations well into the second half of the 20th century, when it was gradually eclipsed by SSB (SSB is actually a form of AM) and FM. We can still hear AM on the ham bands today, mostly coming from stations using vintage gear. AMers usually choose operating times when the bands are less crowded, and often take pride in a clean and clear signal.

The great advantage of AM, and one reason for its long history, is the ease with which a full carrier AM signal can be received. This was all important in broadcasting where, for every transmitter, there were thousands or even millions of receivers. With modern integrated circuits, complex detectors now cost very little. Therefore, the biggest reason for keeping AM broadcasting, at present, is to avoid obsolescing the billions of existing receivers. These will gradually have to be replaced when digital broadcasts begin in the AM and shortwave bands.

There are many ways to produce an AM signal, but all of them involve multiplying the amplitude of the information to be transmitted by the amplitude of the radio wave

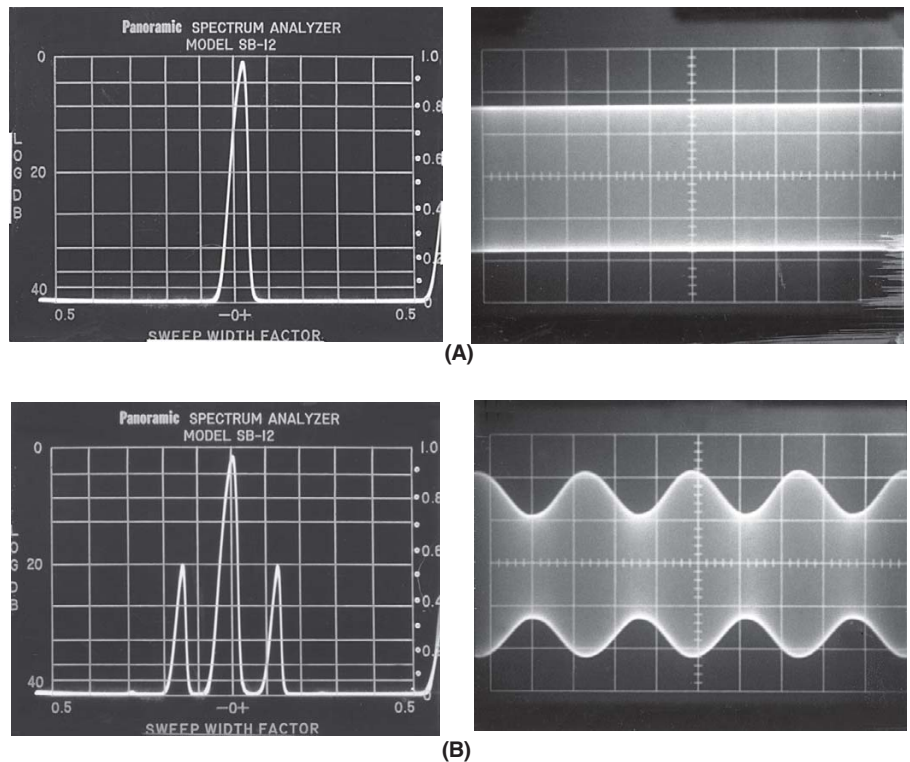

Fig 9.31—Electronic displays of AM signals in the frequency and time domains. A shows an unmodulated carrier or single-tone SSB signal. B shows a full-carrier AM signal modulated 20% with a sine wave.

that will carry it. When multiplication of two signals takes place, as opposed to their simple addition, *mixing* is involved. The result is multiple signals, including the sum and difference of the AF and RF frequencies. These two “products” will appear as sidebands alongside what was the original RF frequency. Mixing, modulation, detection, demodulation, and heterodyning all refer to this multiplication process and can all be analyzed by the same mathematical treatment. See the **Mixers, Modulators and Demodulators** chapter of this *Handbook* for a more detailed discussion of this process.

If an RF signal is modulated by a single audio tone, and observed on an oscilloscope, it will appear as shown on the right in **Fig 9.31B**. Observing the same signal on a spectrum analyzer will show that the composite signal observed on the scope is composed of three discrete parts as shown on the left in **Fig 9.31B**. The center peak, which is identical with the original unmodulated wave shown in **Fig 9.31A**, is usually called the *carrier*, although this terminology is deceiving and imprecise. It is the composite RF signal, as seen on the oscilloscope, which actually carries the audio in the form of variations in its amplitude, so we might well have referred to the center frequency as a “reference” or some other such term.

As a reference signal, the carrier contains important, though not indispensable, infor-

mation. For a signal with both sidebands present, it provides a very important frequency and phase reference that allows simple and undistorted detection, using nothing more than a diode. The carrier also provides an amplitude reference, which is used by AM receivers to set the gain of the receiver, using AGC or automatic gain control. The carrier also contains most of the power of the transmitted signal, while most of the important information is in the sidebands. See the **Mixers, Modulators and Demodulators** chapter in this *Handbook*, which gives details of power distribution in an AM signal.

SINGLE SIDEBAND (SSB)

Telephone engineers developed a system of using only one of the two sidebands, which, being mirror images of each other, contain the same information. SSB systems attracted the attention of hams soon after WWII and gradually became the voice mode of choice for the HF bands. SSB is considered a form of AM, in that it is identical to an AM signal with one sideband, and with all or part of the carrier removed. The complexity of generating a SSB signal, plus the difficulty of tuning the generally unstable receivers common in the 1950s, slowed the changeover to the new mode, but its adoption was inevitable. SSB became popular because of its greater power efficiency,

Fig 9.32—How an occupied radio frequency spectrum shifts with application of an audio (baseband) signal. The dotted line represents the RF carrier point, or in the case of the 3-kHz audio signal, the reference frequency, 0 kHz.

which allowed each watt of RF to go further. The fact that it occupied less bandwidth was a plus also and very welcome on the most crowded bands. See the sidebar **SSB on 20 and 75 Meters** in this chapter.

While systems used for telephone relays used pilot carriers so that the signal could be reproduced without distortion, hams chose to eliminate the carrier entirely. This required generating a reference frequency at the receiver, which, if accurate to within 20 Hz, allowed intelligible speech to be recovered. Since amateur regulations have long prohibited transmission of music, the distortion produced by loss of the exact phase and frequency reference was not serious. The loss of the amplitude reference was overcome with the development of the “hang” AGC, which works on the average value of the received sideband, which is constantly changing. While not as fast or accurate as the carrier-based AGC available in AM, this has proven satisfactory, if proper attention is given to its design (See the **Receivers and Transmitters** chapter of this *Handbook*.)

Thus, SSB, while giving up some fidelity and while increasing complexity, has proven superior to full-carrier AM for speech communication because of its power and bandwidth efficiency. And under certain circumstances, such as selective fading, it can actually have less distortion than DSB AM. On HF, it is possible for the carrier to fade in an DSB AM signal, leaving less than is needed for envelope detection. Medium wave AM broadcasts often have this problem at night. It can be overcome with “exalted carrier detection.” Synchronous detection is a refinement of this method. (See the **Mixers, Modulators and Demodulators** chapter of this *Handbook*.) SSB, in effect, uses exalted carrier detection all the time.

An SSB signal is best visualized as an audio or *baseband* signal that has simply

SSB ON 20 AND 75 METERS —THE 9 TO 5 CONNECTION

SSB experiments began on 75 meters because it was the lowest frequency phone band in widespread use. Due to perpetual crowding and its DX potential, 20 meters also seemed to call for use of SSB. Some early rigs included only these two bands. The popular homebrew W2EWL rig was built on the chassis of a war surplus ARC-5 transmitter using its 5 MHz VFO, and generated the sideband signal on 9 MHz using the phasing method. Nine plus five is 14 MHz, and nine minus five is 4 MHz, yielding 75 or 20 meter coverage by choosing which of the two mix products we would filter out and amplify. Thus, two bands were covered with the same VFO/IF combination. Other rigs used a tunable IF from 5.0 to 5.5 MHz. This was subtracted from a 9-MHz crystal to obtain 4.0 to 3.5 MHz, and added to 9 MHz to cover 14.0 to 14.5 MHz. This process reversed the sidebands, and eventually led to the convention of using LSB on the lower bands and USB on the higher bands. This also explains why on some vintage rigs the 75-meter band dial reads backwards!—*K4ERO*

been shifted upwards into the radio frequency spectrum, as shown in **Fig 9.32**. The relative frequencies, phases and amplitudes of all the components will be the same as the original frequency components except for having had a fixed reference frequency added to them. Surprisingly, this process, called heterodyning, is not done by directly adding the signals together, but by multiplying them and subsequently filtering or phasing out the carrier and one of the sidebands. The **Mixers, Modulators and Demodulators** chapter of this *Handbook* explains this interesting process in detail.

The relative frequencies within the band of information being transmitted may appear inverted; that is, lower frequencies in the original audio signal are higher in the RF signal. When this happens, we call the signal *lower sideband* or LSB. LSB is produced when the final frequency is the result of subtraction rather than addition. If a tone of 1 kHz is heterodyned to 14201 kHz by mixing with a 14200 kHz carrier, the result will be upper sideband, since $14200 + 1$ gives us that result. When the same tone appears at 3979 kHz by mixing it with a 3980 kHz carrier, we know that an LSB signal was produced since $3980 - 1$ gives us the 3979 result. Whenever the audio tone needs a minus sign to find the result, we are on LSB.

Fig 9.33—A method of changing sidebands with virtually no change in the frequency spectrum occupied. Note that the carrier point position *has* changed concurrent with the change from LSB to USB.

In most mixing schemes there will be three frequencies involved (carrier, VFO, and band select crystal) but the principle still holds.

The frequency of an SSB transmission is designated as that of the carrier, which is the frequency (or the sum of several frequencies) used to shift the baseband information into the RF spectrum. In a good SSB signal, little or no energy actually appears on the frequency we say we are using. It is strictly a reference. For this reason, some radio services have chosen to designate SSB channels by the center of the occupied bandwidth rather than the carrier frequency. Ham practice is to designate the carrier frequency and whether the upper or lower sideband is in use. An interesting exception is the new five-channel, 60-m amateur band (a secondary allocation) where the FCC specified a 2.8-kHz bandwidth on five center frequencies: 5332, 5348, 5368, 5373 and 5405 kHz. Only USB voice (2K8J3E emission) is permitted.

Most hams will find it more natural to remember USB at corresponding carrier frequencies of 5330.5, 5346.5, 5366.5, 5371.5 and 5403.5 kHz. Since the USB or the LSB is considered “normal” for each of our bands, it is assumed that the sideband in use is understood. We need to remember when switching sidebands that we will be occupying a different portion of the spectrum than before the switch, and we may inadvertently cause QRM, unless we check for a clear frequency. If you wish to change from LSB to USB without changing the spectrum occupied, you must retune your dial down about 3 kHz, as a careful study of **Fig 9.33** should make clear. This principle applies to digital as well as voice modes, but usually not to CW, where modern rigs make the above adjustment for us. This means that the frequency readout with a CW signal will be the actual frequency occupied, but with analog

voice and digital modes this will probably not be the case.

Another need for understanding where sideband signals actually fall is in operating close to the edge of a band or subband. For example, on 20 meters where USB is used, you must not operate above approximately 14.347 MHz, since the transmission will be outside the band if you operate much higher. Operation with a suppressed carrier exactly on 4.0 MHz could be done on LSB if the signal is very clean, but is not recommended. Most modern rigs prevent out of allocated band transmissions but *do not* preclude the above cases of improper operation.

Today there are many new modes for text, speech and image transmission, and more will be developed in the future. Often these are transmitted using SSB. Knowing exactly where the signal will appear on the band depends on understanding how LSB and USB signals are produced. These modes use either a separate circuit or more recently a computer sound card to produce audio frequency tones that represent the information in coded form. This is then fed into the audio input of an SSB transmitter. They are then heterodyned to the desired amateur band for transmission. In a transceiver, the incoming signals are similarly heterodyned back to the audio range for processing in the computer sound card or other circuitry. Some computer-based digital modes allow reading the actual signal frequency off the screen, provided the transceiver dial is properly set.

Voice signals and some text and image modes require linear amplification. This means that the amplifiers in the transmitter must faithfully represent the amplitude as well as the frequency of the baseband signal. If they fail to do so, intermodulation distortion (IMD) products appear and the signal becomes much wider than it should be, producing interference (QRM) on nearby frequencies. CW and FM do not require a linear amplifier, but you can use one for these modes also, at a small price in efficiency. Some VHF “brick” amplifiers have a choice of either the more efficient class C amplification or the more linear class B amplification. The linear or SSB mode must be chosen if SSB voice and some digital modes are being used. Whenever linear amplification is needed, *flat-topping* must be prevented. This results from overdriving the amplifier so that it goes above the design power limit and becomes non-linear.

SSB transmitters and most linear amplifiers use automatic level control (ALC) to prevent overdrive and flat topping. However, there are limits to ALC and flat topping can still occur if the amplifier is grossly over driven. The surest way to create ill will on any band is to cause spatter by over driving

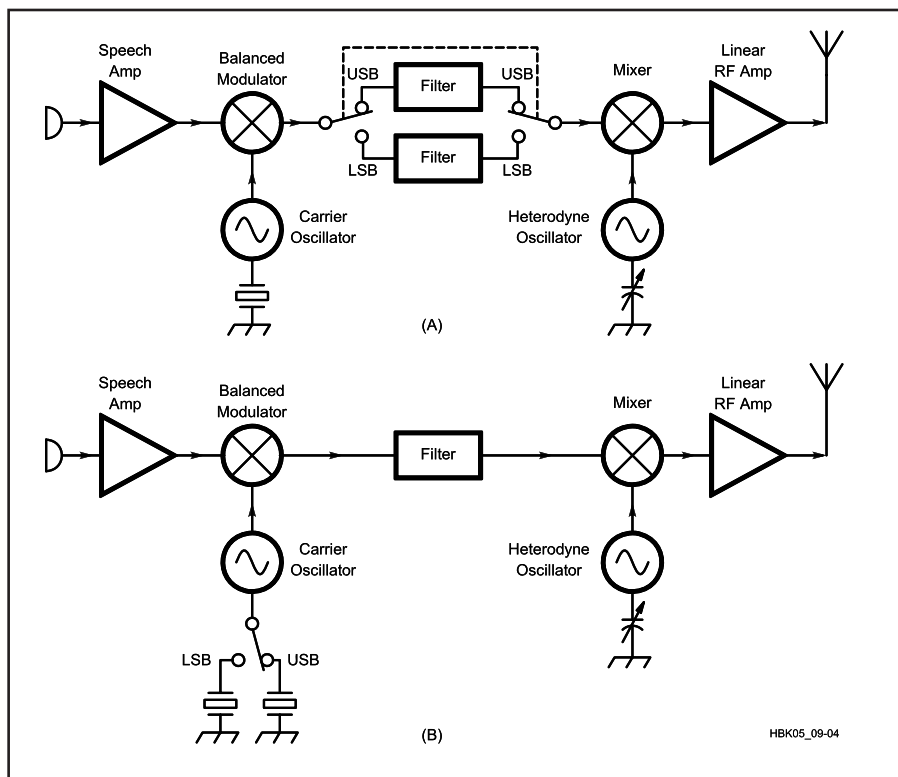

Fig 9.34—Block diagrams of filter-method SSB generators. They differ in the manner that the upper and lower sideband are selected.

your amplifier, regardless of the mode. Amplifiers suitable for both linear and non-linear signals are discussed in the **RF Power Amplifiers** chapter of this *Handbook*. The effects of non-linear amplification are also further treated in the **Mixers, Modulators and Demodulators** chapter.

How an SSB Signal is Produced

When the proper receiver bandwidth is used, an SSB signal will show an effective gain of up to 9 dB over an AM signal of the same peak power. Because the redundant information is eliminated, the required bandwidth is half that of a comparable AM (DSB) emission. Unlike DSB, the phase of the local carrier generated in the receiver is unimportant.

SSB Generation: The Filter Method

If the DSB signal from the balanced modulator is applied to a narrow bandpass filter, one of the sidebands can be greatly attenuated. Because a filter cannot have infinitely steep skirts, the response of the filter must begin to roll off within about 300 Hz of the phantom carrier to obtain adequate suppression of the unwanted sideband. This effect limits the ability to transmit bass frequencies, but those frequencies have little value in voice communications. The filter rolloff can be used to obtain an additional

20 dB of carrier suppression. The bandwidth of an SSB filter is selected for the specific application. For voice communications, typical values are 1.8 to 3.0 kHz.

Fig 9.34 illustrates two variations of the filter method of SSB generation. In A, the heterodyne oscillator is represented as a simple VFO, but may be a premixing system or synthesizer. The scheme at B is perhaps less expensive than that of A, but the heterodyne oscillator frequency must be shifted when changing sidebands in order to maintain dial calibration.

SSB Generation: The Phasing Method

Fig 9.35 shows another method to obtain an SSB signal. The audio and carrier signals are each split into equal components with a 90° phase difference (called *quadrature*) and applied to balanced modulators. When the DSB outputs of the modulators are combined, one sideband is reinforced and the other is canceled. The figure shows sideband selection by means of transposing the audio leads, but the same result can be achieved by switching the carrier leads. The phase shift and amplitude balance of the two channels must be very accurate if the unwanted sideband is to be adequately attenuated. **Table 9.8** shows the required phase accuracy of one channel (AF or RF) for various levels of opposite sideband suppression.

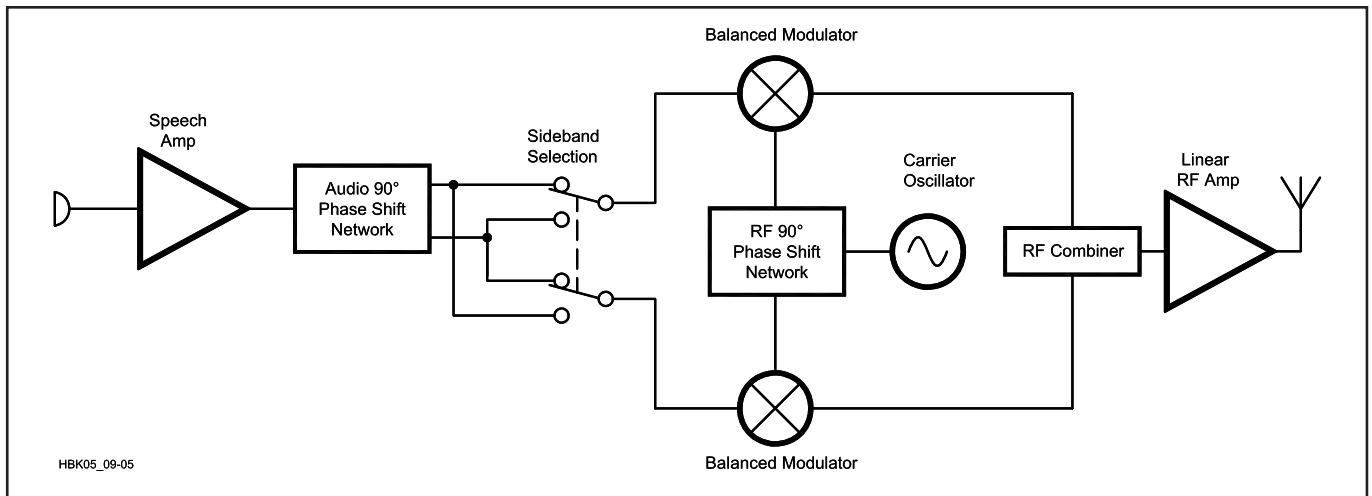

Fig 9.35—Block diagram of a phasing SSB generator.

Table 9.8
Unwanted Sideband Suppression as a Function of Phase Error

Phase Error (deg.)	Suppression (dB)
0.125	59.25
0.25	53.24
0.5	47.16
1.0	41.11
2.0	35.01
3.0	31.42
4.0	28.85
5.0	26.85
10.0	20.50
15.0	16.69
20.0	13.93
30.0	9.98
45.0	6.0

The numbers given assume perfect amplitude balance and phase accuracy in the other channel.

The shows that a phase accuracy of 1° is required to achieve unwanted sideband suppression of greater than 40 dB. It is difficult to achieve this level of accuracy over the entire speech band. The phase-accuracy tolerance can be loosened to 2° if the peak deviations can be made to occur within that spectral gap. The major advantage of the phasing system is that the SSB signal can be generated at the operating frequency without the need of heterodyning. Phasing can be used to good advantage even in fixed-frequency systems. A loose-tolerance (4°) phasing exciter followed by a simple two-pole crystal filter can generate a high-quality signal at low cost.

Audio Phasing Networks

Since the phasing method requires that all baseband signals be presented to the bal-

anced modulators in both a normal (in phase) and quadrature (90° phase shifted) signal, we must provide, in the case of an audio signal, a network that can produce a constant 90° phase shift over a wide frequency range. Fortunately, the absolute phase shift is not as important as the relative phase between the two channels. Various circuits have been devised that will provide this relative shift. Robert Dome, W2WAM, pioneered a simple network using precision components that achieved this and his network was used in early SSB work. The polyphase network, which appeared in this *Handbook* for several editions, required more—but less precise—components. Methods using active filter techniques are also available.

With DSP (Digital Signal Processing), producing a 90° phase shift over a wide frequency range is easily accomplished using the Hilbert transformer. This will likely give new life to the phasing method of SSB generation since many new radios already have DSP capability present for other reasons. See the **Receivers and Transmitters** chapter of this *Handbook* for an example of an SSB receiver using DSP with the phasing method. See also the **Digital Signal Processing** chapter.

Producing 90° phase-shifted signals at RF frequencies has also used several approaches. For VHF and up, a quarter-wave section of coax is possible. Generating an RF signal at four times the desired frequency and dividing down with flip-flops generates quadrature signals accurate over a wide range of frequencies. Phase lock loops provide yet another approach.

The phasing method is useful not only for generating an SSB signal, but for any mixing or frequency-conversion task. In-Phase and Quadrature (I&Q) modulators, demodu-

lators and mixers are in common use in modern communication technology. These allow elimination of image frequencies without filters, or greatly relax the specification of filters that are used. Digital modulation can be generated in an I&Q format that can be directly heterodyned into the RF spectrum using I&Q modulators. The **Digital Signal Processing** chapter of this *Handbook* discusses many of these concepts.

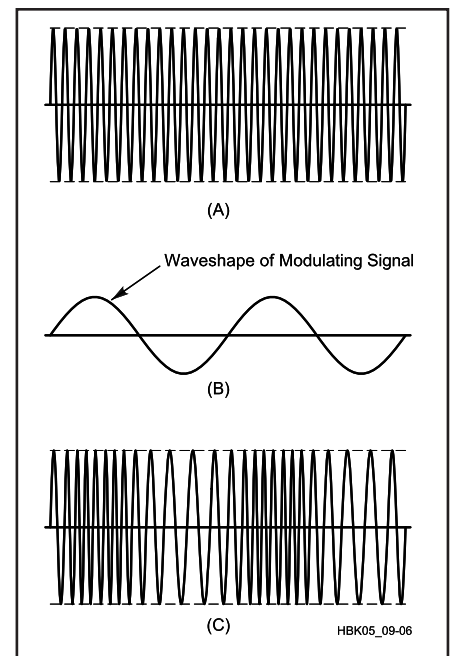

Fig 9.36 – Graphical representation of frequency modulation. In the unmodulated carrier (A) each RF cycle occupies the same amount of time. When the modulating signal (B) is applied, the radio frequency is increased and decreased according to the amplitude and polarity of the modulating signal (C).

FREQUENCY MODULATION (FM)

Unlike AM, which changes the amplitude of a radio wave in accordance with the strength of the modulation signal, FM changes the frequency of the wave so that the instantaneous value of frequency represents a voltage level in the modulating signal as is shown in **Fig 9.36**. This means that the demodulator must extract the information by generating an output whose amplitude is determined by the frequency of the received wave. Thus, FM transmission involves amplitude to frequency conversion and vice-versa. Producing these conversions was not as easy as it was in the case of AM, and thus FM was not employed as early as was AM.

As you can see in **Fig 9.37**, the circuits required for FM were especially difficult in the case of the receiver. See also the AM and Angle-Demodulation subsections of the **Mixers, Modulators and Demodulators** chapter in this *Handbook*. In addition, mathematical analysis seemed to show that FM would require a very large bandwidth (theoretically infinite), and this discouraged early experimenters.

Edwin Armstrong was a ham before the days of call signs. While a young man, he invented the regenerative, super-regenerative and superheterodyne receivers. He went on to challenge the prevailing wisdom and developed a practical FM system. His “Yankee Network” provided high fidelity broadcasts throughout the northeastern United States in the late 1930s, using frequencies below our 6-meter band. After WWII, FM was moved to 88-108 MHz and became FM broadcasting as we now know it. Dependable day and night reception was a result of the frequency chosen, not the mode, but wideband FM, which had dictated the use of a VHF frequency where bandwidth was available, provided the wide audio response, high signal to noise ratio, and freedom from static that AM could never have provided, even at VHF. The advantages of FM were proven even when bandwidths were less than infinity. The math had not been wrong, but had just been taken a bit too literally.

Hams experimented with narrowband FM (NBFM) on the HF bands during the 1950s, but nothing much came of it. The explosion in the use of FM in the amateur bands came after surplus commercial FM equipment, using frequencies near 150 MHz, became available in the 1960s and 1970s. Two meters was the first to use this equipment and is still the workhorse of the VHF FM bands. Hams, like the commercial and public service users before them, discovered that FM has certain advantages—less noise, ease of operation, no fussy tuning and suitability for use through repeaters.

A mathematical analysis of FM is com-

plex, and well beyond the scope of this chapter. Readers who are interested in more details can consult the **Mixers, Modulators and Demodulators** chapter of this *Handbook*. Unlike AM, where the occupied bandwidth is simple to calculate (twice the highest modulating frequency), FM bandwidth depends on both the modulating frequency and the *deviation*, which is equal to the peak frequency excursion above and below the central carrier frequency. As the math predicts, there are sidebands that extend to infinity but, fortunately, these drop off in amplitude rather quickly. As Armstrong surmised, ignoring sidebands that contain only a tiny portion of the total energy does not impair the quality of the received signal.

As a rule of thumb, adequate bandwidth for an FM voice system using narrowband modulation (5 kHz or so) is $B_n = 2(M+D)$ where B_n is the necessary bandwidth in hertz, M is the maximum modulation frequency in hertz, and D is the peak deviation in hertz. For narrowband FM with voice, the bandwidth equals $2 \times (3000+5000) = 16$ kHz. This defines the filter through which the signal can be received without noticeable distortion.

Examples of FM spectra using various modulation indices are found in the **Mixers, Modulators and Demodulators** chapter of this *Handbook*. Note that as more and more sidebands appear, the amplitude of each is reduced. This is because all of the sidebands, plus the carrier, must add together (vectorially) to produce a total wave of constant amplitude. This is characteristic of an FM signal. This constant amplitude signal has the advantage of being easy to amplify without the need for a linear amplifier. Many VHF and UHF brick-type amplifiers have separate settings for FM and SSB. The FM setting is more efficient

since, by giving up the requirement for linearity, we can bias the transistors for greater efficiency. Thus, an FM amplifier is easier to build than one suitable for AM or SSB.

However, this constant amplitude characteristic of FM comes at a price. The full power is being transmitted, even between words or when one is holding down the push to talk, but not actually speaking. For normal speech, the power advantage FM gains by amplifier efficiency is lost compared to SSB, where power is only transmitted when the voice requires it. One should not, however, conclude that the unmodulated FM signal serves no purpose. Its presence “quiets” the channel, opens the squelch of the receiver(s), and turns on any repeater(s) that might be in the circuit. There may also be various control tones (squelch, etc.) present, even though these may be inaudible because they are in a frequency range that the human ear does not easily perceive.

Using FM and PM with Digital Modes

Frequency-shift keying (FSK) is a means of producing frequency modulation that has discrete states; that is, the instantaneous frequency takes on definite values representing digital information. FSK is a form of FM and some of the same principles apply. FSK was covered earlier in the section on RTTY and other digital modes.

Phase modulation (PM) is very similar to FM in that it is not possible to change the frequency of a signal without impacting its phase, and vice versa. Instantaneous frequency can be considered to be the rate of change of phase of a signal. Some FM modulators have used this relationship to produce FM by phase modulation along with audio frequency shaping to convert the PM signal into the equivalent of an FM signal. This issue is discussed further in the **Mixers, Modulators and Demodulators** chapter of

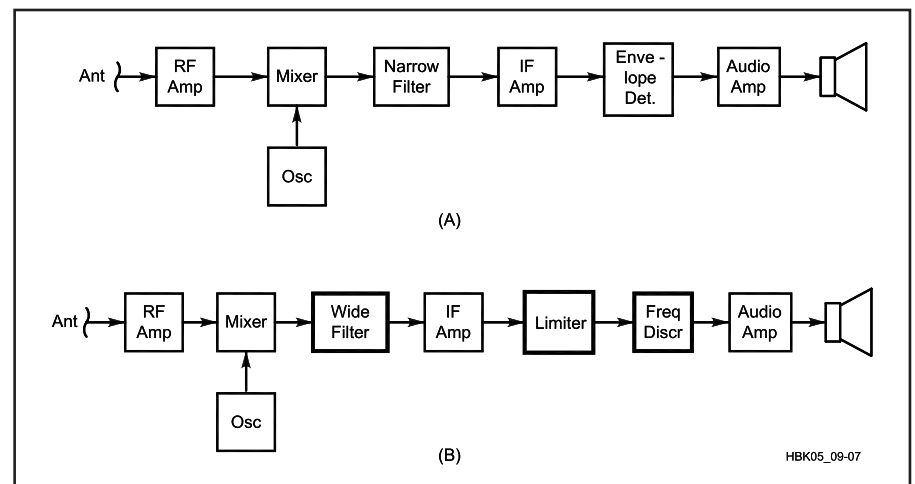

Fig 9.37—At A, block diagram of an AM receiver. At B, an FM receiver. Dark borders outline the sections that are different in the FM set.

this *Handbook*.

Phase shift keying (PSK) is a form of phase modulation suitable for digital transmissions. It is discussed further in the following pages of this chapter. Both FSK and PSK produce sidebands in accordance with the same principles discussed above. However, in order to control bandwidth, digital signals using PSK may depart from the requirement that an FM signal have a constant amplitude. Such signals are really a combination of FM and AM, and linear amplification must be used.

DIGITAL VOICE MODES

There is a risk in saying anything about an area that is developing rapidly both inside and outside Amateur Radio. Amateurs are watching digital voice developments in other radio services but not all are suitable models for Amateur Radio applications.

On MF and HF, transmission of digital voice is difficult owing to multipath propagation, QRM and noise. Several digital voice systems have been developed and more are expected. The most prominent contender is *Digital Radio Mondiale* (DRM). DRM is a non-profit consortium of broadcasters, manufacturers, educational and governmental organizations devoted to developing a single standard for digital sound broadcasting in long, medium and short wave bands. As of 2005, thousands of *software* radios were being used to hear regular DRM broadcasts from a growing number of countries. The software radio consists of a modified HF receiver, a sound card and computer software downloaded from DRM. See www.drmtx.org/ for details. As of mid 2005, there were few if any *hardware* DRM receivers available even at relatively high prices.

The DRM standard has several modes, some aimed at high fidelity music and others suitable for voice. The broadcaster can select the most appropriate mode, and the receiver will switch automatically to that mode. The various DRM modes occupy 4.5, 5, 9, 10 or 20 kHz according to the spectrum available and the quality desired. See **Fig 9.38**. DRM produces excellent quality but is more subject to the effects of interference and propagation than DSB AM.

Another digital sound system used in the broadcasting service is called *IBOC*—In-Band On-Channel. The basic idea is to send a digital signal underneath an existing AM or FM program without one interfering with the other. Although used in the United States, IBOC hasn't caught on for international broadcasting. An article on IBOC at New York station WOR was presented in the March 2003 issue of *QST* (p 28).

The International Telecommunication Union approved a standard known as ITU-R Recommendation BS.1514, *System for digital sound broadcasting in the broadcasting bands below 30 MHz*. It describes DRM and IBOC, and compares the systems.

Amateur Radio Digital Voice

For HF Amateur Radio, digital voice has the potential to provide better quality than SSB. It could have other yet-to-be-exploited possibilities, such as adapting to conditions from a "robotic" sounding speech under marginal propagation to "arm-chair copy" when conditions are good. It is possible to imbed some ancillary information in the digital stream so the receiver will be able to display call signs, graphics and other information of interest to the stations in QSO.

In 2000, the ARRL Board of Directors

created a Digital Voice Working Group to investigate and promote digital voice in the Amateur Radio Service. The pioneering work done by Charles Brain, G4GUO, and Andy Talbot, G4JNT, was published in the May-June 2000 issue of *QEX*. Their system was based on use of the AMBE 2020 encoder-decoder. It uses Orthogonal Frequency Division Multiplexing (OFDM) with 36 carriers in a band of 300-2500 Hz. At least one commercial version of AMBE 2020/G4GUO system is available in the amateur market. See Hallas, Joel, W1ZR, "AOR ARD9800 Digital Voice Modem," *QST*, February 2004.

The January-February 2003 issue of *QEX* (p 49) described a special Amateur Radio adaptation of the DRM system to fit inside a 3-kHz bandwidth. This system has taken on the name *HamDream* and some information can be found on the Web at www.qslnet.de/member/hb9tlk/.

These OFDM standards use many carriers spaced about 50 Hz apart, each using 16QAM (Quadrature Amplitude Modulation with 16 discrete states in each symbol) or some similar modulation scheme. To mitigate the effects of multipath propagation, the symbol rate must be limited to a few hundred bauds. Thus, the high bit rate needed for voice requires both multiple carriers and complex modulation. There are tradeoffs between complexity, weak signal sensitivity, reliability under difficult conditions, speech quality and latency. The most obvious way to generate and demodulate such a signal is to use a computer and a sound card.

While the same digital voice encoder-decoders could be used at MF/HF as well as VHF and above, it may be desirable to optimize the system for best performance in each frequency range. At MF/HF, the emphasis is naturally on reliability in the presence of fading and interference, while at VHF and UHF, it is possible to design for quality of speech reproduction and possibly multimedia (voice/data/image). See **High Speed Multimedia Radio** later in this chapter.

There is much room for innovation and experimentation in this field. A great deal of work will go into developing whatever digital voice mode we will be using 10 years from now. Those interested in being a part of this exciting technology should begin by mastering the material in the **Electrical Signals and Components** and **DSP** chapters of this *Handbook*, and keeping up with *QST* and *QEX* material on digital speech. Fig 9.38—A DRM HF digital broadcast signal. Per-division resolution is 5 kHz horizontal and 10 dB vertical.

Image Modes

FACSIMILE

This section, by Dennis Bodson, W4PWF, Steven Karty, N5SK, and Ralph Taggart, WB8DQT, covers the several facsimile systems most commonly used in Amateur Radio today. For further information on the area of facsimile, its history and the development of related standards asso-

ciated with this mode, refer to *FAX: Facsimile Technology and Systems*.¹ The subject of Weather fax, while of interest to many amateurs, is not a primary activity of the Amateur Radio Service. Information on this subject is contained in the *Weather Satellite Handbook*² and the *ARRL Image Communications Handbook*.³

Facsimile Overview

Facsimile (fax) is a method for transmit-

ting very high resolution still pictures using voice-bandwidth radio circuits. The narrow bandwidth of the fax signal, equivalent to SSTV (Slow Scan TV), provides the potential for worldwide communications on the HF bands. Fax is the oldest of the image-transmitting technologies and has been for years the primary method of transmitting newspaper photos and weather charts. Fax is also used to transmit high-resolution cloud images from both polar-orbit and geostation-

NARROW-BAND TELEVISION

AMATEUR TELEVISION

SLOW-SCAN TELEVISION

FACSIMILE

Fig 9.39—Amateur Image Communications encompass a wide range of activities, a few of which are illustrated here. Narrowband Television (NBTv) experimenters explore the history and technology of the earliest days of television by restoring or recreating mechanical TV gear while exploring the possibilities of narrowband, full motion TV, primarily using computer technology. Amateur Television (ATV) operators use standard broadcast television, typically in color, to communicate on UHF and microwave frequencies. The scope of their operating activities ranges from point-to-point communication (simplex or via local ATV repeaters), roving or portable operation for a variety of reasons, including emergency and public service communications, and the application of ATV to remote sensing via aircraft, high-altitude balloons, and remote-control vehicles of all sorts. Slow-scan Television (SSTV) involves the transmission of medium and high-resolution images, usually in full-color, using standard Amateur voice equipment (typically SSB or FM). Most modern SSTV activity is computer-based, offering international DX on HF frequencies and local, regional, or space communications (satellite, MIR, and now the International Space Station) on VHF and UHF. Facsimile (Fax) encompasses the transmission and reception of very high-resolution still images (typically using computers) over a period of several to many minutes. One of the most popular areas of Amateur experimentation and operation has involved the reception of imagery from polar-orbit and geostationary weather satellite. While this *Handbook* will provide a brief introduction to some of these activities, all of them and more are covered in much greater detail in the *ARRL Image Communications Handbook*.

ary satellites. Many of these images are retransmitted using fax on the HF bands.

The resolution of typical fax images greatly exceeds what can be obtained using SSTV or even conventional television (typical images will be made up of 800 to 1600 scanning lines). This high resolution is achieved by slowing down the rate at which the lines are transmitted, resulting in image transmission times of 4 to 10 minutes.

Modern personal computers have virtually eliminated bulky mechanical fax recorders from most amateur installations. Now the incoming image can be stored in computer memory and viewed on a standard TV monitor or a high-resolution computer graphics display. The use of a color display system makes it entirely practical to transmit color fax images when band conditions permit.

The same computer-based system that handles fax images is often capable of SSTV operation as well, blurring what was once a clear distinction between the two modes. The advent of the personal computer has provided amateurs with a wide range of options within a single imaging installation. SSTV images of low or moderate resolution can be transmitted when crowded band conditions favor short-frame transmission times. When band conditions are stable and interference levels are low, the ability to transmit very high resolution fax images is just a few keystrokes away!

Hardware and Software

The computer allows reception and transmission of various fax modes, where parameters such as line-per-minute rates and indices of cooperation can be altered by simply pressing a key or by pointing and clicking a mouse. Many fax programs are available as either commercial software or shareware. Usually, the shareware packages (and often trial versions of the commercial packages) are available by downloading from the Internet.

A good starting point is the ARRL software repositories. To get to them, set your browser to the *ARRL Web* and go to the FTP (files) link in the site index. You can use any commercial search site to look for “fax” AND “software.” Examples of several fax programs are as follows:

- *JVFAX* is a very popular fax program. It is DOS-based program with a large number of options for installation. It can receive and transmit several fax formats, black-and-white and color. Your computer’s serial port, connected to a very simple interface, provides the connection to your transceiver.
- The *FAX 480* software program can also be used with fax as well as SSTV. For more

information on this program and others including website addresses, see the July 1998 *QST* article “FAX 480 and SSTV Interfaces and Software,” p 32. A copy for downloading of the free software program *vester_n.zip* for *FAX 480* can be found online at the Oakland University FTP site. This program also uses a simple interface almost identical to that for *JVFAX*.

- *Weatherman* is a DOS-based program, using a SoundBlaster (or compatible) card as the interface. The program is shareware and provides receive-only capability. A single, shielded wire from your receiver audio output to the computer audio input is the only connection needed.
- *WXSat* operates under *Windows 3.X*. While specifically set up to decode and store weather-satellite APT pictures, it can also be used for HF-fax reception.

Both *Weatherman* and *WXSat* are samples of what you can find during a search on the Internet. Often, programs are offered and then either withdrawn or improved over the versions previously distributed—To get the latest and greatest you have to periodically search and see what comes up. If you use an online service such as CompuServe or AOL, they are another source of fax software. Check their ham forums or sections for listings.

Many commercial multimode controllers either contain software to receive and transmit fax, or are compatible with PC-hosted software. Available controller suppliers include MFJ, Timewave, and Kantronics; additional software may be required for the Kam Plus. Check the advertising pages of *QST* for the latest units available.

One well-known fax page on the Internet, complete with downloadable software, is posted and maintained by Marius Rensen; it contains listings of commercial fax transmissions for you to test your software or just SWL for interest. Before using a program taken from any Internet source, check other sources for newer versions. It is not uncommon to have older versions posted on one place and newer versions in another. It is always a good idea to virus check software before and after unzipping.

Image transmission using voice bandwidth is a trade-off between resolution and time. In the section on slow-scan television, standards are described that permit 240-line black-and-white images to be transmitted in about 36 seconds, while color images of similar resolution require anywhere from 72 to 188 seconds, depending on the color format. In terms of resolution, 240-line SSTV images are roughly equivalent to what you would obtain with a standard broadcast TV signal recorded on a home VCR. This is more than adequate for routine video com-

munication, but there are many situations that demand images with higher resolution.

HAL Communications Corporation has developed an interesting system that enables a standard fax machine (Group 3 or G3) to send commercial fax images over HF radio. HAL Communications accomplishes this with just two small ancillary devices, which connect between a standard fax machine and an ordinary HF radio transceiver. This method is frequently referred to as “G3 fax over radio.” Any G3 fax machine can be connected to the HAL FAX-4100 controller with just a standard RJ-11 modular connector. The FAX-4100 controller connects directly to the HAL CLOVER-2000 (DSP-4100) radio data modem, which in turn connects to the HF transceiver. This entire setup is duplicated at the opposite end of the link.

A “call” is initiated from the fax machine keypad just as if the fax machine were connected to a phone line. The FAX-4100 controller includes a built-in 9600-baud G3 modem that emulates the telephone system. The controller at the initiating end answers the ring from the originating fax machine, establishes the HF radio link (based on the “phone number”), and handshakes with the controller at the other end to start the receiving fax machine. Fax image data then passes from the fax machine into the controller’s memory at the originating end. The controller also establishes a data link between the CLOVER-2000 modems at both ends, then passes the fax data through them and the controller at the receiving end, and finally into the receiving G3 fax machine. HAL has automated the HF radio operating procedures. To the user, sending a fax over HF radio is a simple three-step process:

1. Lay the page(s) on the fax machine.
2. Enter the ID number of the other station.
3. Push GO on the fax machine.

Housekeeping control functions and indications are also automated, feeding messages back to the fax machine whenever possible (link failed, other station not available, etc). A full page can be sent in 2 to 6 minutes, depending upon ionospheric conditions and the image density of the page being transmitted. The entire link set up and maintenance procedure is transparent to the fax operator, who need not know nor care that an HF radio system is part of the fax link. It all works just like a standard fax telephone transmission. An additional piece of equipment is available from HAL to enable the same fax machine to be shared between HF radio and conventional telephone lines. The HAL LI-4100 Line Interface is a “smart switch” that can be connected between the fax machine, the FAX-4100 controller, and up to two telephone lines.

Courteous SSTV Operating

- Recommended frequencies: 3.845, 7.171, 14.230, 14.233, 21.340, 28.680, 145.5 MHz.
- 14.230 is the most active.
- Make contact by voice before sending SSTV.
- Not all systems recognize the VIS code, so it is good manners to announce the mode before transmitting.

Fig 9.40—Early SSTV operators developed a basic 8-second black and white transmission format. The sync pulses are often called “blacker than black.” A complete picture would have 120 lines (8 seconds at 15 ms per line). Horizontal sync pulses occur at the beginning of every line; a 30 ms vertical sync pulse precedes each frame.

SLOW-SCAN TELEVISION (SSTV)

An ancient Chinese proverb states: “A picture is worth a thousand words.” It’s still true today. Sight is our highest bandwidth sense and the primary source of information about the world around us. What would you think about a TV news program without pictures about the stories? Would you enjoy

reading the comics if there were no drawings with the text? Do you close your eyes when talking to someone in person? Many hams feel the same way about conversing with Amateur Radio: Sending images is a wonderful way to enhance communication. This material was written by John Langner, WB2OSZ.

For decades only a dedicated few kept SSTV alive. The small numbers of commercial equipment were very expensive and home-brewing was much too complicated for most people. Early attempts at computer-based systems were rather crude and frustrating to use.

The situation has changed dramatically in recent years. There is now a wide variety of commercial products and home-brew projects to fit every budget. SSTV activity is experiencing rapid growth. There is much software that uses computer sound cards for SSTV.

The early SSTV 8-second transmission standard is illustrated in **Fig 9.40**. Audio tones in the 1500 to 2300-Hz range represent black, white and shades of gray. A short 1200-Hz burst separates the scan lines and a longer 1200-Hz tone signals the beginning of a new picture.

Color SSTV History

The early experimenters weren’t content with only black and white (B&W) images and soon devised a clever way to send color pictures with B&W equipment. The transmitting station sends the same image three times, one each with red, green and blue filters in front of the TV camera lens. The receiving operator took three long-exposure photographs of the screen, placing red, green and blue filters in front of the film camera’s lens at the appropriate times. This was known as the “frame sequential” method.

In the 1970s, it became feasible to save these three images in solid-state memory and simultaneously display them on an ordinary color TV. The frame-sequential method had some drawbacks. As the first frame was received you’d see a red and black image. During the second frame, green and yellow would appear. Blue, white, and other colors wouldn’t show up until the final frame. Any noise (QRM or QRN) could ruin the image registration (the overlay of the frames) and spoil the picture.

The next step forward was the “line sequential” method. Each line is electronically scanned three times before being transmitted: once each for the red, green, and blue picture components. Pictures could be seen in full color as they were received and registration problems were reduced. The Wraase SC-1 modes are examples of early line-sequential color transmission. They

have a horizontal sync pulse for each of the color component scans. The major weakness here is that if the receiving end gets out of step, it won’t know which scan represents which color.

Rather than sending color images with the usual RGB (red, green, blue) components, Robot Research used luminance and chrominance signals for their 1200C modes. The first half or two thirds of each scan line contains the luminance information, which is a weighted average of the R, G and B components. The remainder of each line contains the chrominance signals with the color information. Existing B&W equipment could display the B&W-compatible image on the first part of each scan line and the rest would go off the edge of the screen. This compatibility was very beneficial when most people still had only B&W equipment.

The luminance-chrominance encoding made more efficient use of the transmission time. A 120-line color image could be sent in 12 s, rather than the usual 24 s. Our eyes are more sensitive to details in changes of brightness than color, so the time could be used more efficiently by devoting more time to luminance than chrominance. The NTSC and PAL broadcast standards also take advantage of this vision characteristic and use less bandwidth for the color part of the signal.

The 1200C introduced another innovation: It encoded the transmission mode in the vertical sync signal. By using narrow FSK encoding around the sync frequency, compatibility was maintained. This new signal just looked like an extra-long vertical sync to older equipment. The luminance-chrominance encoding offers some benefits, but image quality suffers. It is acceptable for most natural images but looks bad for sharp, high-contrast edges, which are more and more common as images are altered via computer graphics. As a result, all newer modes have returned to RGB encoding.

The Martin and Scottie modes are essentially the same except for the timings. They have a single horizontal sync pulse for each set of RGB scans. Therefore, the receiving end can easily get back in step if synchronization is temporarily lost. Although they have horizontal sync, some implementations ignore them on receive. Instead, they rely on very accurate time bases at the transmitting and receiving stations to keep in step. The advantage of this “synchronous” strategy is that missing or corrupted sync pulses won’t disturb the received image. The disadvantage is that even slight timing inaccuracies produce slanted pictures.

In the late 1980s, yet another incompatible mode was introduced. The AVT mode is different from all the rest in that it has *no horizontal sync*. It relies on very accurate

oscillators at the sending and receiving stations to maintain synchronization. If the beginning-of-frame sync is missed, it's all over. There is no way to determine where a scan line begins. However, it's much harder to miss the 5-s header than the 300-ms VIS code. Redundant information is encoded 32 times and a more powerful error-detection scheme is used. It's only necessary to receive a small part of the AVT header in order to achieve synchronization. After this, noise can wipe out parts of the image, but image alignment and colors remain correct. **Table 9.9** lists characteristics of common modes.

Scan Converters

A scan converter is a device that converts signals from one TV standard to another. In this particular case we are interested in converting between SSTV, which can be sent through audio channels, and fast scan (broadcast or ATV), so we can use ordinary camcorders and color televisions to generate and display pictures. From about 1985 to 1992, the Robot 1200C was king.

Fig 9.41 shows a typical SSTV station built around a scan converter such as the Robot 1200C or a SUPERSCAN 2001. The scan converter has circuitry to accept a TV signal from a camera and store it in memory. It also generates a display signal for an ordinary television set. The interface to the radio is simply audio in, audio out and a push-to-talk (PTT) line. In the early days, pictures were stored on audio tape, but now computers store them in memory. Once a picture is in a computer, it can be enhanced with paint programs.

This is the easiest approach. Just plug in the cables, turn on the power and it works. Many people still prefer special dedicated hardware, but most of the recent growth of SSTV has been from these lower cost PC-based systems using sound cards and software.

SSTV with a Computer

There were many attempts to use early home computers for SSTV. Those efforts were hampered by very small computer memories, poor graphics capabilities and poor software development tools.

Surprisingly, little was available for the ubiquitous IBM PC until around 1992, when several systems appeared in quick succession. By this time, all new computers had a VGA display, which is required for this application. Most modern SSTV stations look like **Fig 9.42**. Some sort of interface is used to get audio in and out of the computer. These can be external interfaces connected to a serial or printer port, an internal computer card specifically designed for SSTV or even a peripheral audio card.

Table 9.9
SSTV Transmission Characteristics

<i>Mode</i>	<i>Designator</i>	<i>Color Type</i>	<i>Scan Time (sec)</i>	<i>Scan Lines</i>	<i>Notes</i>

Notes

RGB—Red, green and blue components sent separately.

YC—Sent as Luminance (Y) and Chrominance (R-Y and B-Y).

BW—Black and white.

A—Similar to original 8-second black & white standard.

B—Top 16 lines are gray scale. 240 usable lines.

C—Top 8 lines are gray scale. 120 usable lines.

D—AVT modes have a 5-second digital header and no horizontal sync.

E—Robot 1200C doesn't really have B&W mode but it can send red, green or blue memory separately. Traditionally, just the green component is sent for a rough approximation of a b&w image.

F—JV Fax Color mode allows the user to set the number of lines sent, the maximum horizontal resolution is slightly less than 640 pixels. This produces a slow but very high resolution picture. SVGA graphics are required.

G—Available only on Martin 4.6 chipset in Robot 1200C.

H—Vester version of FAX480 (with VIS instead of start signal and phasing lines).

I—Tricolor version of Vester Truscan.

Perhaps the single most significant breakthrough in computer-based SSTV is the wide range of Windows- and DOS-based programs using the PC's soundcard as the main transmit/receive interface. Many operators nowadays use the popular freeware program *MMSSTV* by JE3HHT (see mmhamsoft.ham-radio.ch/mmsstv/), with a simple hardware interface to go into and to come out of the PC's soundcard. Information on current computer SSTV software is available at www.tima.com/~djones. The subject of computer SSTV software and interfacing is also discussed at length in the *Image Communications Handbook* published by ARRL.

A simple "clipper" hardware interface to the computer's soundcard can be built with less than \$15 worth of RadioShack parts. **Fig 9.43** shows such an interface circuit used for receiving and transmitting. Connect the output of T2 to the phone patch input (sometimes labeled LINE INPUT) of your transceiver, if it has one. Otherwise, you'll have to use the microphone input. R3 is set to the proper level for the audio going to the transmitter. You must set the audio signal into the transceiver at a level it can handle without distortion.

There is no low-pass filtering in the audio line between the computer output and transmitter audio input. On-the-air checks with many stations reveal that no additional external filtering is required when using SSB transmitters equipped with mechanical or

Fig 9.41—Diagram of an older SSTV station based on a scan converter.

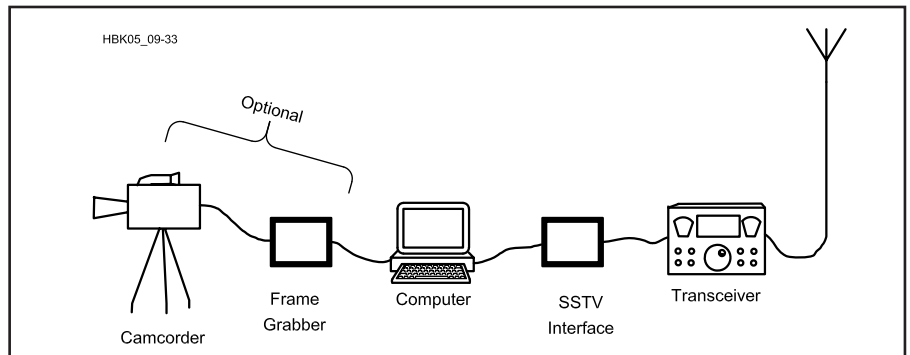

Fig 9.42—A modern SSTV station that utilizes the soundcard in a PC.

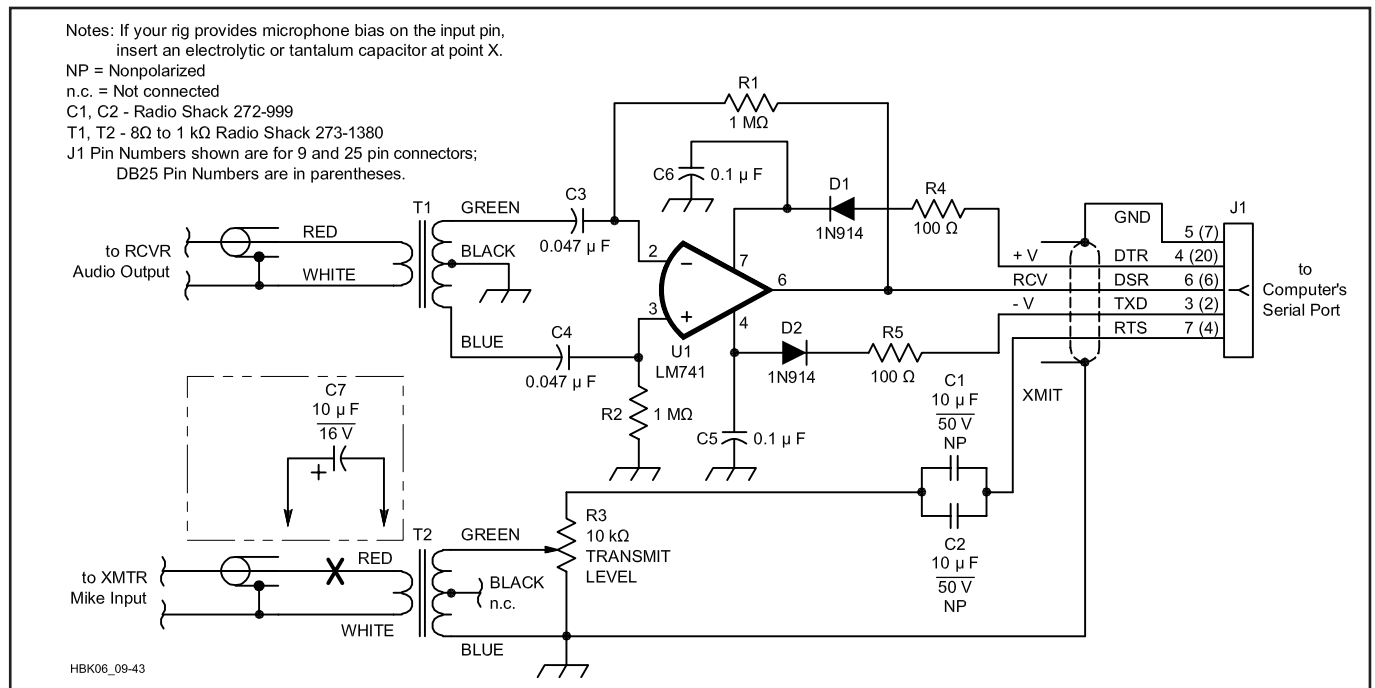

Fig 9.43—Schematic of the simple SSTV receive and transmit circuit from July 1998 *QST*. T1 and T2 are RadioShack 273-1380 audio-output transformers; the 20- μ F, 50-V capacitor is a parallel combination of two RadioShack 272-999 10- μ F, 50-V non-polarized capacitors; equivalent parts can be substituted. Unless otherwise specified, resistors are 1/4-W, 5%-tolerance carbon composition or film units. At J1, numbers in parentheses are for 25-pin serial port connectors; other numbers are for 9-pin connectors.

crystal filters. If you intend to use this circuit with an AM or phasing-type SSB rig (or with VHF/UHF FM transmitters), add audio filtering to provide the required spectral purity. An elliptical low-pass filter such as described by Campbell (see references) should be adequate for most cases.

Circuit component values aren't critical, nor is the circuit's physical construction. A PC board is available from FAR Circuits, but perf-board construction employing short leads works fine.

Digital Slow-Scan Television

DSSTV is a method of transmitting computer image files, such as JPEG or GIF over Amateur Radio, as described in an article by Ralph Taggart, WB8DQT, in the Feb 2004

issue of *QST*. The signal format phase modulates a total of eight subcarriers (ranging from 590 to 2200 Hz at intervals of 230 Hz). Each subcarrier has nine possible modulation states. This signal modulation format is known as *redundant digital file transfer* (RDFT) developed by Barry Sanderson, KB9VAK. RDFT is also used with SCAMP, described earlier in this chapter.

SSTV Summary

For decades there was a convenient excuse for not trying SSTV: it cost kilobucks to buy a specialized piece of equipment. But you can't use that excuse anymore. There are free programs that only require trivial hardware interfaces to receive and transmit slow-scan pictures. Once you get hooked,

there are plenty of other home-brew projects and commercial products available at affordable prices. You need not be a computer wizard to install and use these systems.

SSTV Glossary

ATV—Amateur Television. Sending pictures by Amateur Radio. You'd expect this abbreviation to apply equally to fast-scan television (FSTV), slow-scan television (SSTV) and facsimile (fax), but it's generally applied only to FSTV.

AVT—Amiga Video Transceiver. 1) Interface and software for use with an Amiga computer, developed by Ben Blish-Williams, AA7AS, and manufactured by Advanced Electronic Applications (AEA); 2) a family of transmission modes first introduced with the AVT product.

Back porch—The blank part of a scan line immediately following the horizontal sync pulse.

Chrominance—The color component of a video signal. NTSC and PAL transmit color images as a black-and-white compatible luminance signal along with a color subcarrier. The subcarrier phase represents the hue and the subcarrier's amplitude is the saturation. Robot color modes transmit pixel values as luminance (Y) and chrominance (R-Y [red minus luminance] and B-Y [blue minus luminance]) rather than RGB (red, green, blue).

Demodulator—For SSTV, a device that extracts image and sync information from an audio signal.

Field—Collection of top to bottom scan lines. When interlaced, a field does not contain adjacent scan lines and there is more than one field per frame.

Frame—One complete scanned image. The Robot 36-second color mode has 240 lines per frame. NTSC has 525 lines per frame with about 483 usable after subtracting vertical sync and a few lines at the top containing various information.

Frame Sequential—A method of color SSTV transmission that sent complete, sequential frames of red, then green and blue. Now obsolete.

Front porch—The blank part of a scan line just before the horizontal sync.

FSTV—Fast-Scan TV. Same as common, full-color, motion commercial broadcast TV.

Interlace—Scan line ordering other than the usual sequential top to bottom. For example, NTSC sends a field with just the even lines in 1/60 second, then a field with just the odd lines in 1/60 second. This results in a complete frame 30 times a second. AVT "QRM" mode is the only SSTV mode that uses interlacing.

Line Sequential—A method of color SSTV transmission that sends red, green, and blue information for each sequential scan line. This approach allows full-color

images to be viewed during reception.

Luminance—The brightness component of a video signal. Usually computed as Y (the luminance signal) = $0.59 G$ (green) + $0.30 R$ (red) + $0.11 B$ (blue).

Martin—A family of amateur SSTV transmission modes developed by Martin Emmerson, G3OQD, in England.

NTSC—National Television System Committee. Television standard used in North America and Japan.

PAL—Phase alteration line. Television standard used in Germany and many other parts of Europe.

Pixel—Picture element. The dots that make up images on a computer's monitor.

P7 monitor—SSTV display using a CRT having a very-long-persistence phosphor.

RGB—Red, Green, Blue. One of the models used to represent colors. Due to the characteristics of the human eye, most colors can be simulated by various blends of red, green, and blue light.

Robot—(1) Abbreviation for Robot 1200C scan converter; (2) a family of SSTV transmission modes introduced with the 1200C.

Scan converter—A device that converts one TV standard to another. For example, the Robot 1200C converts SSTV to and from FSTV.

Scottie—A family of amateur SSTV transmission modes developed by Eddie Murphy, GM3SBC, in Scotland.

SECAM—Sequential color and memory. Television standard used in France and the Commonwealth of Independent States.

SSTV—Slow Scan Television. Sending still images by means of audio tones on the MF/HF bands using transmission times of a few seconds to a few minutes.

Sync—That part of a TV signal that indicates the beginning of a frame (vertical sync) or the beginning of a scan line (horizontal sync).

VIS—Vertical Interval Signaling. Digital encoding of the transmission mode in the vertical sync portion of an SSTV image. This allows the receiver of a picture to automatically select the proper mode. This was introduced as part of the Robot modes and is now used by all SSTV software designers.

Wraase—A family of amateur SSTV transmission modes first introduced with the Wraase SC-1 scan converter developed by Volker Wraase, DL2RZ, of Wraase Elektronik, Germany.

FAST-SCAN TELEVISION

Fast-scan amateur television (FSTV or just ATV) is a wide-band mode that uses standard broadcast, or NTSC, television scan rates. It is called "fast scan" only to differentiate it from slow-scan TV. In fact, no scan conversions or encoder/decoders are necessary with FSTV. Any standard TV set can display the amateur video and audio. Standard (1 V P-P into 75 Ω) composite video

Fig 9.44—Students enjoy using ATV to communicate between science and computer classes.

Fig 9.45—The ATV view shows the aft end of the Space Shuttle cargo bay during mission STS-9.

Table 9.10

Line-of-Sight Snow-Free 70-cm ATV Communication Distances

This table relates transmit and receive station antenna gains to communication distances in miles for 1/10/100 W PEP at 440 MHz. To find the possible snow-free distance under line-of-sight conditions, select the column that corresponds to transmit antenna gain and the row for the receive antenna gain. Read the distance where the row and column intersect. Multiply the result by 0.5 for 902 MHz and 0.33 for 1240 MHz.

The table assumes 2 dB of feed-line loss, a 3 dB system noise figure at both ends and snow-free is greater than 40 dB picture:noise ratio (most home cameras give 40 to 45 dB picture:noise; this is used as the limiting factor to define snow-free ATV pictures). The P unit picture rating system goes down about 6 dB per unit. For instance, P4 pictures would be possible at double the distances in the table.

from home camcorders, cameras, VCRs or computers is fed directly into an AM ATV transmitter. The audio has a separate connector and goes through a 4.5 MHz FM subcarrier generator that is mixed with the video. This section was written by Tom O'Hara, W6ORG.

Amateurs regularly show themselves in the shack, zoom in on projects, show home video tapes, computer programs and just about anything that can be shown live or by tape (see **Figs 9.44** and **9.45**). Whatever the camera "sees" and "hears" is faithfully transmitted, including color and sound information. Picture quality is about equivalent to that of a VCR, depending on video signal level and any interfering carriers. All of the sync and signal-composition information is present in the composite-video output of modern cameras and camcorders. Most camcorders have an accessory cable or jacks that provide separate video and audio outputs. Audio output may vary from one camera to the next, but usually it has been amplified from the built-in microphone to between 0.1 to 1 V P-P (into a 10-k Ω load).

ATV transmitters have been carried by helium balloons to above 100,000 ft, to the edge of space. The result is fantastic video transmissions, showing the curvature of the Earth, that have been received as far as 500 miles from the balloon. Small cameras have been put into the cockpits of R/C model airplanes to transmit a pilot's-eye view. Many ATV repeaters retransmit Space Shuttle video and audio from NASA during missions. This is especially exciting for schools involved with SAREX. ATV is used for public service events, such as parades, races, Civil Air Patrol searches and remote damage assessment.

Emergency service coordinators have found that live video from a site gives a better

understanding of a situation than is possible from voice descriptions alone. Weather-radar video, WEFAX, or other computer generated video has also been carried by ATV transmitters for RACES groups during significant storms. This use enables better allocation of resources by presenting real-time information about the storm track. Computer graphics and video special effects are often transmitted to dazzle the viewers.

How Far Does ATV Go?

The theoretical snow-free line-of-sight distance for 10 W, given 15.8-dBd antennas and 2-dB feed-line loss at both ends, is 91 miles. (See **Table 9.11**.) However, except for temperature-inversion skip conditions, reflections, or through high hilltop repeaters, direct line-of-sight ATV contacts seldom exceed 25 miles. The RF horizon over flat terrain with a 50-ft tower is 10 miles. For best DX, use low-loss feed line and a broadband high-gain antenna, up as high as possible. The antenna system is the most important part of an ATV system because it affects both receive and transmit signal strength.

A snow-free, or "P5," picture rating (see **Fig 9.46**) requires at least 200 μ V (−61 dBm) of signal at the input of the ATV receiver, depending on the system noise figure and bandwidth. The noise floor increases with bandwidth. Once the receiver system gain and noise figure reaches this

P5—Excellent

P4—Good

P3—Fair

P2—Poor

P1—Barely perceptible

Fig 9.46—An ATV quality reporting system.

floor, no additional gain will increase sensitivity. At 3-MHz bandwidth the noise floor is $0.8 \mu\text{V}$ (-109 dBm) at standard temperature. If you compare this to an FM voice receiver with 15 kHz bandwidth; there is a 23 dB difference in the noise floor. However the eye, much like the ear of experienced CW operators, can pick out sync bars in the noise below the noise floor. Sync lock and large well contrasted objects or lettering can be seen between 1 and $2 \mu\text{V}$. Color and subcarrier sound come out of the noise between 2 and $8 \mu\text{V}$ depending on their injection level at the transmitter and TV-set differences.

Two-meter FM is used to coordinate ATV contacts. Operators must take turns transmitting on the few available channels and the 2-m link allows full-duplex audio from many receiving stations to the ATV transmitting station, who speaks on the sound subcarrier. This is great for interactive show and tell. It is also much easier to monitor a squelched 2-m channel using an omni antenna rather than searching out each station with a beam. Depending on the third-harmonic relationship to the video on 70 cm, 144.34 MHz and 146.43 MHz (simplex) are the most popular frequencies. They are often mixed with the subcarrier sound on ATV repeater outputs.

Getting the Picture

Since the 70-cm band corresponds to cable TV channels 57 through 61, seeing your first ATV picture may be as simple as connecting a good outside 70-cm antenna (aligned for the customary local polarization) to a cable-ready TV set's antenna input jack. Cable channel 57 is 421.25 MHz, and each channel is progressively 6 MHz higher. (Note that cable and broadcast UHF channel frequencies are different.) Check the *ARRL Repeater Directory* for a local ATV repeater output that falls on one of these cable channels. Cable-ready TVs may not be as sensitive as a low-noise downconverter designed just for ATV, but this technique is well worth a try.

Most stations use a variable tuned downconverter specifically designed to convert the whole amateur band down to a VHF TV channel. Generally the 400 and 900-MHz bands are converted to TV channel 3 or 4, whichever is not used in the area. For 1200 MHz converters, channels 7 through 10 are used to get more image rejection. The downconverter consists of a low-noise preamp, mixer and tunable or crystal-controlled local oscillator. Any RF at the input comes out at the lower frequencies. All signal processing is done in the TV set. A complete receiver with video and audio output would require all the TV sets circuitry, less the sweep and CRT components. There is no

picture-quality gain by going direct from a receiver to a video monitor (as compared with a TV set) because IF and detector bandwidth are still the limiting factors.

A good low-noise amateur downconverter with 15 dB gain ahead of a TV set will give sensitivity close to the noise floor. A preamp located in the shack will not significantly increase sensitivity, but rather will reduce dynamic range and increase the probability of intermodulation interference. Sensitivity can be increased by increasing antenna-system gain:

- Reducing feed-line loss
- Increasing antenna gain
- Or adding an antenna mounted preamp (which will eliminate the coax loss, plus any loss through transmit linear amplifier TR relays).

Remember that each 6 dB increase in combination of transmitted power, reduced coax loss, antenna gain or receiver sensitivity can double the line-of-sight distance.

Foliage greatly attenuates the signal at UHF, so place antennas above the tree tops for the best results. Beams made for 432-MHz weak-signal work or 440-MHz FM may not have enough SWR bandwidth to cover all the ATV frequencies for transmitting, but they are okay for reception. A number of manufacturers now make ATV beam antennas to cover the whole band from 420 to 450 MHz. Use low-loss coax (such as Belden 9913: 2.5 dB/100 ft at 400 MHz) or Hardline for runs over 100 ft. All outside connectors must be weatherproofed with tape or coax sealer—Any water that gets inside the coax will greatly increase the attenuation. Almost all ATV antennas use N connectors, which are more resistant to moisture contamination than other types.

Antenna polarization varies from area to area. Technically, the polarization should be chosen to give additional isolation (up to 20 dB) from other users near the channel. It is more common to find that the polarity was

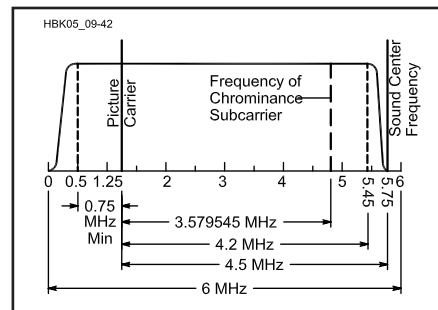

Fig 9.47—A 6-MHz video channel with the video carrier 1.25 MHz up from the lower edge. The color subcarrier is at 3.58 MHz and the sound subcarrier at 4.5 MHz above the video carrier.

determined by the first local ATV operators (which antennas they had in place for other modes). Generally, those on 432 MHz SSB and weak-signal DX have horizontally polarized antennas, and those into FM, public service or repeaters will have vertical antennas. Check with local ATV operators before permanently locking down the antenna-mast clamps. Circularly polarized antennas let you work all modes, including satellites, with only 3 dB sacrificed when working a fixed polarity.

ATV Frequencies

Standard broadcast TV channels are 6 MHz wide to accommodate the composite video, 3.58 MHz color and 4.5 MHz sound subcarriers. (See Fig 9.47.) Given the NTSC 525 horizontal line and 30 frames per second scan rates, the resulting horizontal resolution bandwidth is 80 lines per MHz. Therefore, with the typical TV set's 3-dB rolloff at 3 MHz (primarily in the IF filter), up to 240 vertical black lines can be seen. Color bandwidth in a TV set is less than this, resulting in up to 100 color lines. Lines of resolution are often confused with the number of horizontal scan lines per frame. The video quality should be every bit as good as on a home video recorder.

The lowest frequency amateur band wide enough to support a TV channel is 70 cm (420 - 450 MHz), and it is the most popular. With transmit power, antenna gains and coax losses equal, decreasing frequency increases communication range. The 33-cm band goes half the distance that 70 cm does, but this can be made up to some extent with high-gain antennas, which are physically smaller at the higher frequency. A Technician class or higher license is required to transmit ATV on this band, and Novices can transmit ATV only in the 1270 to 1295 MHz segment of the 23-cm band. Depending on local band plan options, there is room for no more than two simultaneous ATV channels in the 33- and 70-cm bands without interference. Generally, because only two channels are available in the 70-cm band, an ATV repeater input on 439.25 or 434.0 MHz is shared with simplex stations. 421.25 MHz is the most popular in-band repeater output frequency. At least 12 MHz of separation is necessary for in-band repeaters because of filter-slope attenuation characteristics and TV-set adjacent-channel rejection. Some repeaters have their output on the 33-cm or 23-cm bands (the 923.25 and 1253.25 MHz output frequencies are most popular). This frees up a channel on 70 cm for simplex. Such cross-band repeaters also make it easier for the transmitting operator to monitor the repeated video with only proper antenna separation needed to prevent receiver desensitization. 426.25 MHz is used for sim-

Fig 9.48—A spectrum-analyzer photo of a color ATV signal. Each vertical division represents 10 dB; horizontal divisions are 1 MHz. Spectrum power density varies with picture content, but typically 90% of the sideband power is within the first 1 MHz.

plex, public service and R/C models in areas with cross-band repeaters, or as a alternative to the main ATV activities on 434.0 or 439.25 MHz. Before transmitting, check with local ATV operators, repeater owners and frequency coordinators listed in the *ARRL Repeater Directory* for the coordinated frequencies used in your area.

Since a TV set receives a 6-MHz bandwidth, ATV is more susceptible to interference from many other sources than are narrower modes. Interference 40 dB below the desired signal can be seen in video. Many of our UHF (and above) amateur bands are shared with radar and other government radio positioning services. These show up as horizontal bars in the picture. Interference from amateurs who are unaware of the presence of the ATV signal (or in the absence of a technically sound and publicized local band plan) can wipe out the sound or color or put diagonal lines in the picture.

DSB and VSB Transmission

While most ATV is double sideband (DSB) with the widest component being the sound subcarrier out ± 4.5 MHz, over 90% of the spectrum power is in the first 1 MHz on both sides of the carrier for DSB or VSB (vestigial sideband). As can be seen in Fig 9.48, the video power density is down more than 30 dB at frequencies greater than 1 MHz from the carrier. DSB and VSB are both compatible with standard TV receivers, but the lower sound and color subcarriers are rejected in the TV IF filter as unnecessary. In the case of VSB, less than 5% of the lower sideband energy is attenuated. The other significant energy frequencies are the sound (set in the ATV transmitter at 15 dB below the peak sync) and the color at 3.58 MHz (greater than 22 dB down).

Narrowband modes operating greater than 1 MHz above or below the video carrier are rarely interfered with or know that

Fig 9.49—A photo of an ATV image of the Space Shuttle interior with K6KMN's repeater ID overlaid. Automatic video overlay in the picture easily solves the 10-minute ID requirement for Space Shuttle retransmissions and other long transmissions.

the ATV transmitter is on unless the narrowband signal is on one of the subcarrier frequencies or the stations are too near one another. If the band is full and the lower sideband color and sound subcarrier frequencies need to be used by a dedicated link or repeater, a VSB filter in the antenna line can attenuate them another 20 to 30 dB, or the opposite antenna polarization can be used for more efficient packing of the spectrum. Since all amateur linear amplifiers reinsert the lower sideband to within 10 dB of DSB, a VSB filter in the antenna line is the only cost-effective way to reduce the unnecessary lower sideband subcarrier energy if more than 1 W is used. In the more populated areas, 2-m calling or coordination frequencies are often used to work out operating time shifts, and so on, between all users sharing or overlapping the same segment of the band.

ATV Identification

ATV identification can be on video or the sound subcarrier. A large high-contrast call-letter sign on the wall behind the operating table in view of the camera is the easiest way to fulfill the requirement. Transmitting stations fishing for DX during band openings often make up call-ID signs using fat black letters on a white background to show up best in the snow. Their city and 2-m monitoring frequency are included at the bottom of the sign to make beam alignment and contact confirmation easier.

Quite often the transmission time exceeds 10 minutes, especially when transmitting demonstrations, public-service events, space-shuttle video, balloon flights or a video tape. A company by the name of Intuitive Circuits makes a variety of boards that will overlay text on any video looped through them. Call letters and other information can be programmed into the board's non-volatile memory by on-board push buttons or an EIA-232 line from a computer

(depending on the version and model of the OSD board). There is even a model that will accept NMEA-0183 GPRMC data from a GPS receiver and overlay latitude, longitude, altitude, direction and speed, as well as call letters, on the applied camera video. This is ideal for ATV rockets, balloons and R/C vehicles. The overlaid ID can be selected to be on, off or flashed on for a few seconds every 10 minutes to automatically satisfy the ID requirement of §97.119 (see Fig 9.49). The PC Electronics VOR-2 board has an automatic nine-minute timer, and it also has an end-of-transmission hang timer that switches to another video source for ID.

Driving Amplifiers with ATV

Wide-band AM video requires some special design considerations for linear amplifiers (as compared to those for FM and SSB amplifiers). Many high-power amateur amplifiers would oscillate (and possibly self destruct) from high gain at low frequencies if they were not protected by feedback networks and power RF chokes. These same

Fig 9.50—An oscilloscope used to observe a video waveform. The lower trace is the video signal as it comes out of the sync stretcher. The upper trace is the signal from the Mirage D1010-N amplifier.

stability techniques can affect some of the 5-MHz video bandwidth. Sync, color and sound can be very distorted unless the amplifier has been carefully designed for both stability and AM video modulation.

Mirage, Teletec and Down East Microwave either make special ATV amplifiers or offer standard models that were designed for all modes, including ATV. Basically the collector and base bias supplies have a range of capacitors to keep the voltage constant under modulation, while at the same time using the minimum-value low-resistance series inductors or chokes to prevent self oscillation.

Almost all amateur linear power amplifiers have gain compression from half to their full rated peak envelope power. To compensate for this, the ATV exciter/modulator has a sync stretcher to maintain the proper transmitted video to sync ratio (see Fig 9.50). With both video and sound subcarrier disconnected, the pedestal control is set for maximum power output. Peak sync should first be set to 90% of the rated peak envelope power. (This is necessary to give some head room for the 4.5 MHz sound that is mixed and adds with the video waveform.) The TXA5-70 exciter/modulator has a RF power control to set this. Once this is done, the blanking pedestal control can be set to 60% of the peak sync value. For example, a 100-W amplifier would first be set for 90 W with the RF power control and then 54 W with the pedestal control. Then the sound subcarrier can be turned back on and the video plugged in and adjusted for best picture. If you could read it on a peak-reading power meter made for video, the power would be between 90 and 100 W PEP. On a dc oscilloscope connected to a RF diode detector in the antenna line, it can be seen that the sync and blank-

ing pedestal power levels remain constant at their set levels regardless of video gain setting or average picture contrast. On an averaging meter like a Bird 43, however, it is normal to read something less than the pedestal set-up power.

ATV Repeaters

Basically there are two kinds of ATV repeaters: in band and cross band. 70-cm in-band repeaters are more difficult to build and use, yet they are more popular because equipment is more available and less expensive. Indeed, cable-ready TV sets tune the 70-cm band with no modifications.

Why are 70-cm repeaters more difficult to build? The wide bandwidth of ATV makes for special filter requirements. Response across the 6-MHz passband must be as flat as possible with minimum insertion loss, but also must sharply roll off to reject other users as little as 12 MHz away. Special multipole interdigital or combline VSB filters are used to meet the requirement. An ATV duplexer can be used to feed one broadband omnidirectional antenna, but an additional VSB filter is needed in the transmitter line for sufficient attenuation of noise and IMD products.

A cross-band repeater, because of the great frequency separation between the input and output, requires less sophisticated filtering to isolate the transmitter and receiver. In addition, a cross-band repeater makes it easier for users to see their own video (no duplexer is needed, only sufficient antenna spacing). Repeater linking is easier too, if the repeater outputs alternate between the 23- and 33-cm bands.

Fig 9.51 shows a block diagram for a simple 70-cm in-band repeater. No duplexer is shown because the antennas and VSB filters provide adequate isolation. The repeater

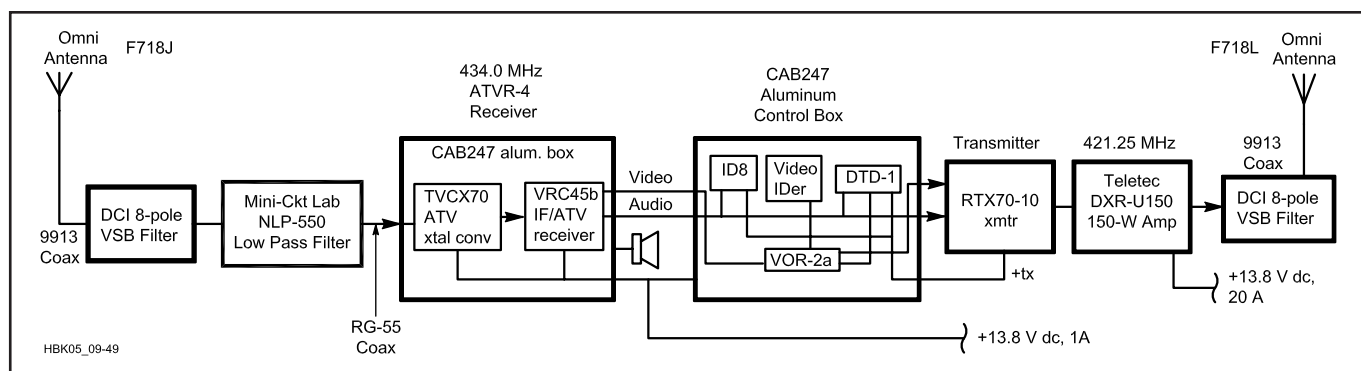

Fig 9.51—A block diagram of a 70-cm in-band ATV repeater. The antennas are Diamond omnidirectional verticals, which require 20 ft (minimum) of vertical separation to prevent receiver desensitization. The VSB filters are made by DCI; they have the proper band-pass characteristics and only 1 dB insertion loss. A low pass filter on the receiver is also necessary because cavity type filters repeat a pass-band at odd harmonics and the third-harmonic energy from the transmitter may not be attenuated enough. The receiver, 10-W transmitter and VOR are made by PC Electronics. The Communications Specialists DTD-1 DTMF decoder and ID8 Morse identifier (optional if a video ID is used) are used to remotely turn the repeater transmitter on or off and to create a CW ID, respectively. Alternatively, an Intuitive Circuits ATV4-4 ATV repeater controller board can do all the control box functions as well as remotely select from up to four video sources.

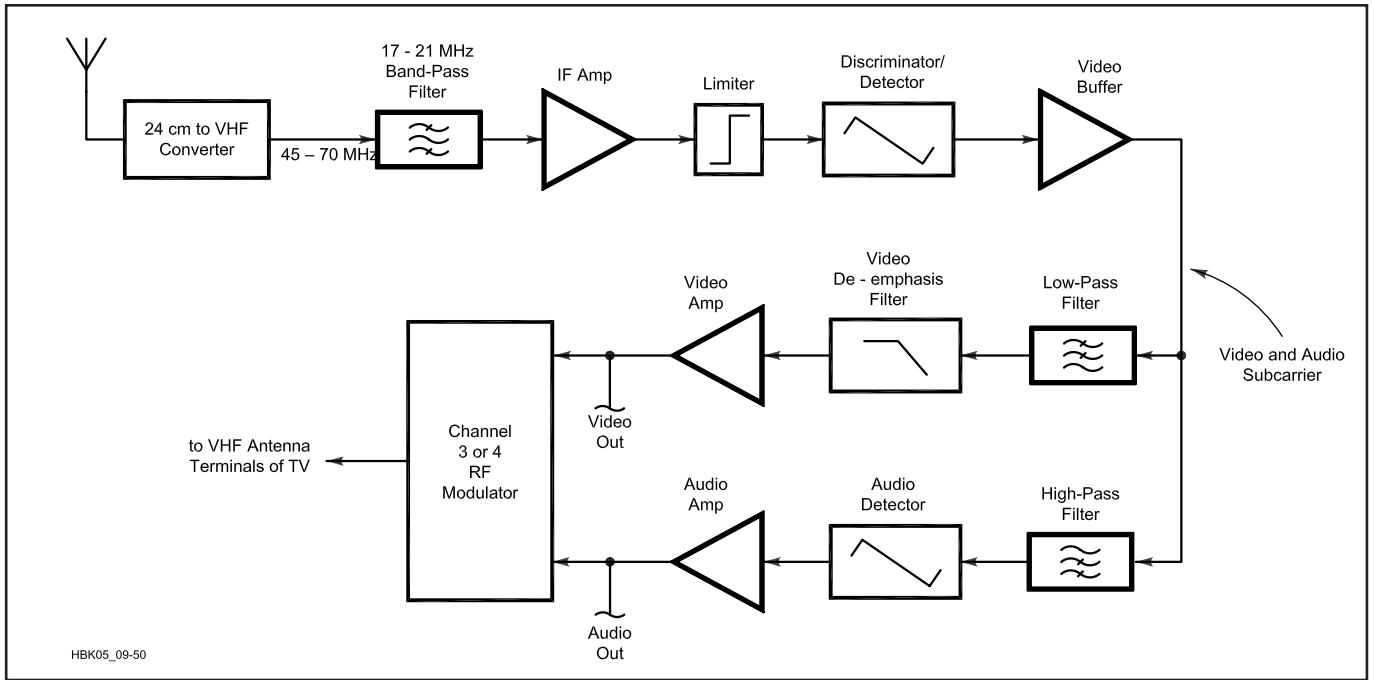

Fig 9.52—Block diagram of an FMATV receiver.

transmitter power supply should be separate from the receiver and exciter supply. ATV is amplitude modulated, therefore the current varies greatly from maximum at the sync tip to minimum during white portions of the picture. Power supplies are not generally made to hold tight regulation with such great current changes at rates up to several megahertz. Even the power supply leads become significant inductors at video frequencies; they will develop a voltage across them that can be transferred to other modules on the same power-supply line.

To prevent unwanted key up from other signal sources, ATV repeaters use a video operated relay (VOR). The VOR senses the horizontal sync at 15,734 Hz in much the same manner that FM repeaters use CTCSS tones. Just as in voice repeaters, an ID timer monitors VOR activity and starts the repeater video ID generator every nine minutes, or a few seconds after a user stops transmitting.

Frequency Modulated ATV (FMATV)

While AM is the most popular mode because of greater equipment availability, lower cost, less occupied bandwidth and use of a standard TV set, FMATV is gaining interest among experimenters and also repeater owners for links. FM on the 1200-MHz band is the standard in Europe because there is little room for video in their allocated portion of the 70-cm band. FMATV occupies 17 to 21 MHz depending on deviation and sound subcarrier frequency. The US 70-cm band is wide enough but has great interference potential in all but the less popu-

lated areas. Most available FMATV equipment is made for the 1.2, 2.4 and 10.25-GHz bands. Fig 9.52 is a block diagram of an FMATV receiver.

The US standard for FMATV is 4 MHz deviation with the 5.8-MHz sound subcarrier set to 10 dB below the video level. 1252 or 1255 MHz are suggested frequen-

cies in order to stay away from FM voice repeaters and other users higher in the band, while keeping sidebands above the 1240-MHz band edge. Using the US standard, with Carson's rule for FM occupied bandwidth, it comes out to just under 20 MHz. So 1250 MHz would be the lowest possible frequency. Almost all modern FMATV equip-

Fig 9.53—Two approaches to ATV receiving. This chart compares AM (A) and FM (F) ATV as seen on a TV receiver and monitor. Signal levels are into the same downconverter with sufficient gain to be at the noise floor. The FM receiver bandwidth is 17 MHz, using the US standard.

ment is synthesized, but if yours is not, use a frequency counter to monitor the frequency for warm up drift. Check with local frequency coordinators before transmitting because the band plan permits other modes in that segment.

Experimentally, using the US standard, FMATV gives increasingly better picture-to-noise ratios than AMATV at receiver input signals greater than 5 μV . Because of the wider noise bandwidth and FM threshold effect, AM video can be seen in the noise well before FM. For DX work, it has been shown that AM signals are recognizable signals in the snow at four times (12 dB) greater distance than FM signals, with all other factors equal. Above the FM threshold, however, FM rapidly overtakes AM. Snow-free pictures occur above 50 μV , or four times farther away than with AM signals. The crossover point is near the signal level where sound and color begin to appear for both systems. **Fig 9.53** compares AM and FMATV across a wide range of signal strengths.

There are a variety of methods to receive FMATV. Older satellite receivers have a 70 or 45-MHz input and require a down converter with 40 to 50 dB gain ahead of them. Also satellite receivers are made for wider deviation and need some video gain to give the standard 1 volt peak-to-peak video output when receiving a signal with standard 4-MHz deviation. Current satellite receivers directly tune anywhere from 900 to 2150 MHz and they only need a preamp added at the antenna for use on the 33 and 23-cm ham bands. The additional video gain can often be had by adjusting an internal pot or changing the gain with a resistor.

Some of the inexpensive Part 15 license-free wireless video receivers in the 33 cm band use 4-MHz deviation FM video, and most of the 2.4-GHz ones are FM, which can be used directly. However, they may or may not have the standard de-emphasis video network, which then may have to be added. On 2.4 GHz, some of the Part 15 frequen-

Fig 9.54—N8QPJ mounted an ATV setup aboard this model Humvee.

cies are outside the band and care should be taken to use only those inside the 2390 to 2450 MHz ham band if modified. Wavecom Jr has been the most popular 2.4 GHz license-free video transmitter and receiver (available from ATV Research). These have been modified for higher power and other features, as well as having all four of the channels in the ham band using interface boards from PC Electronics.

Gunnplexers on 10.4 GHz make inexpensive point to point ATV links for public-service applications or between repeaters. A 10-mW Gunnplexer with 17-dB horn can cover over 2 miles line-of-sight when received on a G8OZP low noise 3-cm LNB and satellite receiver. An application note for construction of the 3-cm transmitter comes with the GVM-1 Gunnplexer video modulator board from PC Electronics.

For short distance ATV from R/C vehicles, low-power FM ATV modules with 50 to 100-mW output in the 33, 23 or 13-cm bands are often used. These offer less desense possibility to the R/C receiver. An example can be seen on the model Humvee in **Fig 9.54**.

DIGITAL AMATEUR TELEVISION (DATV)

German amateurs have lead the way in digital ATV. For the past few years, Uwe Kraus, DJ8DW, and others have had a stand at HamRadio—the large European Amateur Radio gathering in Friedrichshafen, Germany. The motivation for DATV is about the same as for commercial digital television, particularly high quality pictures even with weak signals and a distinctively smaller bandwidth than that occupied by analog TV. A breakthrough occurred in September 1998 when the DATV team transmitted digital pictures over a 62-mile path with a 2 MHz bandwidth at 434 MHz using MPEG-1 encoding.

Spread Spectrum

Contributors to this section were André Kesteloot, N4ICK, John Champa, K8OCL, and Kris Mraz, N5KM. *The ARRL Spread Spectrum Sourcebook* contains a more complete treatment of the subject. The following information takes the subject from early experiments by the Amateur Radio Research and Development Corporation (AMRAD) to contemporary Amateur Radio use of spread spectrum technology for high-speed multimedia (HSMM) applications.

Spread spectrum originated in the 1930s, shrouded in secrecy. In 1942, Hollywood

movie actress Hedy Lamarr and composer George Antheil were granted a patent for spread spectrum. Despite the fact that John Costas, W2CRR, published a paper on non-military applications of spread spectrum communications in 1959, spread spectrum was used almost solely for military purposes until the late 1970s. In 1981, the FCC granted AMRAD a Special Temporary Authorization to conduct Amateur Radio spread spectrum experiments. In June 1986, the FCC authorized all US amateurs to use spread spectrum above 420 MHz. These

FCC grants were intended to encourage the development of spread spectrum, which was an important element in commercial wireless systems that emerged in the 1990s.

WHY SPREAD SPECTRUM

Faced with increasing noise and interference levels on most RF bands, traditional wisdom still holds that the narrower the RF bandwidth, the better the chances that "the signal will get through." This is not so.

In 1948, Claude Shannon published his famous paper, "A Mathematical Theory of

Communication” in the *Bell System Technical Journal*, followed by “Communications in the Presence of Noise” in the *Proceedings of the IRE* for January 1949. A theorem that follows Shannon’s, known as the Shannon-Hartley theorem, states that the channel capacity C of a band-limited Gaussian channel is:

$$C = W \log_2 \left(1 + \frac{S}{N} \right) \text{ bits/s} \quad (\text{Eq 1})$$

where

W is the bandwidth,

S is the signal power and

N is the noise within the channel bandwidth.

This theorem states that should the channel be perfectly noiseless, the capacity of the channel is infinite. It should be noted, however, that making the bandwidth W of the channel infinitely large does *not* make the capacity infinite, because the channel noise increases proportional to the channel bandwidth.

Within reason, however, you can trade power for bandwidth. In addition, the power density at any point of the occupied bandwidth can be very small, to the point that it may be well *below* the noise floor of the receiver. The US Navy Global Positioning System (GPS) is an excellent example of the use of what is called direct-sequence spread spectrum. The average signal at the GPS receiver’s antenna terminals is approximately -160 dBW (for the C/A code). Since most sources of interference are relatively narrowband, spread-spectrum users will also benefit, as narrowband interfering signals are rejected automatically during the despreading process, as will be explained later in this section.

These benefits are obtained at the cost of

fairly intricate circuitry: The transmitter must spread its signal over a wide bandwidth in accordance with a certain prearranged code, while the receiver must somehow synchronize on this code and recombine the received energy to produce a usable signal. To generate the code, use is made of pseudo-noise (PN) generators. The PN generators are selected for their correlation properties. This means that when two similar PN sequences are compared out of phase their correlation is nil (that is, the output is 0), but when they are exactly in phase their correlation produces a huge peak that can be used for synchronization purposes.

This synchronization process has been (and still is) the major complicating factor in

any spread spectrum link, for how can one synchronize on a signal that can be well below the receiver’s noise floor? Because of the cost associated with the complicated synchronization processes, spread spectrum applications were essentially military-related until the late 1970s. The development of ICs then allowed for the replacement of racks and racks of tube equipment by a few plug-in PC boards, although the complexity level itself did not improve. Amateur Radio operators could not afford such levels of complexity and had to find simpler solutions, at the cost of robustness in the presence of interference.

Spread-Spectrum Transmissions

A transmission can be called “spread spectrum” if the RF bandwidth used is (1) much larger than that needed for traditional modulation schemes and (2) independent of the modulation content. Although numerous spread spectrum schemes are in existence, amateurs can use any of them as long as the modulation scheme has been published, for example on the ARRL website. By far, frequency-hopping (FH) and direct-sequence spread spectrum (DSSS) are the most popular forms within the Amateur Radio community.

To understand FH, let us assume a transmitter is able to transmit on any one of 100 discrete frequencies $F1$ through $F100$. We now force this equipment to transmit for 1 second on each of the frequencies, but in an apparently random pattern (for example, $F1, F62, F33, F47, \dots$) See Fig 9.55. Should some signal interfere with the receiver site on three of those discrete frequencies, the system will still have achieved reliable transmission 97% of the time. Because of the built-in redundancy in human speech, as well as the availability of error-correcting

Fig 9.55—Power vs frequency for frequency-hopping spread spectrum signals. Emissions jump around to discrete frequencies in pseudo-random fashion.

Fig 9.56—Power vs frequency for a direct-sequence modulated spread spectrum signal. The envelope assumes the shape of a $(\sin x/x)^2$ curve. With proper modulating techniques, the carrier is suppressed.

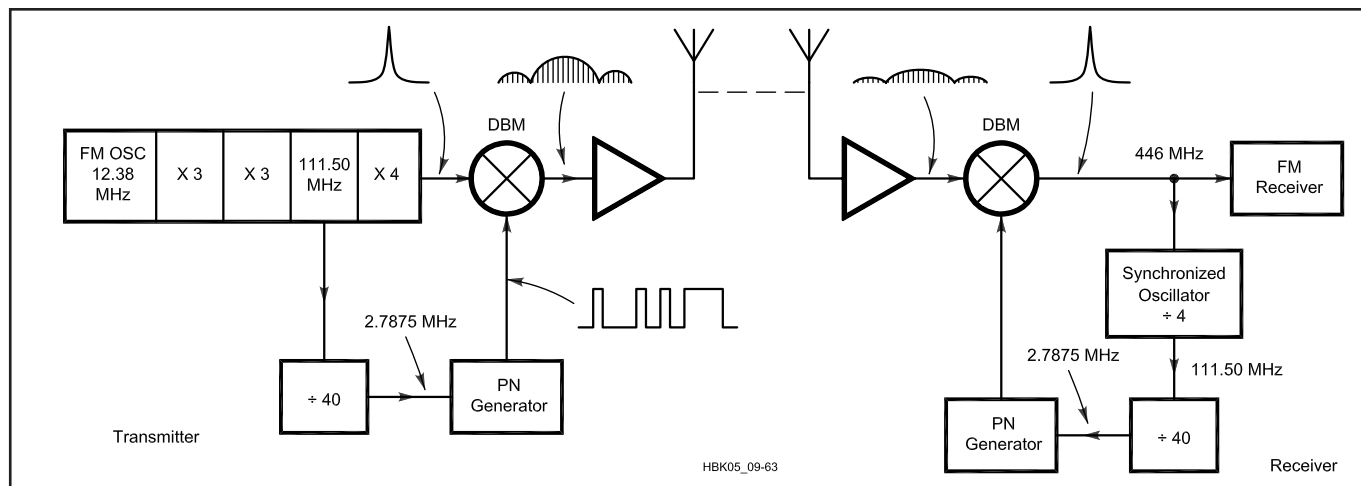

Fig 9.57—A block diagram of the practical spread spectrum link. The success of this arrangement lies in the use of a synchronized oscillator (right) to recover the transmitter clock signal at the receiving site.

Fig 9.58—(A) The envelope of the unfiltered biphasemodulated spread spectrum signals as viewed on a spectrum analyzer. In this practical system, band-pass filtering is used to confine the spread spectrum signal to the amateur band. (B) At the receiver end of the line, the filtered spread spectrum signal is apparent only as a 10-dB hump in the noise floor. (C) The despread signal at the output of the receiver DBM. The original carrier—and any modulation components that accompany it—has been recovered. The peak carrier is about 45 dB above the noise floor—more than 30 dB above the hump shown at B. (These spectrograms were made at a sweep rate of 0.1 s/division and an analyzer bandwidth of 30 kHz; the horizontal scale is 1 MHz/division.)

codes in data transmissions, this approach is particularly attractive for systems that must operate in heavy interference.

In a DSSS transmitter, an RF carrier and a pseudo-random pulse train are mixed in a doubly balanced mixer (DBM). In the process, the RF carrier disappears and is replaced by a noise-like wideband transmission, as shown in **Fig 9.56**. At the receiver, a similar pseudo-random signal is reintroduced and the spread spectrum signal is correlated, or despread, while narrowband interference is spread simultaneously by the same process.

The technical complexity mentioned above is offset by several important advantages for military and space applications:

- **Interference rejection.** If the interference is not synchronized with the original spread spectrum signal, it will not appear after despreading at the receiver.
- **Security.** The length and sophistication of the pseudo-random codes used can be such as to make unauthorized recovery difficult, if not impossible.
- **Power density.** Low power density makes for easy hiding of the RF signal and a resulting lower probability of detection.

So far as the Amateur Radio community is concerned, particular benefit will be derived from the interference rejection just mentioned, since it offers both robustness and reliability of transmissions, as well as a low probability of interference to other users. Additionally, spread spectrum has the potential to allow better utilization of the RF spectrum allocated to amateurs. There is a limit as to how many conventional signals can be placed in a given band before serious transmission degradation takes place. Additional spread spectrum signals will not cause severe interference, but may instead only

raise the background noise level. This becomes particularly important in bands shared with other users and in our VHF and UHF bands increasingly targeted by would-be commercial users. The utilization of a channel by many transmitters is essentially the concept behind CDMA (Code Division Multiple Access), a system in which several DSSS transmissions can share the same RF bandwidth, provided they utilize orthogonal pseudo-random sequences.

Amateur Radio Spread Spectrum

Experimentation sponsored by AMRAD began in 1981 led to the design and construction of a practical DSSS UHF link. This project was described in May 1989 *QST* and was reprinted in *The ARRL Spread Spectrum Sourcebook*. In it, André Kesteloot, N4ICK, offered a simple solution to the problem of synchronization. The block diagram is shown in **Fig 9.57**, and **Fig 9.58** shows the RF signals at the transmitter output, at the receiver antenna terminals and the recovered signal after correlation. James Vincent, G1PVZ, replaced the original FM scheme with a continuously variable delta modulation system, or CVSD. In 1989 in a paper titled *License-Free Spread Spectrum Packet Radio*, Al Broscius, N3FCT, suggested the use of Part 15 spread spectrum wireless local area network (WLAN) devices that were becoming available to be put to use in amateur radio.

In 1997 TAPR started the development of a 1-W, 128-kbit/s, FHSS radio for the amateur radio 902 MHz band. In late 1999 the FCC considerably relaxed the Amateur Radio service rules regarding the use of spread spectrum. These changes allowed amateurs to use commercial off-the-shelf (COTS) Part 15 spread spectrum devices used under § 97.311 of the FCC rules.

Emergence of Commercial Part 15 Equipment

Just as military surplus radio equipment fueled Amateur Radio in the 1950s, and commercial FM radios and repeaters snowballed the popularity of VHF/UHF amateur repeaters in the 1960s and 1970s, the availability of commercial wireless LAN (WLAN) equipment is driving the direction and popularity of Amateur Radio use of spread spectrum in the 2000s. FCC Part 15 documents the technical rules for commercial spread-spectrum equipment. The Institute of Electrical and Electronics Engineers (IEEE) has provided the standards under which manufacturers have developed equipment for sale commercially. IEEE 802.11 standardized FHSS and DSSS for the 2.4 GHz band at data rates of 1 and 2 Mbit/s. Next came the release of 802.11b, which provided the additional data rates of 5.5 and 11 Mbit/s but only for DSSS. FHSS was not carried forward. This was followed by 802.11g, which does not use SS but uses OFDM for data rates of 6, 9, 12, 18, 24, 36, 48 and 54 Mbit/s as well as backward compatibility with 802.11b. As of this writing the most recent release of the standard is 802.11a. This release addresses the use of OFDM in certain parts of the 5 GHz band. It provides the same data rates as 802.11g. The currently unreleased 802.11n standard promises data rates in excess of 108 Mbit/s.

Frequency Hopping Spread Spectrum

FHSS radios, as specified in 802.11, hop among 75 of 79 possible non-overlapping frequencies in the 2.4 GHz band. Each hop occurs approximately every 400 ms with a hop time of 224 μs. Since these are Part 15 devices, the radios are limited to a maximum peak output power of 1 W and a maxi-

mum bandwidth of 1 MHz (−20 dB) at any given hop frequency. The rules allow using a smaller number of hop frequencies at wider bandwidths (and lower power: 125 mW) but most manufacturers have opted not to develop equipment using these options. Consequently, off-the-shelf equipment with this wider bandwidth capability is not readily available to the amateur.

The hopping sequences are well defined by 802.11. There are three sets of 26 such sequences (known as *channels*) consisting of 75 frequencies each. The ordering of the frequencies is designed as a pseudo-random sequence hopping at least 6 MHz higher or lower than the current carrier frequency such that no two channels are on the same frequency at the same time. Channel assignment can be coordinated among multiple collocated networks so that there is minimal interference among radios operating in the same band.

The FHSS radio can operate at data rates of 1 and 2 Mbit/s. The binary data stream modulates the carrier frequency using frequency shift keying. At 1 Mbit/s the carrier frequency is modulated using 2-Level Gaussian Frequency Shift Keying (2GFSK) with a shift of ±100 kHz. The data rate can be doubled to 2 Mbit/s by using 4GFSK modulation with shifts of ±75 kHz and ±225 kHz.

Direct Sequence Spread Spectrum

DSSS uses a fast digital sequence to accomplish signal spreading. That is, a well-known pseudo-random digital pattern of ones and zeros is used to modulate the data at a very high rate. In the simplest case of DSSS, defined in 802.11, an 11-bit pattern known as a Barker sequence (or Barker code) is used to modulate every bit in the input data stream. The Barker sequence is 10110111000. Specifically, a “zero” data bit is modulated with the Barker sequence resulting in an output sequence of 10110111000. Likewise, a “one” data bit becomes 01001000111 after modulation (the inverted Barker code). These output patterns are known as *chipping* streams; each bit of the stream is known as a *chip*. It can be seen that a 1 Mbit/s input data stream becomes an 11 Mbit/s output data stream.

The DSSS radio, like the FHSS radio, can operate at data rates of 1 and 2 Mbit/s. The

chipping stream is used to phase modulate the carrier via phase shift keying. Differential Binary Phase Shift Keying (DBPSK) is used to achieve 1 Mbit/s, and Differential Quadrature Phase Shift Keying (DQPSK) is used to achieve 2 Mbit/s. Fig 9.58 shows a typical 1 or 2 Mbit/s DSSS signal having a major lobe bandwidth of ±11 MHz (−30 dB). The first minor sidelobe is down at least 30 dB and the second minor sidelobe is down 50 dB as required by Part 15 rules.

The higher data rates specified in 802.11b are achieved by using a different pseudo-random code known as a *Complimentary Sequence*. Recall the 11-bit Barker code can encode one data bit. The 8-bit Complimentary Sequence can encode 2 bits of data for the 5.5-Mbit/s data rate or 6 bits of data for the 11-Mbit/s data rate. This is known as *Complimentary Code Keying (CCK)*. Both of these higher data rates use DQPSK for carrier modulation. DQPSK can encode two data bits per transition. **Table 9.12** shows how four bits of the data stream are encoded to produce a 5.5-Mbit/s data rate and eight bits are encoded to produce an 11-Mbit/s data rate. There are 64 different combinations of the 8-bit Complimentary Sequence

that have mathematical properties that allow easy demodulation and interference rejection. At 5.5 Mbit/s, only four of the combinations are used. At 11 Mbit/s, all 64 combinations are used.

As an example, for an input data rate of 5.5 Mbit/s, four bits of data are sampled at the rate of 1.375 million samples per second. Two input bits are used to select one of four eight-bit CCK sequences. These eight bits are clocked out at a rate of 11 Mbit/s. The two remaining input bits are used to select the phase at which the eight bits are transmitted. **Fig 9.59A** shows a conceptual block diagram of a 5.5-Mbit/s CCK transmitter modulator, while Fig 9.59B shows an 11-Mbit/s modulator.

Orthogonal Frequency Division Modulation

OFDM provides its spreading function by transmitting the data simultaneously on multiple carriers. 802.11g and 802.11a specify 20-MHz wide channels with 52 carriers spaced every 312.5 kHz. Of the 52 carriers, four are non-data pilot carriers that carry a known bit pattern to simplify demodulation. The remaining 48 carriers are modulated at 250 thousand transitions per

Table 9.12

Bit encoding for 5.5 Mbps and 11 Mbps CCK transmissions

Data Rate, Mbps	CCK encoded bit	DQPSK encoded bits
5.5	2	2
11	6	2

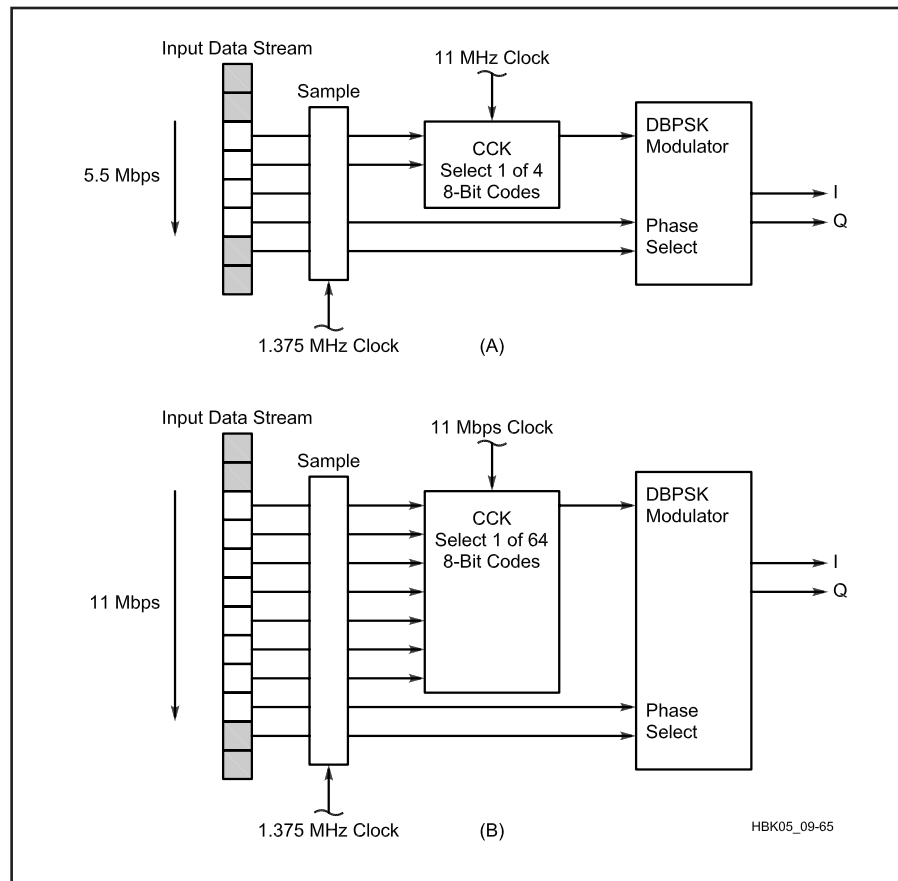

Fig 9.59—Conceptual block diagram of a modulator for a CCK Spread Spectrum transmitter. (A) 5.5 Mbit/s data rate. (B) 11 Mbit/s data rate. See text.

second. Taking all 48 transitions in parallel is known as a symbol. That is, at any given instant in time 48 bits of data are being transmitted.

The term *orthogonal* is derived from the fact that these carriers are positioned such that they do not interfere with one another. The center frequency of one carrier's signal falls within the nulls of the signals on either side of it.

OFDM radios can be used to transmit data rates of 6, 9, 12, 18, 24, 36, 48 and 54 Mbit/s as specified by both 802.11a and 802.11g. In order to transmit at faster and faster data rates in the same 20-MHz channel, different modulation techniques are employed: BPSK, QPSK, 16QAM and 64QAM. In addition, some of the bits transmitted are used for error correction, so the raw data rates could be reduced by up to half of what they would be without error correction. For instance, assuming BPSK (one bit

Table 9.13

Summary of the modulation techniques used by OFDM to achieve the different data rates.

Data Rate Mbps	Modulation	Coding Rate, R
6	BPSK	1/2
9	BPSK	3/4
12	QPSK	1/2
18	QPSK	3/4
24	16QAM	1/2
36	16QAM	3/4
48	64QAM	2/3
54	64QAM	3/4

per carrier) and assuming half the bits are used for error correction (known as the coding rate, R); the resulting data rate would be 6 Mbit/s.

$48 \text{ carriers} \times 1 \text{ bit per carrier} \times 1/2 R = 24 \text{ bits (effective)}$

$24 \text{ bits} \times 250 \text{ kilo transitions per second} = 6 \text{ Mbit/s.}$

Table 9.13 shows a complete list of the modulation methods and coding rates employed by OFDM. The higher data rates will require better signal strength to maintain error free reception due to using few error correction bits and more complex modulation methods.

Multimedia Systems

In January 2001, the ARRL Board of Directors voted unanimously that the ARRL should proceed with the development of High Speed Digital Networks for the Amateur Service. The ARRL President appointed a group of individuals knowledgeable in the field from the international Amateur Radio community and industry. The group would report to the Technology Task Force (TTF). The TTF established the High Speed Multimedia (HSMM) Working Group, with John Champa, K8OCL, as its chairman. Champa identified two initial goals for the working group, so as to immediately begin the development of such high speed digital amateur radio networks:

1. Encourage the amateur adoption and modification of commercial off-the-shelf (COTS) IEEE 802.11 spread spectrum hardware and software for Part 97 uses.
2. Encourage or develop other high-speed digital radio networking techniques, hardware, and applications.

These efforts were rapidly dubbed *HSMM Radio*. Although initially dependent on adaptation of COTS 802.11 gear to Part 97, it is obvious from these goals that HSMM radio is not a specific operating mode, but more of a direction or driving force within amateur radio.

Furthermore, in HSMM radio, the emphasis has shifted away from primarily keyboard radio communication, as in conventional packet radio, to multimedia radio. This includes simultaneous voice, video, data and text over radio.

In HSMM radio these individual medi-

ums have different names, much like their Internet counterparts. For example, voice modes, although technically digital voice, are most often called *streaming audio*. However, since it is two-way voice over an IP network similar to the direction being taken by contemporary commercial telephony technology, the same technology use to link many amateur radio repeaters over the Internet, the name *voice-over-IP* (VoIP) may be more appropriate.

Video modes, although sometimes called amateur digital video (ADV), are also known as *streaming video*. Again, perhaps the commercial term for such two-way video QSOs may be more appropriate: IPVC (*IP videoconferencing*).

Text exchanges via a keyboard are often used in HSMM radio, but they are similarly called by their Internet or Packet Radio name: *Chat mode*. File transfers using FTP can also be done, just as on the Internet. This combination of Internet terminology, coupled with this dramatic shift in emphasis within amateur radio from traditional analog point-to-point radio toward networked digital radios, has resulted in many amateurs nick naming HSMM radio *The Hinternet*. Although the name implies some under-dog status to some, the name seems to be sticking.

HSMM RADIO APPLICATIONS

HSMM radio has some unique ham radio networking applications and operational practices that differentiate the Hinternet from normal Wi-Fi hotspots at coffee houses and airports, which you may have

read about in the popular press. HSMM radio techniques are used, for example, for system RC (remote control) of amateur radio stations.

In this day of environmentally sensitive neighborhoods, one of the greatest challenges, particularly in high density residential areas, is constructing ham radio antennas, particularly high, tower-mounted HF beam antennas. In addition, such amateur installations represent a significant investment in time and resources. This burden could be easily shared among a small group of friendly hams, a radio club or a repeater group.

Implementing a link to a remote HF station via HSMM radio is easy to do. Most computers now come with built-in multimedia support. Most amateur radio transceivers are capable of PC control. Adding the radio networking is relatively simple. Most HSMM radio links use small 2.4-GHz antennas mounted outdoors or pointed through a window. These UHF antennas are relatively small and inconspicuous when compared to a full-size 3-element HF Yagi on a tall steel tower.

For example, Darwin Thompson, K6USW, has performed remote control of a Kenwood TS-480SAT/HX transceiver, which can be controlled over a LAN and the Internet, or in this case the Hinternet. The Kenwood International website provides two programs for the TS-480SAT/HX at: www.kenwood.net/indexKenwood.cfm?do=SupportFileCategory&FileCatID=3.

The *ARHP-10* program is the radio host

program. It operates the computer attached to the transceiver. Just follow the instructions included with the software to make the cables to interface the radio to your computer. The *ARCP-480* program is the radio control software. *ARCP-480* operates the computer at the other end of the remote control link. By attaching a suitable headset to this remote PC, the operator now has full control of the transceiver via the HSMM radio link and can use voice-over-Internet-protocol (VoIP) to transmit and receive audio.

A ham does not have to have an antenna-unfriendly homeowners association (HOA) or a specific deed restriction problem to put RC via HSMM radio to good use. This system RC concept could be extended to other types of amateur radio stations. For example, it could be used to link a ham's home to a shared, high-performance amateur radio DX station, EME station or OSCAR satellite ground station for a special event, or on a regular basis.

SHARED HIGH-SPEED INTERNET ACCESS

Sharing high-speed Internet access (Cable, DSL, etc) with another ham is a popular application for HSMM radio. Half of the US population is restricted to slow dial-up Internet connections (usually around 20 to 40 kbit/s) over regular analog telephone lines. Getting a high-speed Internet connection, even a shared one, can dramatically change the surfing experience! Just remember that if you use an HSMM radio to share high speed access to the Internet, which Amateur Radio has content restrictions, for example no commercial for-profit business e-mails, etc. An example might be an amateur television station (ATV) transmitting an outdoor scene and inadvertently picking-up a billboard in the station camera. Such background sources are merely incidental to your transmission. They are not the primary purpose of your communications, plus they are not intended for rebroad-

cast to the public.

Just as on the Internet, it is possible to do such things as playing interactive games, complete with sound effects and full-motion animation with HSMM radio. This can be lots of fun for new and old hams alike, plus it can attract others in the "Internet Generation" to get interested in amateur radio and perhaps become new radio club members. In the commercial world these activities are called "WLAN Parties." Such e-games are also an excellent method for testing the true speed of your station's Hinternet link.

HSMM RADIO IN EMERGENCY COMMUNICATIONS

There are a number of significant reasons and exciting new examples why HSMM radio is the way of the future for many Emergency Communications (EmComm) situations. These may or may not be under ARES or RACES auspices.

1. The amount of digital radio traffic on

SS and HSMM Glossary

Ad Hoc Mode—An operating mode of a client RIC that allows it to associate directly with any other RIC without having to go through an Access Point. See Infrastructure mode.

AP—Access Point

APRS—Automatic Position Reporting System

Association—The service used to establish access point/station mapping and enable station use of the WLANs services in infrastructure mode.

Authentication—Process by which the wireless communications system verifies the identity of a user attempting to use a WLAN prior to the user associating with the AP.

Band-limited Gaussian Channel—A "brickwall" linear filter that is equal to a constant over some frequency band and equal to zero elsewhere, and by white Gaussian noise with a constant power spectrum over the channel bandwidth.

Barker Code—An 11-bit digital sequence used to modulate (spread) the input data stream. A one bit is represented by the sequence 1011011000 and a zero bit is represented by the sequence 01001000111.

CCK—Complimentary Code Keying. A spreading technique in which the input data stream is modulated with a digital sequence (the complimentary code) depending on the value of the data stream. In 802.11b, for example, the complimentary code consists of 64 eight-bit values. Six data bits from the input stream are used to select which of the complimentary codes is used to modulate the data. See Barker Code.

Correlation—A measure of how closely a signal matches a delayed version of itself shifted n units in time.

COTS—Commercial Off The Shelf equipment.

DBPSK—Differential Binary Phase Shift Keying. A method of modulating data onto a carrier by changing the phase of the carrier relative to its current phase. A binary "1" is represented by a +90 degree phase shift and a binary "0" is represented by a 0 degree phase shift.

DHCP—Dynamic Host Configuration Protocol. A protocol used by a client computer to obtain an IP address for use on a network.

DSSS—Direct Sequence Spread Spectrum. A spread spectrum system in which the carrier has been modulated by a high speed spreading code and an information data stream. The high speed code sequence dominates the "modulating function" and is the direct cause of the wide spreading of the transmitted signal. (Title 47,

Chapter 1, Part 2, subpart A, section 2.1 Terms and Definitions).

DQPSK—Differential Quadrature Phase Shift Keying. A method of modulating data onto a carrier by changing the phase of the carrier similar to DBPSK except that two bits can be represented by a single phase shift such as following this scheme:

2-Bit Value	Phase Shift (degrees)
00	0
01	+90
10	-90
11	180

FHSS—Frequency Hopping Spread Spectrum. A spread spectrum system in which the carrier is modulated with the coded information in a conventional manner causing a conventional spreading of the RF energy about the frequency carrier. The frequency of the carrier is not fixed but changes at fixed intervals under the direction of a coded sequence. The wide RF bandwidth needed by such a system is not required by spreading of the RF energy about the carrier but rather to accommodate the range of frequencies to which the carrier frequency can hop. The test of a frequency hopping system is that the near term distribution of hops appears random, the long term distribution appears evenly distributed over the hop set, and sequential hops are randomly distributed in both direction and magnitude of change in the hop set. (Title 47, Chapter 1, Part 2, subpart A, section 2.1 Terms and Definitions).

GPS—Global Positioning System

IEEE—Institute of Electrical and Electronic Engineering

IEEE 802.11—An IEEE standard specifying FHSS and DSSS in the 2.4 GHz band at 1 Mbit/s and 2 Mbit/s data rates.

802.11 is also used as a general term for all spread spectrum devices operating under Part 15. For example "The 802.11 network" could be referring to a collection of RICs and APs using 802.11b and 802.11g based devices.

IEEE 802.11a—An IEEE standard specifying OFDM in the 5.8 GHz band at 6, 12, 16, 24, 36, 48, and 54 Mbit/s data rates.

IEEE 802.11b—An IEEE standard specifying DSSS in the 2.4 GHz band at 5.5 and 11 Mbit/s data rates in addition to being backward compatible with DSSS at 1 and 2 Mbit/s specified in 802.11.

IEEE 802.11g—An IEEE standard specifying OFDM in the 2.4 GHz band 6, 12, 16, 24, 36, 48, and 54 Mbit/s data

2.4 GHz is increasing and operating under low powered, unlicensed Part 15 limitations cannot overcome this noise.

2. EmComm organizations increasingly need high-speed radio networks that can simultaneously handle voice, video, data and text traffic.
3. The cost of a commercially installed high-speed data network can be more than emergency organizations and communities can collectively afford.
4. EmComm managers also know that they need to continuously exercise any emergency communications system and have trained operators for the system in order for it to be dependable.

Being able to send live digital video images of what is taking place at a disaster site to everybody on the HSMM radio network can be invaluable in estimating the severity of the situation, planning appropriate responding resources and other reactions. The

Emergency Operations Center (EOC) can actually see what is happening while it is happening. Submitting a written report while simultaneously talking to the EOC using Voice over IP (VoIP) would provide additional details.

With HSMM radio, often all that is needed to accomplish such immediacy in the field is a laptop computer equipped with a wireless local area network card (PCMCIA) with an external antenna jack. In HSMM radio jargon such a card is simply called a RIC (radio interface card). Connect any digital camera with a video output port or any webcam, and a headset to the laptop's sound card. Then connect the RIC to a short Yagi antenna (typically 18 inches of antenna boom length) and point the antenna back to the EOC.

HSMM RADIO RELAY

There are a number of ways to extend the HSMM link. The most obvious means would

be to run higher power and to place the antennas as high as possible, as is the case with VHF/UHF FM repeaters. In some densely populated urban areas of the country this approach with 802.11, at least in the 2.4 GHz band, may cause some interference with other users. Other means of getting greater distances using 802.11 on 2.4 GHz or other amateur bands should be considered. One approach is to use highly directive, high-gain antennas, or what is called the directive link approach.

Another approach used by some HSMM radio networks is what is called a low-profile radio network design. They depend on several low power sources and radio relays of various types. For example, two HSMM radio repeaters (known commercially as *access points*, or APs, about \$100 devices) may be placed back-to-back in what is known as bridge mode. In this configuration they will simply act as an automatic radio relay for the high-speed data. Using a series of such radio

rates in addition to being backward compatible with DSSS at 1, 2, 5.5, and 11 Mbit/s specified in 802.11b.

IEEE 802.11n—An IEEE standard specifying data rates up to 250 Mbit/s and being backward compatible with 802.11a and 802.11g.

IEEE 802.16—An IEEE standard specifying wireless last-mile broadband access in the Metropolitan Area Network (MAN). Also known as WiMAX.

ISM—Industrial, Scientific, and Medical. Specific frequency bands authorized by Part 18 rules for non-communication equipment such as microwave ovens, RF lighting, etc. The ISM spectrum where spread spectrum is allowed is located at 2.4 – 2.5 GHz and 5.725 – 5.875 GHz band.

Infrastructure Mode—An operating mode of a client RIC that requires all communications to go through an Access Point.

NMEA 0183—National Marine Electronics Association interface standard which defines electrical signal requirements, data transmission protocol and time, and specific sentence formats for a 4800-baud serial data bus.

OFDM—Orthogonal Frequency Division Multiplexing. A modulation method in which the communication channel is divided into multiple subcarriers each being individually modulated. While not meeting the Part 2 definition of spread spectrum the FCC has given specific authorization for OFDM systems.

Orthogonal—A mathematical term derived from the Greek word *orthos*, which means straight, right, or true. In terms of RF, orthogonal applies to the frequencies of the subcarriers which are selected so that at each one of these subcarrier frequencies, all the other subcarriers do not contribute to the overall waveform. In other words, the subcarrier channel is independent of the other channels.

PCMCIA—Personal Computer Manufacturer Interface Adaptor.

Pigtail—A short piece of coaxial cable with a appropriate connectors to match the RIC antenna port and an external antenna system.

QAM—Quadrature Amplitude Modulation. A method of modulating data onto a carrier by changing both the phase and amplitude of the carrier. In its simplest form, 2QAM, the modulation is identical to BPSK. 16QAM represents 4 bits by changing among 16 phase/amplitude states. 64QAM represents six bits by changing among 64 phase/amplitude states.

RIC—Radio Interface Card. The radio equivalent of a Network Interface Card (NIC).

RLAN—Radio Local Area Network. See also WLAN.

RMAN—Radio Metropolitan Area Network

Spread Spectrum—An information bearing communications system in which: (1) Information is conveyed by modulation of a carrier by some conventional means, (2) the bandwidth is deliberately widened by means of a spreading function over that which would be needed to transmit the information alone. (Title 47, Chapter 1, Part 2, subpart A, section 2.1 Terms and Definitions).

SSID—Service Set Identifier. A unique alphanumeric string used to identify a WLAN, or in the case of HSMM, RLAN, by using the individual call sign and perhaps the name of the amateur radio club or repeater group.

UNII—Unlicensed National Information Infrastructure. The UNII spectrum is located at 5.15 - 5.35 GHz, 5.725 - 5.825 GHz, and the recently added 5.470-5.725 GHz band.

USB—Universal Serial Bus.

VPN—Virtual Private Network.

WEP—Wired Equivalent Privacy. An encryption algorithm used by the authentication process for authenticating users and for encrypting data payloads over a WLAN.

WEP Key—An alphanumeric character string used to identify an authenticating station and used as part of the data encryption algorithm.

Wi-Fi—Wireless Fidelity. Refers to products certified as compatible by the Wi-Fi Alliance. See www.wi-fi.org. This term is also applied in a generic sense to mean any 802.11 capability.

WiMAX—Familiar name for the IEEE 802.16 standard.

WISP—Wireless Internet Service Provider

WLAN—Wireless Local Area Network.

relays on a series of amateur towers between the end-points of the link, it is possible to cover greater distances with relatively low power and yet still move lots of multimedia data.

BASIC HSMM RADIO STATION

How do you set up an HSMM radio base station? It is really very easy. HSMM radio amateurs can go to any electronics outlet or office supply store and buy commercial off-the-shelf (COTS) Wireless LAN gear, either IEEE 802.11b or IEEE 802.11g. They then connect external outdoor antennas. That is all there is to it.

There are some purchasing guidelines to follow. First, decide what interfaces you are going to need to connect to your computer. Equipment is available for all standard computer interfaces: Ethernet, USB and PCMCIA. If you use a laptop in your station, get the PCMCIA card. Make certain it is the type with an external antenna connection. If you have a PC, get the Wireless LAN adaptor type that plugs into either the USB port or the RJ45 Ethernet port. Make certain it is the type that has a removable rubber duck antenna or external antenna port! The included directions will explain how to install these devices.

The core of any HSMM radio station is a computer-operated HSMM 2.4-GHz radio transceiver, and it will probably cost about \$60 to \$80. Start off teaming up with a nearby ham radio operator. Do your initial testing in the same room together. Then as you increase distances going toward your separate station locations, you can coordinate using a suitable local FM simplex frequency. Frequently hams will use 146.52 MHz or 446.00 MHz, the National FM Simplex Calling Frequencies for the 2-m and 70-cm bands, for voice coordination. More recently, HSMM radio operators have tended to use 1.2-GHz FM transceivers and handheld (HT) radios. The 1.2-GHz amateur band more closely mimics the propagation characteristics of the 2.4-GHz amateur band. The rule of thumb is that if you cannot hear the other station on the 1.2-GHz FM radio, you probably will not be able to link up the HSMM radios either.

Hams frequently ask why 802.11 transmitter output and receiver sensitivity are stated typically in dBm. The simple answer is that this convention simplifies certain calculations. For transmitter output, convert dBm to power using the formula for dB. The reference power level is 1 mW. That means that +10 dBm = 10 mW and +20 dBm = 100 mW.

For receive, it's a bit more complicated if you want the more familiar units. First, calculate power level and then convert that to voltage across 50 Ω. A good RIC receiver is

Fig 9.60—Back panel of a typical HSMM-style repeater. This device is known commercially as a wireless access point (AP). It is essentially a computer wireless network hub to enable multiple radio stations to share the various resources of the network. This particular model is a Cisco Model 1200. Note that the left, or secondary antenna's rubber duck has been removed from the TNC connector to show that the connector is of the reverse polarity (RP) type. This is designated as a female TNC/RP connector. Manufacturers of 802.11 gear typically install a RP-type of some type connector to prevent FCC Part 15 unlicensed users from employing their equipment in a non-certified manner. Of course, this is not an issue for licensed Part 97 users, however as in this case, a male RP-type plug will be required in order to connect the device to an outside antenna. The provision of a secondary antenna is to provide space diversity, which helps reduce the negative impact of multipath propagation of the radio signals. The secondary antenna may be ignored when connecting the primary antenna to a single outside antenna, especially if it is a highly directive antenna, which would help reduce multipath effects. (Photo: John Champa, K8OCL).

able to receive down to -96 dBm. That would be equal to 0.00000000025 mW, which is 3.54 μV across 50 Ω.

HSMM RADIO REPEATERS

Access Points

What hams would call a repeater, and computer buffs would call a hub, the WiFi industry refers to as a *wireless access point*, or simply *AP*. This is a device that allows several amateur radio stations to share the radio network and all the devices and circuits connected to it.

An 802.11b AP will sell for about \$80 and an 802.11g AP for about \$100. The AP acts as a central collection point for digital radio traffic, and can be connected to a single computer or to another radio or wired network.

The AP is provided with an *SSID*, which is the station identification it constantly broadcasts. For ham purposes, the *SSID* can be set as your call sign, thus providing automatic, and constant station identification. To use an AP in a radio network the wireless computer users have to exit ad-hoc mode and enter what is called the *infrastructure mode*, in their operating software. Infrastructure mode requires that you specify the radio network your computer station is intended to connect to, so set your computer station to recognize the *SSID* you assigned to the AP (yours or another ham's AP) to which you wish to connect.

Point-to-Point Links

The AP can also be used as one end of a point-to-point radio network. If you want to extend a radio network connection from one location to another, for example in order to remotely operate an HF station, you could use an AP at the network end and use it to communicate to a computer at the remote station location.

An AP allows for more network features and improved information security than is provided by ad-hoc mode. Most APs provide DHCP service, which is another way of saying they will automatically assign an Internet (IP) address to the wireless computers connected to the radio network. In addition, they can provide filtering, which allows only known users to access the network.

MOBILE HSMM OPERATING

When hams use the term mobile HSMM station what they are normally talking about is a wireless computer set-up in their vehicle to operate in a stationary portable fashion. Nobody is suggesting that you try to drive a vehicle and look at a computer screen at the same time! That would be very dangerous. So unless you have somebody else driving the vehicle, keep your eyes on the road and not on the computer screen.

What sort of equipment is needed to operate an HSMM mobile station?

- Some type of portable computer, such

as a laptop. Some hams use a PDA, notebook or other small computing device. The operating system can be *Microsoft Windows*, *Linux*, or *Mac OS*, although *Microsoft XP* offers some new and innovative WLAN functionality.

- Some type of radio software hams would call an *automatic monitor*, and computer buffs would call a *sniffer utility*. The most common type being used by hams is Marius Milner's *Network Stumbler for Windows* frequently just called, *NetStumbler*. All operating systems have monitoring programs that are available. *Linux* has *Kismet*; *MAC OS* has *MacStumbler*. Marius Milner has a version for the PocketPC, which he calls *MiniStumbler*.
- A RIC (*Radio Interface Card*=PCMCIA WiFi computer adapter card with external antenna port), which is supported by the monitoring utility you are using. The most widely supported RIC is the Orinoco line. The Orinoco line is inexpensive and fairly sensitive.
- An external antenna attached to your RIC. This is often a magnetically mounted omni-directional vertical antenna on the vehicle roof, but small directional antennas pointed out a window or mounted on a small ground tri-pod are also frequently used.
- A pigtail or short strain-relief cable will be needed to connect from the RIC antenna port to the N-series, RP/TNC or other type connector on the external antenna.
- A GPS receiver that provides NMEA 0183 formatted data and computer interface cable. This allows the monitoring utility to record where HSMM stations are located on a map, just as in APRS. GPS capability is optional, but just as with APRS capability, it makes the monitored information much more useful for locating HSMM stations.

Warning

While operating your HSMM mobile station, if you monitor an unlicensed Part 15 station (non-ham), some types of WiFi equipment will automatically associate or link to such stations, if they are not encrypted, and many are not (that is, WEP is not enabled). Although Part 15 stations share the 2.4-GHz band on a non-interfering basis with hams, they are operating in another service. In another part of this section we will provide various steps you can take to prevent Part 15 stations from automatically linking with HSMM stations. So in like manner, except in the case of a communications emergency, we recommend that you do not use a Part 15 station's Internet connection for any ham purpose.

Fig 9.61—View of HSMM equipment (802.11b) inside an antenna-mounted NEMA-4 box. Mounting the equipment at the end of the dish antenna's pigtail significantly reduces feed line losses and greatly enhances the performance of the station. The box contains both a bridge, and a 500 mW bidirectional amplifier or BDA (lower left). Amplifier power is provided by the power insertion module seen in the upper left corner of the enclosure. (Photo: John Champa, K8OCL).

HSMM AREA SURVEYS

Both licensed amateurs and unlicensed (Part 15) stations use the 2.4-GHz band. To be a good neighbor, find out what others are doing in your area before designing your community HSMM radio network. This is easy to do using IEEE 802.11 modulation. Unless it has been disabled, an active repeater (AP) is constantly sending out an identification beacon known as the SSID. In HSMM practice this is simply the ham station call sign (and perhaps the local radio club name) entered into the software configuration supplied with the CD that comes with the repeater. So every HSMM repeater is also a continuous beacon.

A local area survey using appropriate monitoring software, for example the free *NetStumbler* software downloaded and running on your PC (www.netstumbler.com/index.php), is recommended prior to starting up any HSMM operations. Slew your station's directional antenna through a 360° arc, or drive your HSMM mobile station (described earlier) around your local area.

This HSMM area survey will identify and automatically log most other 802.11 station activity in your area. There are many different ways to avoid interference with other users of the band when planning your HSMM operating. For example, moving your operating frequency 2-3 channels away from the other stations is often suffi-

cient. Why several channels and not just one? Because the channels have considerable overlap. Why this situation exists is beyond the scope of this section, but here is the situation: The channels are only 5 MHz wide, but the DSSS or OFDM modulation of 802.11 is 22 MHz wide. Commercial users often recommend moving 5 channels away from the nearest AP to completely avoid interference. There are six channels within the amateur 2.4 GHz band, but there are problems for hams with two of them. Channel 1 centered on 2412 MHz overlaps with OSCAR satellite downlink frequencies. Channel 6 centered on 2437 MHz is by far the most common out-of-the-box default channel for the majority of WLAN equipment sold in the US, so that often is not the best choice. Subsequently, most HSMM radio groups end up using either channel 3 or channel 4, depending on their local situation. Again, an area survey is recommended before putting anything on the air.

However, because of the wide sidebands used in these inexpensive broad banded 802.11 modulations, even moving 2-3 channels away from such activity may not be enough to totally avoid interference, especially if you are running what in HSMM is considered high power (typically 1800 mW RF output—more on that subject later). You may have to take other steps. For example, you may use a different polarization with your antenna system. Many HSMM stations use horizontal polarization because much 802.11 activity in their area is primarily vertically polarized.

HSMM ANTENNA SYSTEMS

There are a number of factors that determine the best antenna design for a specific HSMM radio application. Most commonly, HSMM stations use horizontal instead of vertical polarization.

Furthermore, most HSMM stations use highly directional antennas instead of omnidirectional antennas. Directional antennas provide significantly more gain and thus better signal-to-noise ratios, which in the case of 802.11 modulations means higher rate data throughput. Higher data throughput, in turn, translates into more multimedia radio capability.

Highly directional antennas also have many other advantages. Such antennas can allow two hams to shoot over, or shoot around, or even shoot between, other wireless stations on the band.

However, the nature of 802.11 modulations coupled with the various configurations of many COTS devices allows hams to economically experiment with many other fascinating antenna designs. Such unique antenna system designs can be used to simply help avoid interference, or to extend the

range of HSMM links, or both.

Space Diversity

Some APs and some RICs have space-diversity capability built-into their design. However, it is not always operated in the same fashion, so check the literature or the website of your particular device's manufacturer to be certain how the dual antenna ports are used. For example, many APs come equipped with two rubber ducky antennas and two antenna ports. One antenna port may be the primary and the other port the secondary input to the transceiver. Which signal input is used may depend on which antenna is providing the best S/N ratio at that specific instant. Experimentation using two outside high-gain antennas spaced 10 or more wavelengths apart (that is only about one meter on the 2.4-GHz band) may be very worthwhile in improving data throughput on long links. Such extended radio paths tend to experience more multipath signal distortion. This multipath effect is caused by multiple signal reflections off various objects in the path of the linking signal. The use of space diversity techniques may help reduce this effect and thus improve the data rate throughput on the link. Again, the higher the data rates the more multimedia radio techniques that can be used on that network.

Circular Polarization

The use of circular polarization created using helical antennas, patch feed-points on dish antennas or other means, warrants further study by radio amateurs. Remember this is high-speed digital radio. To avoid symbol errors, circularly polarized antennas should be used at both ends of the link. Also, be certain that the antennas are of the same *handedness*, for example, right-hand circular polarization (RHCP). The ability of circular polarization to enhance propagation of long-path HSMM radio signals should not be overlooked.

Circularly Polarized Space Diversity

A combination or hybrid antenna design combining both circularly polarized antennas and space diversity could yield some extraordinary signal propagation results. For example, it has been suggested that perhaps using a RHCP for one antenna and LHCP for the other antenna, especially using spacing greater than 10 wavelengths, in such a system could provide a nearly "bullet-proof" design. Only actual field testing of such designs under different terrain features would reveal such potential.

Mixed Antenna Design Problem

In conventional wide-bandwidth analog radio antennas systems, so long as both antennas at both ends of a radio link have

Fig 9.62—FM voice repeater, amateur television (ATV), and HSMM antennas mounted on a hydraulically operated mast. This portable installation was used to provide shared high-speed Internet access and other special communications support to the many hams attending the 2003 Pacificon Hamvention in San Ramon, CA. The HSMM station is also used to provide streaming video or amateur digital video (ADV) to the Mount Diablo ARC's analog FM ATV repeater on the nearby mountain. (Photo: John Champa, K8OCL)

broad bandwidths and the same polarization, all is fine. While this may be true for wide bandwidth analog signals, such as amateur television VSB (vestigial sideband) signals or FM ATV signals, it may not be true for broad bandwidth high-speed digital signals.

First, 802.11 modulations produce very broadband signals, typically 22 MHz. Secondly, the evidence to date indicates that the use of a same polarized antenna with one type of feed point at one end of the link and the use of a same polarized antenna with a different type of feed point at the other end of the link, may introduce a problem with high-speed digital signals. A common example of this potential mixed-antenna issue would be if one HSMM station uses a horizontally polarized linear Yagi, while the other HSMM station at the opposite end of the link uses a horizontally polarized loop Yagi.

Here is another typical situation. Let us say the ham at one end of the radio path uses a dish antenna with a horizontal dipole feed-point. The other ham at the opposite end of

the path uses a horizontally polarized loop Yagi. Both antennas have gain, both antennas are broadband width designs, and both antennas are horizontally polarized. Nonetheless, the hams may experience higher BER (bit error rate) because of symbol errors caused by the different manner in which the two antennas manipulate the digital radio signal wave front. Further radio amateur experimentation with HSMM radio signals is warranted to determine the full impact on the radio link of using mixed antenna types.

RUNNING HIGHER POWER

Hams often ask why operate 802.11 modes under licensed Part 97 regulations when we may also operate such modes under unlicensed Part 15 regulations, and without the content restrictions imposed on the Amateur Radio service?

A major advantage of operating under Amateur Radio regulations is the feasibility of operating with more RF power output and larger, high-gain directive antennas. These added capabilities enable hams to increase the range of their operations. The enhanced signal-to-noise ratio provided by running high power will also allow better data packet throughput. This enhanced throughput, in turn, enables more multimedia experimentation and communication capability over such increased distances.

In addition, increasing the effective radiated power (ERP) of an HSMM radio link provides for more robust signal margins and consequently a more reliable link. These are important considerations in providing effective emergency communications services and accomplishing other important public service objectives in a band increasingly occupied by unlicensed stations and other noise sources.

It should be noted that the existing FCC amateur radio regulations covering spread spectrum (SS) at the time this is being written were implemented prior to 802.11 being available. The provision in the existing regulations calling for automatic power control (APC) for RF power outputs in excess of 1 W is not considered technologically feasible in the case of 802.11 modulations for various reasons. As a result the FCC has communicated to the ARRL that the APC provision of the existing SS regulations are therefore not applicable to 802.11 emissions under Part 97.

However, using higher than normal output power in HSMM radio, in the shared 2.4 GHz band, is also something that should be done with considerable care, and only after careful analysis of link path conditions and the existing 802.11 activity in your area. Using the minimum power necessary for the communications is the law and has always been a good operating practice for hams.

There are also other excellent and far less

expensive alternatives to running higher power when using 802.11 modes. For examples, amateurs are also allowed to use higher-gain directional antennas. Such antennas increase both the transmit and receive effectiveness of the transceiver. Also, by placing equipment as close to the station antenna as possible, a common amateur OSCAR satellite and VHF/UHF DXing technique, the feed-line loss is significantly reduced. This makes the HSMM station transceiver more sensitive to received signals, while also getting more of its transmitter power to the antenna.

Only after an HSMM radio link analysis (see the link calculations portion at www.arrl.org/hsmm/ or go to logidac.com/gfk/80211link/pathAnalysis.html) clearly indicates that additional RF output power is required to achieve the desired path distance should more power output be considered.

At that point in the analysis showing that higher power is required, what is needed is called a bi-directional amplifier (BDA). This is a super fast switching pre-amplifier/amplifier combination that is usually mounted at the end of the antenna pig-tail near the top of the tower or mast. A reasonably priced 2.4-GHz 1800-mW watt output BDA is available from the FAB Corporation (www.fab-corp.com). It is specifically designed for amateur HSMM radio experimenters. Be certain to specify HSMM when placing your order. Also, to help prevent unauthorized use by unlicensed Part 15 stations, the FAB Corp may request a copy of your amateur license to accompany the order, and they will only ship the BDA to your licensee address as recorded in the FCC database.

This additional power output of 1800 mW should be sufficient for nearly all amateur operations. Even those supporting EmComm, which may require more robust signal margins than normally needed by amateurs, seldom will require more power output than this level. If still greater range is needed, there are other less expensive ways to achieve such ranges as described in the section HSMM Radio Relays.

When using a BDA and operating at higher than normal power levels on the channels 2 through 5 recommended for Amateur Radio use. These channels are arbitrary channels intended for Part 15 operation and are not required for Amateur Radio use, but they are hard-wired into the gear so we are stuck with them. You should also be aware of the sidebands produced by 802.11 modulation. These sidebands are in addition to the normal 22 MHz wide spread spectrum signal. Accordingly, if your HSMM radio station is next door to an OSCAR ground station or other licensed user of the band, you may need to take extra steps in order to avoid interfering with them.

The use of a tuned output filter may be necessary to avoid causing QRM. Even when operating on the recommended channels in the 2-5 range, whenever you use higher than normal power, some of your now amplified sidebands may go outside the amateur band, which stops at 2450 MHz. So from a practical point of view, whenever the use of a BDA is required to achieve a specific link objective, it is a good operating practice to install a tuned filter on the BDA output. Such filters are not expensive and they're readily available from several commercial sources. It should also be noted that most BDAs currently being marketed, while suitable for 802.11b modulation, they are often not suitable for the newer, higher speed 802.11g modulation.

There is another point to consider. Depending on what other 802.11 operating may be taking place in your area, it may be a good practice to only run higher power when using directional or sectional antennas. Such antennas allow hams to operate over and around other licensed stations, but also including unlicensed Part 15 activity in your area that you don't want to disrupt (a local school WLAN, WISP, etc). Again, before running high power, it is recommended that an area survey be conducted using a mobile HSMM rig as described earlier to determine what other 802.11 activity is in your area and what channels are already in use.

INFORMATION SECURITY

An HSMM radio station could be considered a form of software defined radio. Your computer running the appropriate software combined with the RIC makes a single unit, which is now your station HSMM transceiver. However, unlike other radios, your HSMM radio is now a networked radio device. It could be connected directly to other computers and to other radio networks and even to the Internet. So each HSMM radio (PC + RIC + software) needs to be protected. There are at least two basic steps that should be taken with regards to all HSMM radios:

The PC should be provided with an anti-virus program. This anti-virus software must be regularly updated to remain effective. Such programs may have come with the PC when it was purchased. If that is not the case, reasonably priced anti-virus programs are readily available from a number of sources.

Secondly, it is important to use a firewall software program on your HSMM radio. The firewall should be configured to allow all outgoing traffic, but to restrict all incoming traffic without specific authorization. Commercial personal computer firewall products are available from Symantec, ZoneLabs and McAfee Network Associates.

Check this URL for a list of freeware firewalls for your personal computer:

www.webattack.com/freeware/security/fwfirewall.shtml.

Check this URL for a list of shareware firewalls for your personal computer: www.webattack.com/Shareware/security/swfirewall.shtml.

Once a group of HSMM stations has set-up and configured a repeater (AP) into a radio local area network (RLAN) then additional steps may need to be taken to restrict access to the repeater. Only Part 97 stations should be allowed to associate with the HSMM repeater. Remember, in the case of 802.11 modulations, the 2.4-GHz band is shared with Part 15 unlicensed 802.11 stations. How do you keep these unlicensed stations from automatically associating (auto-associate) with your licensed ham radio HSMM network?

Many times the steps taken to avoid interference with other stations also limits those other stations' capability to auto-associate with the HSMM repeater and to improve the overall security of the HSMM station. For example, you could use a different antenna polarization than the Part 15 station, or you could operate with a directional antenna oriented toward the desired coverage area rather than using an omnidirectional antenna.

The most effective method to keep unlicensed Part 15 stations off the HSMM repeater is to simply enable the *Wired Equivalent Protection* (WEP) already built into the 802.11 equipment. The WEP encrypts or scrambles the digital code on the HSMM repeater based on the instruction or "key" given to the software. Such encryption makes it impossible for unlicensed stations not using the specific code to accidentally auto-associate with the HSMM repeater.

The primary purpose of this WEP implementation in the specific case of HSMM operating is to restrict access to the ham network by requiring all stations to authenticate themselves. Ham stations do this by using the WEP implementation with the appropriate ham key. Hams are permitted by FCC regulations to encrypt their transmission in specific instances; however, ironically at the time of this writing, this is not one of them. Accordingly, for hams to use WEP for authentication and not for encryption, the key used to implement the WEP must be published. The key must be published in a manner accessible by most of the amateur radio community. This fulfills the traditional ham radio role as a self-policing service. The current published ham radio WEP key is available at the home page of the ARRL Technology Task Force High Speed Multimedia Working Group: www.arrl.org/hsmm/.

Before implementing WEP on your HSMM repeater be certain that you have

checked the website to ensure that you are using the current published WEP key. The key may need to be occasionally changed.

HSMF FREQUENCIES

Up to this point all the discussion has been regarding HSMF radio operations on the 2.4-GHz amateur band. However, 802.11 modulations can be used on any amateur band above 902 MHz.

On the 902 MHz band, using 802.11 modulations would occupy nearly the entire band. This may not be a problem in your area depending on the nature of the other existing users of the band in your area, either licensed or unlicensed. FM repeaters may not have a problem with sharing the frequency with 802.11 operations, since they would likely just hear an 802.11 modulated signal as weak background noise, and the 802.11 modulation, especially the OFDM channels used by 802.11g, would simply work around the FM interference with little negative impact. There is some older 802.11 gear (FHSS) available on the surplus market for amateur experimentation. Alternatively, some form of frequency transverter may be used to take 2.4 GHz to the 902-MHz band.

The 1.2-GHz band has some potential for 802.11 experimenting. Some areas have several FM voice repeaters and even ATV FM repeaters on the band. But again these relatively narrow bandwidth signals would likely hear any 802.11 modulations as simply background noise. Looking at the potential interference from the HSMF perspective, even in the case of the FM ATV, it is unlikely the signal would significantly disrupt the 802.11 modulation unless the two signals were on exactly the same center frequency or at least with complete overlap in bandwidth. Keep in mind that the FM ATV signal is only several megahertz wide, but the 802.11 modulation is 22 MHz wide. For the analog signal to wipe out the spread spectrum signal, it would need to overpower or completely swamp the 802.11 RIC receiver's front end.

The 3.5-GHz band offers some real possibilities for 802.11 developments. Frequency transverters are available to get to the band from 2.4 GHz and there is little other activity on the band at this time. Developments in Europe of 802.16 with 108 Mbit/s data throughput may make 3.5-GHz gear available for amateur experimentation in the US. Hams are investigating the feasibility of using such gear when it becomes available in the US for providing a RMAN or *radio metropolitan area networks*. The RMAN would be used to link the individual HSMF repeaters (AP) or RLANs together in order to provide county-wide or regional HSMF coverage, depending on the ham radio population density.

The 5-GHz band is also being investi-

gated. The COTS 802.11a modulation gear has OFDM channels that operate in this Amateur Radio band. The 802.11a modulation could be used in a ham RLAN operating much as 802.11g is in the 2.4-GHz band. It is also being considered by some HSMF groups as a means of providing MAN links. This band is also being considered by AMSAT for what is known as a C-N-C transponder. This would be an HSMF transponder onboard probably a Phase-3 high-altitude or a Phase-4 geostationary OSCAR with uplink and downlink bandpass both within the 5-GHz amateur band. Some other form of modulation other than 802.11 would likely have to be used because of timing issues and other factors, but the concept is at least being seriously discussed.

RMAN link alternatives are also being tested by hams. One of these is the use of *virtual private networks* (VPN) similar to the method currently used to provide worldwide FM voice repeater links via the Internet. Mark Williams, AB8LN, of the HSMF Working Group is leading a team to test the use of various VPN technologies for linking HSMF repeaters.

HF is not being ignored either. It is possible that a modulation form that, while it is neither SS nor HSMF, might be able to produce data rates fast enough to efficiently handle e-mail type traffic on the HF bands, while still occupying an appropriate bandwidth. Such modulation would be helpful in an emergency with providing an outlet for RMAN e-mail traffic. Neil Sablatzky, K8IT, is leading a team of ham investigators on the HF and VHF bands.

Finally there are commercial products being developed such as the Icom D-STAR system that could readily be integrated into a RMAN infrastructure.

Oscillators and Synthesizers

Just say in public that oscillators are one of the most important, fundamental building blocks in radio technology and you will immediately be interrupted by someone pointing out that *tuned-RF (TRF)* receivers can be built without any form of oscillator at all. This is certainly true, but it shows how some things can be taken for granted. What use is any receiver without signals to receive? All intentionally transmitted signals trace back to some sort of signal generator—an oscillator or frequency synthesizer. In contrast with the TRF receivers just mentioned, a modern, all-mode, feature-laden MF/HF transceiver may contain in excess of a dozen RF oscillators and synthesizers, while a simple QRP CW transmitter may consist of nothing more than a single oscillator. (This chapter was written by David Stockton, GM4ZNX. Frederick J. Telewski, WA7TZY, also contributed to the Frequency Synthesizers section.)

In the 1980s, the main area of progress in the performance of radio equipment was the recognition of receiver intermodulation as a major limit to our ability to communicate, with the consequent development of receiver front ends with improved ability to handle large signals. So successful was this campaign that other areas of transceiver performance now require similar attention. One indication of this is any equipment review receiver dynamic range measurement qualified by a phrase like “limited by oscillator phase noise.” A plot of a receiver’s effective selectivity can provide another indication of work to be done: An IF filter’s high-attenuation region may appear to be wider than the filter’s published specifications would suggest—

almost as if the filter characteristic has grown sidebands! In fact, in a way, it has: This is the result of local-oscillator (LO) or synthesizer *phase noise* spoiling the receiver’s overall performance. Oscillator noise is the prime candidate for the next major assault on radio performance.

The sheer number of different oscillator circuits can be intimidating, but their great diversity is an illusion that evaporates once their underlying pattern is seen. Almost all RF oscillators share one fundamental principle of operation: an amplifier and a filter operate in a loop (**Fig 10.1**). There are plenty of filter types to choose from:

- LC
- Quartz crystal and other piezoelectric materials
- Transmission line (stripline, microstrip, troughline, open-wire, coax and so on)
- Microwave cavities, YIG spheres, dielectric resonators
- Surface-acoustic-wave (SAW) devices

Should any new forms of filter be invented, it’s a safe guess that they will also

be applicable to oscillators. There is an equally large range of amplifiers to choose from:

- Vacuum tubes of all types
- Bipolar junction transistors
- Field effect transistors (JFET, MOSFET, GaAsFET, in all their varieties)
- Gunn diodes, tunnel diodes and other negative-resistance generators

It seems superfluous to state that anything that can amplify can be used in an oscillator, because of the well-known propensity of all prototype amplifiers to oscillate! The choice of amplifier is widened further by the option of using single- or multiple-stage amplifiers and discrete devices versus integrated circuits. Multiply all of these options with those of filter choice and the resulting set of combinations is very large, but a long way from complete. Then there are choices of how to couple the amplifier into the filter and the filter into the amplifier. And then there are choices to make in the filter section: Should it be tuned by variable capacitor, variable inductor or some form of sliding cavity or line?

Despite the number of combinations that are possible, a manageably small number of types will cover all but very special requirements. Look at an oscillator circuit and “read” it: What form of filter—*resonator*—does it use? What form of amplifier? How have the amplifier’s input and output been coupled into the filter? How is the filter tuned? These are simple, easily answered questions that put oscillator types into appropriate categories and make them understandable. The questions themselves may make more

Fig 10.1—Reduced to essentials, an oscillator consists of a filter and an amplifier operating in a feedback loop.

sense if we understand the mechanics of oscillation, in which *resonance* plays a major role.

HOW OSCILLATORS WORK

Maintained Resonance

The pendulum, a good example of a resonator, has been known for millennia and understood for centuries. It is closely analogous to an electronic resonator, as shown in **Fig 10.2**. The weighted end of the pendulum can store energy in two different forms: The *kinetic energy* of its motion and the *potential energy* of it being raised above its rest position. As it reaches its highest point at the extreme of a swing, its velocity is zero for an instant as it reverses direction. This means that it has, at that instant, no kinetic energy, but because it is also raised above its rest posi-

tion, it has some extra potential energy.

At the center of its swing, the pendulum is at its lowest point with respect to gravity and so has lost the extra potential energy. At the same time, however, it is moving at its highest speed and so has its greatest kinetic energy. Something interesting is happening: The pendulum's stored energy is continuously moving between potential and kinetic forms. Looking at the pendulum at intermediate positions shows that this movement of energy is smooth. Newton provided the keys to understanding this. It took his theory of gravity and laws of motion to explain the behavior of a simple weight swinging on the end of a length of string and calculus to perform a quantitative mathematical analysis. Experiments had shown the period of a pendulum to be very stable and predictable. Apart from side effects of air drag and friction, the length of

the period should not be affected by the mass of the weight, nor by the amplitude of the swing.

A pendulum can be used for timing events, but its usefulness is spoiled by the action of drag or friction, which eventually stops it. This problem was overcome by the invention of the *escapement*, a part of a clock mechanism that senses the position of the pendulum and applies a small push in the right direction and at the right time to maintain the amplitude of its swing or oscillation. The result is a mechanical oscillator: The pendulum acts as the filter, the escapement acts as the amplifier and a weight system or wound-up spring powers the escapement.

Electrical oscillators are closely analogous to the pendulum, both in operation and in development. The voltage and current in the tuned circuit—often called *tank circuit* because of its energy-storage ability—both vary sinusoidally with time and are 90° out of phase. There are instants when the current is zero, so the energy stored in the inductor must be zero, but at the same time the voltage across the capacitor is at its peak, with all of the circuit's energy stored in the electric field between the capacitor's plates. There are also instants when the voltage is zero and the current is at a peak, with no energy in the capacitor. Then, all of the circuit's energy is stored in the inductor's magnetic field.

Just like the pendulum, the energy stored in the electrical system is swinging smoothly between two forms; electric field and magnetic field. Also like the pendulum, the tank circuit has losses. Its conductors have resistance, and the capacitor dielectric and inductor core are imperfect. Leakage of electric and magnetic fields also occurs, inducing currents in neighboring objects and just plain radiating energy off into space as radio waves. The amplitudes of the oscillating voltage and current decrease steadily as a result. Early intentional radio transmissions, such as those of Heinrich Hertz's experiments, involved abruptly dumping energy into a tuned circuit and letting it oscillate, or *ring*, as shown in **Fig 10.3**. This was done by applying a spark to the resonator. Hertz's resonator was a gapped ring, a good choice for radiating as much of the energy as possible. Although this looks very different from the LC tank of Fig 10.2, it has inductance *distributed* around its length and capacitance distributed across it and across its gap, as opposed to the *lumped* L and C values in Fig 10.2. The gapped ring therefore works just the same as the LC tank in terms of oscillating voltages and currents. Like the pendulum and the LC tank, its period, and

Fig 10.2—A resonator lies at the heart of every oscillatory mechanical and electrical system. A mechanical resonator (here, a pendulum) and an electrical resonator (here, a tuned circuit consisting of L and C in parallel) share the same mechanism: the regular movement of energy between two forms—potential and kinetic in the pendulum, electric and magnetic in the tuned circuit. Both of these resonators share another trait: Any oscillations induced in them eventually die out because of losses—in the pendulum, due to drag and friction; in the tuned circuit, due to the resistance, radiation and inductance. Note that the curves corresponding to the pendulum's displacement vs velocity and the tuned circuit's voltage vs current, differ by one quarter of a cycle, or 90°.

Fig 10.3—Stimulating a resonance, 1880s style. Shock-exciting a gapped ring with high voltage from a charged capacitor causes the ring to oscillate at its resonant frequency. The result is a damped wave, each successive alternation of which is weaker than its predecessor because of resonator losses. Repetitively stimulating the ring produces trains of damped waves, but oscillation is not continuous.

therefore the frequency at which it oscillates, is independent of the magnitude of its excitation.

Making a longer-lasting signal with the Fig 10.3 arrangement merely involves repeating the sparks. The problem is that a truly continuous signal cannot be made this way. The sparks cannot be applied often enough or always timed precisely enough to guarantee that another spark re-excites the circuit at precisely the right instant. This arrangement amounts to a crude spark transmitter, variations of which served as the primary means of transmission for the first generation of radio amateurs. The use of damped waves is now entirely forbidden by international treaty because of their great impurity. Damped waves look a lot like car-ignition waveforms and sound like car-ignition interference when received.

What we need is a *continuous wave* (CW) oscillation—a smooth, sinusoidal signal of constant amplitude, without phase jumps, a “pure tone.” To get it, we must add to our resonator an equivalent of the clock’s escapement—a means of synchronizing the application of energy and a fast enough system to apply just enough energy every cycle to keep each cycle at the same amplitude.

Amplification

A sample of the tank’s oscillation can be extracted, amplified and reinserted. The

gain can be set to exactly compensate the tank losses and perfectly maintain the oscillation. The amplifier usually need only give low gain, so active devices can be used in oscillators not far below their unity (unity = 1) gain frequency. The amplifier’s output must be lightly coupled into the tank—the aim is just to replace lost energy, not forcibly drive the tank. Similarly, the amplifier’s input should not heavily load the tank. It is a good idea to think of *coupling* networks rather than *matching* networks in this application, because a matched impedance extracts the maximum available energy from a source, and this would certainly spoil an oscillator.

Fig 10.4A shows the block diagram of an oscillator. Certain conditions must be met for oscillation. The criteria that separate oscillator loops from stable loops are often attributed to Barkhausen by those aiming to produce an oscillator and to Nyquist by those aiming for amplifier stability, although they boil down to the same boundary. Fig 10.4B shows the loop broken and a test signal inserted. (The loop can be broken anywhere; the amplifier input just happens to be the easiest place to do it.) The criterion for oscillation says that at a frequency at which the phase shift around the loop is exactly zero, the net gain around the loop must equal or exceed unity (that is, one). (Later, when we design phase-locked

loops, we must revisit this concept in order to check that *those* loops *cannot* oscillate.) Fig 10.4C shows what happens to the amplitude of an oscillator if the loop gain is made a little higher or lower than one.

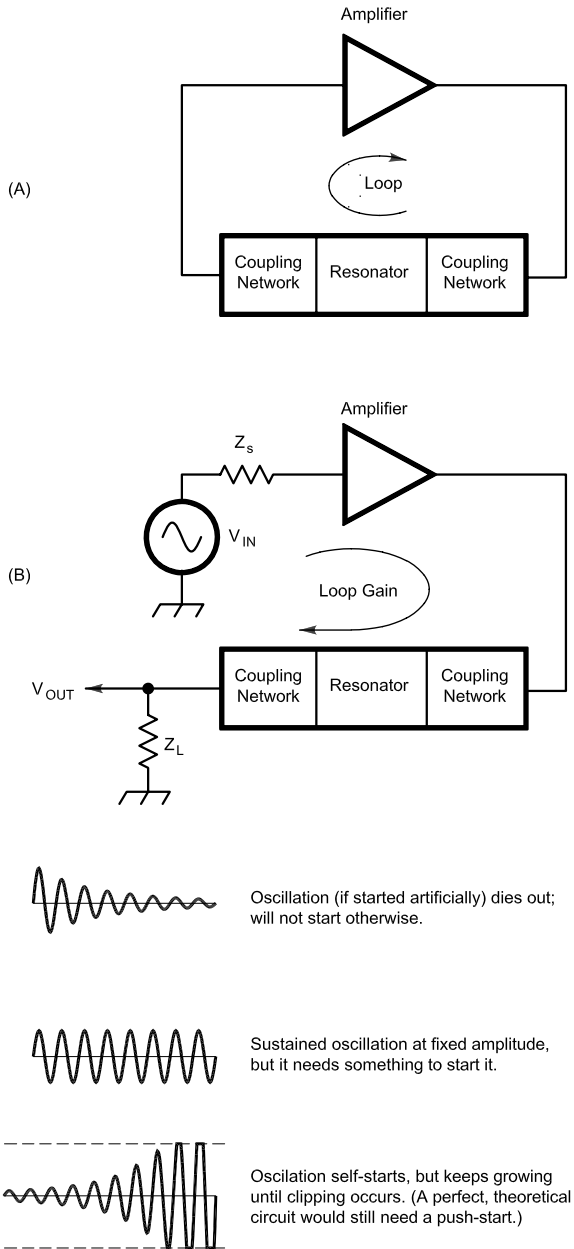

The loop gain has to be precisely one if we want a stable amplitude. Any inaccuracy will cause the amplitude to grow to clipping or shrink to zero, making the oscillator useless. Better accuracy will only slow, not stop this process. Perfect precision is clearly impossible, yet there are enough working oscillators in existence to prove that we are missing something important. In an amplifier, nonlinearity is a nuisance, leading to signal distortion and intermodulation, yet nonlinearity is what makes stable oscillation possible. All of the vacuum tubes and transistors used in oscillators tend to reduce their gain at higher signal levels. With such components, only a tiny change in gain can shift the loop’s operation between amplitude growth and shrinkage. Oscillation stabilizes at that level at which the gain of the active device sets the loop gain at exactly one.

Another gain-stabilization technique involves biasing the device so that once some level is reached, the device starts to turn off over part of each cycle. At higher levels, it cuts off over more of each cycle. This effect reduces the effective gain quite strongly, stabilizing the amplitude. This badly distorts the signal (true in most common oscillator circuits) in the amplifying device, but provided the amplifier is lightly coupled to a high-Q resonant tank, the signal in the tank should not be badly distorted.

Many radio amateurs now have some form of circuit-analysis software, usually running on a PC. Attempts to analyze oscillators by this means often fail by predicting growing or shrinking amplitudes, and often no signal at all, in circuits that are known to work. Computer analysis of oscillator circuits can be done, but it requires a sophisticated program with accurate, nonlinear, RF-valid models of the devices used, to be able to predict operating amplitude. Often even these programs need some special tricks to get their modeled oscillators to start. Such software is likely to be priced higher than most private users can justify, and it still doesn’t replace the need for the user to understand the circuit. With that understanding, some time, some parts and a little patience will do the job, unassisted.

Textbooks give plenty of coverage to the frequency-determining mechanisms of oscillators, but the amplitude-determining mechanism is rarely covered. It is often not even mentioned. There is a

Fig 10.4—The bare-bones oscillator block diagram of Fig 10.1 did not include two practical essentials: Networks to couple power in and out of the resonator (A). Breaking the loop, inserting a test signal and measuring the loop's overall gain (B) allows us to determine whether the system can oscillate, sustain oscillation or clip (C).

good treatment in Clarke and Hess, *Communications Circuits: Analysis and Design*.

Start-Up

Perfect components don't exist, but if we could build an oscillator from them, we would naturally expect perfect performance. We would nonetheless be disappointed. We could assemble from our perfect components an oscillator that exactly met the criterion for oscillation, having slightly excessive gain that falls to the correct amount at the target operating level and so is capable of sustained, stable oscillation. But being capable of something is not the same as doing it, for there is another stable condition. If the amplifier in the loop shown in Fig 10.4 has no input signal, and is perfect, it will give no output! No signal returns to the amplifier's input via the resonator, and the result is a sustained and stable *lack* of oscillation. Something is needed to start the oscillator.

This fits the pendulum-clock analogy: A wound-up clock is stable with its pendulum at rest, yet after a push the system will sustain oscillation. The mechanism that drives the pendulum is similar to a Class C amplifier: It does not act unless it is driven by a signal that exceeds its threshold. An electrical oscillator based on a Class C amplifier can sometimes be kicked into action by the turn-on transient of its power supply. The risk is that this may not always happen, and also that should some external influence stop the oscillator, it will not restart until someone notices the problem and cycles the power. This can be very inconvenient!

A real-life oscillator whose amplifier does not lose gain at low signal levels can self-start due to noise. Fig 10.5 shows an oscillator block diagram with the amplifier's noise shown, for our convenience, as a second input that adds with the true input. The amplifier amplifies the noise. The resonator filters the output noise, and this signal returns to the amplifier input. The importance of having slightly excessive gain until the oscillator reaches operating amplitude is now obvious. If the loop gain is slightly above one, the recirculated noise must, within the resonator's bandwidth, be larger than its original level at the input. More noise is continually summed in as a noise-like signal continuously passes around the loop, undergoing amplification and filtering as it does. The level increases,

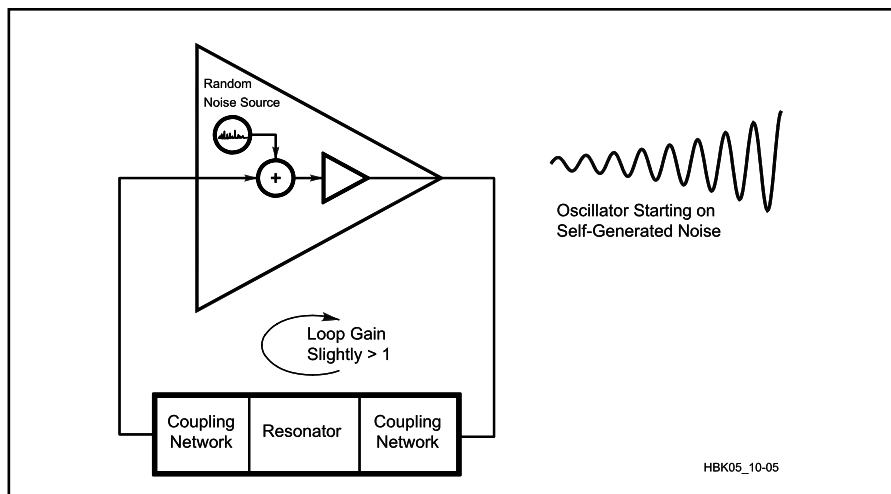

Fig 10.5—An oscillator with noise. Real-world amplifiers, no matter how quiet, generate some internal noise; this allows real-world oscillators to self-start.

causing the gain to reduce. Eventually, it stabilizes at whatever level is necessary to make the net loop gain equal to one.

So far, so good. The oscillator is running at its proper level, but something seems very wrong. It is not making a proper sine wave; it is recirculating and filtering a noise signal. It can also be thought of as a Q multiplier with a controlled (high) gain, filtering a noise input and amplifying it to a set level. Narrow-band filtered noise approaches a true sine wave as the filter is narrowed to zero width. What this means is that we cannot make a true sine-wave signal—all we can do is make narrow-band filtered noise as an approximation to one. A high-quality, low-noise oscillator is merely one that does tighter filtering. Even a kick-started Class-C-amplifier oscillator has noise continuously entering its circulating signal, and so behaves similarly.

A small-signal gain greater than one is absolutely critical for reliable starting, but having too much gain can make the final operating level unstable. Some oscillators are designed around limiting amplifiers to make their operation predictable. AGC systems have also been used, with an RF detector and dc amplifier used to servo-control the amplifier gain. It is notoriously difficult to design reliable crystal oscillators that can be published or mass-produced without having occasional individuals refuse to start without some form of shock.

Mathematicians have been intrigued by “chaotic systems” where tiny changes in initial conditions can yield large changes in outcome. The most obvious example is meteorology, but much of the necessary math was developed in the study of oscillator start-up, because it is a case of chaotic activity in a simple system. The equations that describe oscillator start-up are similar to those used to generate many of the popular, chaotic fractal images.

PHASE NOISE

Viewing an oscillator as a filtered-noise generator is relatively modern. The older approach was to think of an oscillator making a true sine wave with an added, unwanted noise signal. These are just different ways of visualizing the same thing: They are equally valid views, which are used interchangeably, depending which best makes some point clear. Thinking in terms of the signal-plus-noise version, the noise surrounds the carrier, looking like sidebands and so can also be considered to be equivalent to random-noise FM and AM on the ideal sine-wave signal. This gives us a third viewpoint. Strangely, these noise sidebands are called *phase noise*. If we consider the addition of a noise voltage to a sinusoidal voltage, we

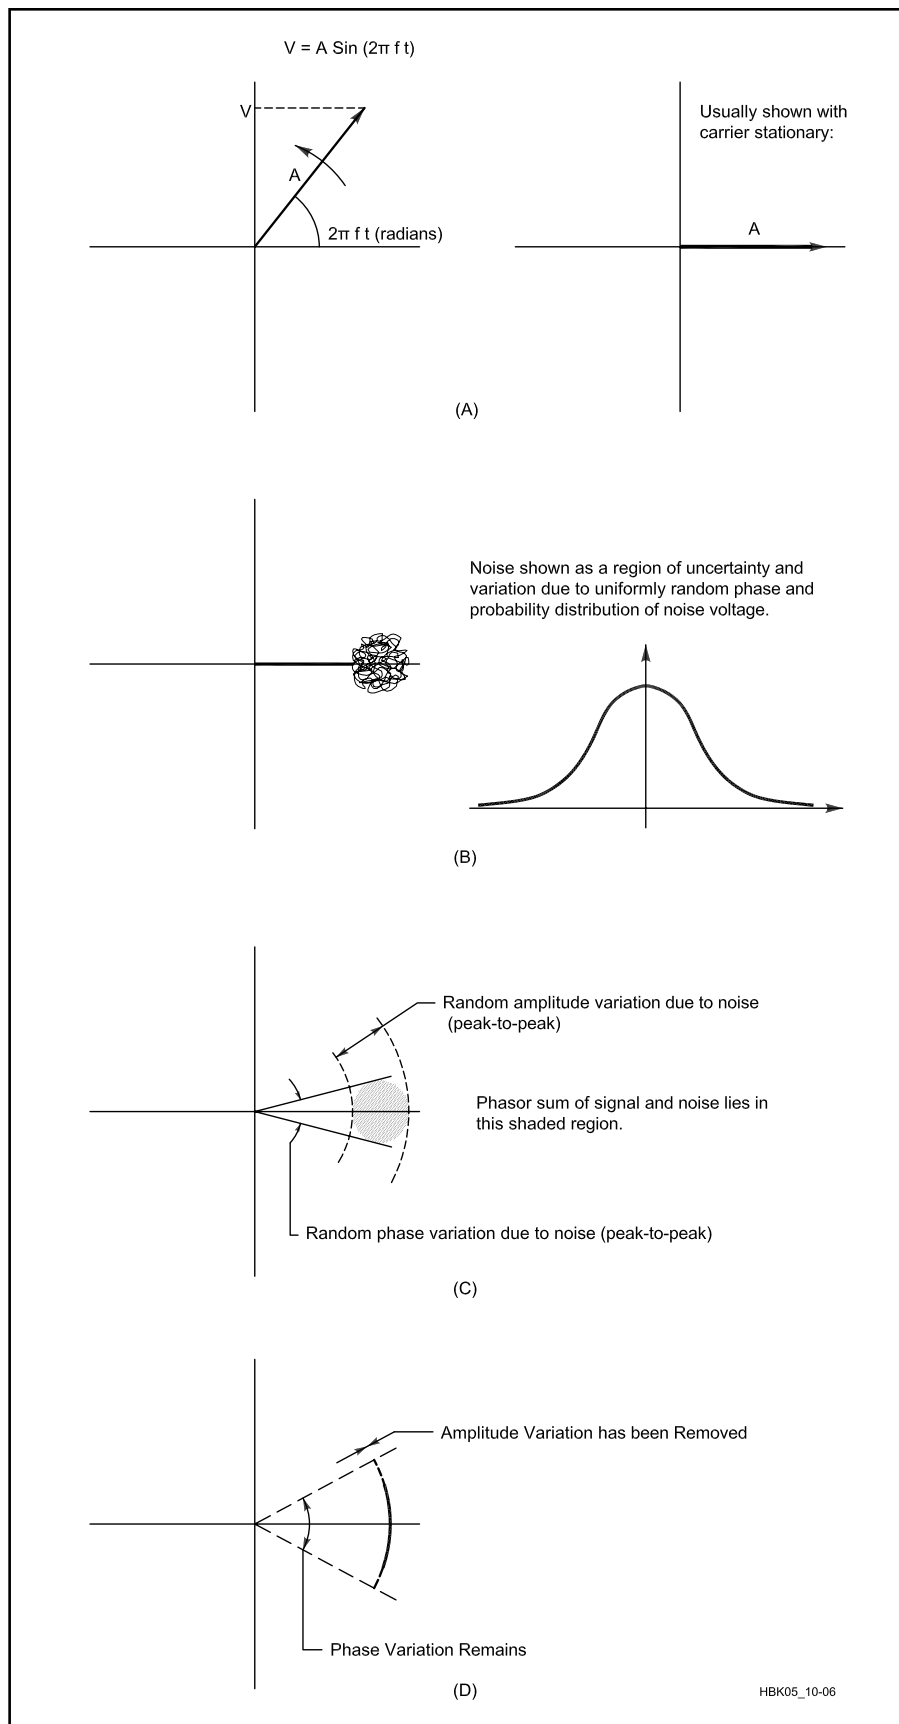

Fig 10.6—At A, a phasor diagram of a clean (ideal) oscillator. Noise creates a region of uncertainty in the vector’s length and position (B). AM noise varies the vector’s length; PM noise varies the vector’s relative angular position (C) Limiting a signal that includes AM and PM noise strips off the AM and leaves the PM (D).

must take into account the phase relationship. A *phasor diagram* is the clearest way of illustrating this. **Fig 10.6A** represents a clean sine wave as a rotating vector whose length is equal to the peak amplitude and whose frequency is equal to the number of revolutions per second of its rotation. Moving things are difficult to depict on paper, so phasor diagrams are usually drawn to show the dominant signal as stationary, with other components drawn relative to this.

Noise contains components at many frequencies, so its phase with respect to the dominant, theoretically pure signal—the “carrier”—is random. Its amplitude is also random. Noise can only be described in statistical terms because its voltage is constantly and randomly changing, yet it does have an average amplitude that can be expressed in rms volts. Fig 10.6B shows noise added to the carrier phasor, with the noise represented as a fuzzy, uncertain region in which the sum phasor wanders randomly. The phase of the noise is uniformly random—no direction is more likely than any other—but the instantaneous magnitude of the noise obeys a probability distribution like that shown, higher values being progressively rarer. Fig 10.6C shows how the extremities of the noise region can be considered as extremes of phase and amplitude variation from the normal values of the carrier.

Phase modulation and frequency modulation are closely related. Phase is the integral of frequency, so phase modulation resembles frequency modulation in which deviation decreases with increasing modulating frequency. Thus, there is no need to talk of “frequency noise” because *phase noise* already covers it.

Fig 10.6C clearly shows AM noise as the random variation of the length of the sum phasor, yet “amplitude noise” is rarely discussed. The oscillator’s amplitude control mechanism acts to reduce the AM noise by a small amount, but the main reason is that the output is often fed into some form of limiter that strips off AM components just as the limiting IF amplifier in an FM receiver removes any AM on incoming signals. The limiter can be obvious, like a circuit to convert the signal to logic levels, or it can be implicit in some other function. A diode ring mixer may be driven by a sine-wave LO of moderate power, yet this signal drives the diodes hard on and hard off, approximating square-wave switching. This is a form of limiter, and it removes the effect of any AM on the LO. Fig 10.6D shows the result of passing a signal with noise through a limiting amplifier. For these reasons, AM noise sidebands are rarely a problem in

oscillators, and so are normally ignored. There is one subtle problem to beware of, however. If a sine wave drives some form of switching circuit or limiter, and the threshold is offset from the signal’s mean voltage, any level changes will affect the exact switching times and cause *phase jitter*. In this way, AM sidebands are translated into PM sidebands and pass through the limiter. This is usually called *AM-to-PM conversion* and is a classic problem of limiters.

Effects of Phase Noise

You would be excused for thinking that

phase noise is a recent discovery, but all oscillators have always produced it. Other changes have elevated an unnoticed characteristic up to the status of a serious impairment. Increased crowding and power levels on the ham bands, allied with greater expectations of receiver performance as a result of other improvements, have made phase noise more noticeable, but the biggest factor has been the replacement of VFOs in radios by frequency synthesizers. It is a major task to develop a synthesizer that tunes in steps fine enough for SSB and CW while competing with the phase-noise performance of a reasonable-quality LC

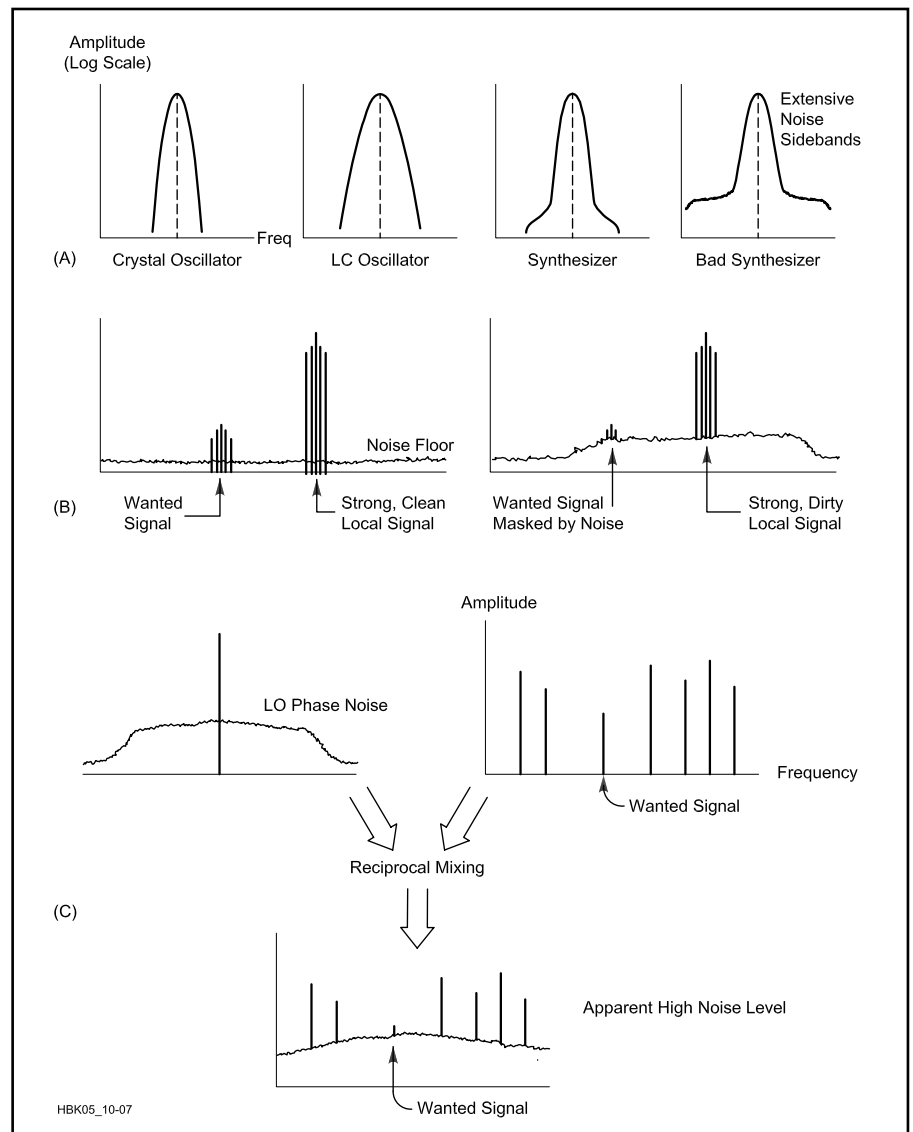

Fig 10.7—The effects of phase noise. At A, the relative phase-noise spectra of several different signal-generation approaches. At B, how transmitted phase noise degrades the weak-signal performance even of nearby receivers with phase-quiet oscillators, raising the effective noise floor. What is perhaps most insidious about phase noise in Amateur Radio communication is that its presence in a receiver LO can allow strong, clean transmitted signals to degrade the receiver’s noise floor just as if the transmitted signals were dirty. This effect, reciprocal mixing, is shown at C.

VFO. Many synthesizers have fallen far short of that target. Phase noise is worse in higher-frequency oscillators and the trend towards general-coverage, upconverting structures has required that local oscillators operate at higher and higher frequencies. Fig 10.7A shows sketches of the relative phase-noise performance of some oscillators. The very high Q of the quartz crystal in a crystal oscillator gives it the potential for much lower phase noise than LC oscillators. A medium-quality synthesizer has close-in phase noise performance approaching that of a crystal oscillator, while further from the carrier frequency, it degrades to the performance of a modest-quality LC oscillator. There may be a small bump in the noise spectrum at the boundary of these two zones. A bad synthesizer can have extensive noise sidebands extending over many tens (hundreds in extreme cases) of kilohertz at high levels.

Phase noise on a transmitter's local oscillators passes through its stages, is amplified and fed to the antenna along with the intentional signal. The intentional signal is thereby surrounded by a band of noise. This radiated noise exists in the same proportion to the transmitter power as the phase noise was to the oscillator power if it passes through no narrow-band filtering capable of limiting its bandwidth. This radiated noise makes for a noisier band. In bad cases, nearby stations can be unable to receive over many tens of kilohertz. Fig 10.7B illustrates the difference between clean and dirty transmitters.

The effects of receiver-LO phase noise are more complicated, but at least it doesn't affect other stations' reception. The process is called *reciprocal mixing*.

Reciprocal Mixing

This is an effect that occurs in all mixers, yet despite its name, reciprocal mixing is an LO, not a mixer, problem. Imagine that the outputs of two supposedly unmodulated signal generators are mixed together and the mixer output is fed into an FM receiver. The receiver produces sounds, indicating that the resultant signal is modulated nonetheless. Which signal generator is responsible? This is a trick question, of course. A moment spent thinking about how a change in the frequency of either input signal affects the output signal will show that FM or PM on either input reaches the output. The best answer to the trick question is therefore "either or both."

The modulation on the mixer output is the combined modulations of the inputs. This means that modulating a receiver's local oscillator is indistinguishable from using a clean LO and having the same

modulation present on *all* incoming signals. (This is also true for AM provided that a fully linear multiplier is used as the mixer, but mixers are commonly driven into switching, which strips any AM off the LO signal. This is the chief reason why the phase component of oscillator noise is more important than any AM component.)

The word *indistinguishable* is important in the preceding paragraph. It does not mean that the incoming signals are themselves modulated, but that the signals in the receiver IF and the noise in the IF, sound exactly as if they were. What really happens is that the noise components of the LO are extra LO signals that are offset from the carrier frequency. Each of them mixes other signals that are appropriately offset from the LO carrier into the receiver's IF. Noise is the sum of an infinite number of infinitesimal components spread over a range of frequencies, so the signals it mixes into the IF are spread into an infinite number of small replicas, all at different frequencies. This amounts to scrambling these other signals into noise. It is tedious to look at the effects of receiver LO phase noise this way. The concept of reciprocal mixing gives us an easier, alternative view that is much more digestible and produces identical results.

A poor oscillator can have significant noise sidebands extending out many tens of kilohertz on either side of its carrier. This is the same, as far as the signals in the receiver IF are concerned, as if the LO were clean and every signal entering the mixer had these noise sidebands. Not only will the wanted signal (and its noise sidebands) be received, but the noise sidebands added by the LO to signals near, but outside, the receiver's IF passband will overlap it. If the band is busy, each of many signals present will add its set of noise sidebands—and the effect is cumulative. This produces the appearance of a high background-noise level on the band. Many hams tend to accept this, blaming "conditions."

Hams now widely understand reception problems due to intermodulation, and almost everyone knows to apply RF attenuation until the signal gets no clearer. Intermodulation is a nonlinear effect, and the levels of the intermod products fall by greater amounts than the reduction in the intermodulating signals. The net result is less signal, but with the intermodulation products dropped still further. This improvement reaches a limit when more attenuation pushes the desired signal too close to the receiver's noise floor.

Reciprocal mixing is a linear process, and the mixer applies the same amount of noise "deviation" to incoming signals as that present on the LO. Therefore the ratio

of noise-sideband power to signal power is the same for each signal, and the same as that on the LO. Switching in RF attenuation reduces the power of signals entering the mixer, but the reciprocal mixing process still adds the noise sidebands at the same *relative* power to each. Therefore, no reception improvement results. Other than building a quieter oscillator, the only way of improving things is to use narrow preselection to band-limit the receiver's input response and reduce the number of incoming signals subject to reciprocal mixing. This reduces the number of times the phase noise sidebands get added into the IF signal. Commercial *tracking preselectors*—selective front-end circuits that tune in step with a radio's band changes and tuning, are expensive, but one that is manually tuned would make a modest-sized home-brew project and could also help reduce intermodulation effects. When using a good receiver with a linear front end and a clean LO, amateurs accustomed to receivers with poor phase-noise performance report the impression is of a seemingly emptier band with gaps between signals—and then they begin to find readable signals in some of the gaps.

Fig 10.7C shows how a noisy oscillator affects transmission and reception. The effects on reception are worst in Europe, on 40 m, at night. Visitors from North America, and especially Asia, are usually shocked by the levels of background noise. In ITU Region 1, the Amateur Radio 40-m allocation is 7.0 to 7.1 MHz; above this, ultra-high-power broadcasters operate. The front-end filters in commercial ham gear are usually fixed band-pass designs that cover the wider 40-m allocations in the other regions. This allows huge signals to reach the mixer and mix large levels of LO phase noise into the IF. Operating collocated radios, on the same band, in a multioperator contest, requires linear front ends, preselection and state-of-the-art phase-noise performance. Outside of amateur circles, only warship operation is more demanding, with kilowatt transmitters and receivers sharing antennas on the same mast.

A Phase Noise Demonstration

Healthy curiosity demands some form of demonstration so the scale of a problem can be judged "by ear" before measurements are attempted. We need to be able to measure the noise of an oscillator alone (to aid in the development of quieter ones) and we also need to be able to measure the phase noise of the oscillators in a receiver (a transmitter can be treated as an oscillator). Conveniently, a receiver contains most of the functions needed to

demonstrate its own phase noise.

No mixer has perfect port-to-port isolation, and some of its local-oscillator signal leaks through into the IF. If we tune a general-coverage receiver, with its antenna disconnected, to exactly 0 Hz, the local oscillator is exactly at the IF center frequency, and the receiver acts as if it is tuned to a very strong unmodulated carrier. A typical mixer might give only 40 dB of LO isolation and have an LO drive power of at least 10 mW. If we tune away from 0 Hz, the LO carrier tunes away from the IF center and out of the passband. The apparent signal level falls. Although this moves the LO carrier out of the IF passband, some of its noise sidebands will not be, and the receiver will respond to this energy as an incoming noise signal. To the receiver operator, this sounds like a rising noise floor as the receiver is tuned toward 0 Hz. To get good noise floor at very low frequencies, some professional/military receivers, like the Racal RA1772, use very carefully balanced mixers to get as much port-to-port isolation as possible, and they also may switch a crystal notch filter into the first mixer's LO feed.

This demonstration cannot be done if the receiver tunes amateur bands only. As it is, most general-coverage radios inhibit tuning in the LF or VLF region. It could be suggested by a cynic that how low manufacturers allow you to tune is an indication of how far they think their phase-noise sidebands could extend!

The majority of amateur transceivers with general-coverage receivers are programmed not to tune below 30 to 100 kHz, so means other than the "0 Hz" approach are needed to detect LO noise in these radios. Because reciprocal mixing adds the LO's sidebands to clean incoming signals, in the same proportion to the incoming carrier as they exist with respect to the LO carrier, all we need do is to apply a strong, clean signal wherever we want within the receiver's tuning range. This signal's generator must have lower phase noise than the radio being evaluated. A general-purpose signal generator is unlikely to be good enough; a crystal oscillator is needed.

It's appropriate to set the level into the receiver to about that of a strong broadcast carrier, say S9 + 40 dB. Set the receiver's mode to SSB or CW and tune around the test signal, looking for an increasing noise floor (higher hiss level) as you tune closer towards the signal, as shown in Fig 10.8. Switching in a narrow CW filter allows you to hear noise closer to the carrier than is possible with an SSB filter. This is also the technique used to measure a receiver's effective selectivity, and some equipment

reviewers kindly publish their plots in this format. *QST* reviews, done by the ARRL Lab, often include the results of specific phase-noise measurements.

Measuring Receiver Phase Noise

There are several different ways of measuring phase noise, offering different tradeoffs between convenience, cost and effort. Some methods suit oscillators in isolation, others suit them in-situ (in their radios).

If you're unfamiliar with noise measurements, the units involved may seem strange. One reason for this is that a noise signal's power is spread over a frequency range, like an infinite number of infinitesimal sinusoidal components. This can be thought of as similar to painting a house. The area that a gallon of paint can cover depends on how thinly it's spread. If someone asks how much paint was used on some part of a wall, the answer would have to be in terms of paint volume per square foot. The wall can be considered to be an infinite number of points, each with an infinitesimal amount of paint applied to it. The question of what volume of paint has been applied at some specific point is unanswerable. With noise, we must work in terms of *power density*, of watts per hertz. We therefore express phase-noise level as a ratio of the carrier power to the noise's power density. Because of the large ratios involved, expression in decibels is convenient. It has been a convention to use *dBc* to mean

"decibels with respect to the carrier."

For phase noise, we need to work in terms of a standard bandwidth, and 1 Hz is the obvious candidate. Even if the noise is measured in a different bandwidth, its equivalent power in 1 Hz can be easily calculated. A phase-noise level of -120 dBc in a 1-Hz bandwidth (often written as -120 dBc/Hz) translates into each hertz of the noise having a power of 10^{-12} of the carrier power. In a bandwidth of 3 kHz, this would be 3000 times larger.

The most convenient way to measure phase noise is to buy and use a commercial phase noise test system. Such a system usually contains a state-of-the-art, low-noise frequency synthesizer and a low-frequency spectrum analyzer, as well as some special hardware. Often, a second, DSP-based spectrum analyzer is included to speed up and extend measurements very close to the carrier by using the Fast Fourier Transform (FFT). The whole system is then controlled by a computer with proprietary software. With a good system like this costing about \$100,000, this is not a practical method for amateurs, although a few fortunate individuals have access to them at work. These systems are also overkill for our needs, because we are not particularly interested in determining phase-noise levels very close to and very far from the carrier.

It's possible to make respectable receiver-oscillator phase-noise measurements with less than \$100 of parts and a multimeter. Although it's time-consuming, the technique is much more in keeping with the amateur spirit than using a \$100k system! An ordinary multimeter will produce acceptable results, a meter capable of indicating "true rms" ac voltages is preferable because it can give correct readings on sine waves *and* noise. Fig 10.9 shows the setup. Measurements can only be made around the frequency of the crystal oscillator, so if more than one band is to be tested, crystals must be changed, or else a set of appropriate oscillators is needed. The oscillator should produce about +10 dBm (10 mW) and be *very* well shielded. (To this end, it's advisable to build the oscillator into a die-cast box and power it from internal batteries. A noticeable shielding improvement results even from avoiding the use of an external power switch; a reed-relay element inside the box can be positioned to connect the battery when a small permanent magnet is placed against a marked place outside the box.)

Likewise, great care must be taken with attenuator shielding. A total attenuation of around 140 dB is needed, and with so much attenuation in line, signal leakage can easily exceed the test signal that

Fig 10.8—Tuning in a strong, clean crystal-oscillator signal can allow you to hear your receiver's relative phase-noise level. Listening with a narrow CW filter switched in allows you to get better results closer to the carrier.

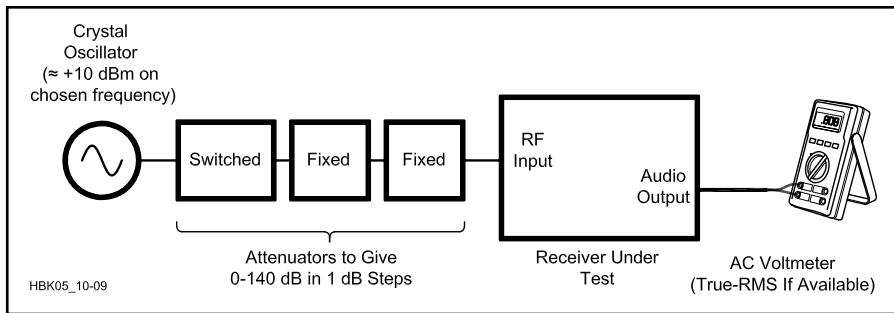

Fig 10.9—Setup for measuring receiver-oscillator phase noise.

reaches the receiver. It's not necessary to be able to switch-select all 140 dB of the attenuation, nor is this desirable, as switches can leak. (The 1995 and older editions of this *Handbook* contained a step attenuator that's satisfactory.) All of the attenuators' enclosure seams must be soldered. A pair of boxes with 30 dB of fixed attenuation each are needed to complete the set. With 140 dB of attenuation, coax cable leakage is also a problem. The only countermeasure against this is to minimize all cable lengths and to interconnect test-system modules with BNC plug-to-plug adapters (UG-491As) where possible.

Ideally, the receiver could simply be tuned across the signal from the oscillator and the response measured using its signal-strength (S) meter. Unfortunately, receiver S meters are notoriously imprecise, so an equivalent method is needed that does not rely on the receiver's AGC system.

The trick is not to measure the response to a fixed level signal, but to measure the changes in applied signal power needed to give a fixed response. Here is a step-by-step procedure based on that described by John Grebenkemper, KI6WX, in March and April 1988 *QST*:

1. Connect the equipment as shown in Fig 10.9, but with the crystal oscillator off. Set the step attenuator to maximum attenuation. Set the receiver for SSB or CW reception with its narrowest available IF filter selected. Switch out any internal preamplifiers or RF attenuators. Select AGC off, maximum AF and RF gain. It may be necessary to reduce the AF gain to ensure the audio amplifier is at least 10 dB below its clipping point. The ac voltmeter or an oscilloscope on the AF output can be used to monitor this.

2. To measure noise, it is important to know the bandwidth being measured. A true-RMS ac voltmeter measures the power in the noise reaching it. To calculate the noise density, we need to divide by the receiver's *noise bandwidth*. The receiver's -6 -dB IF bandwidth can be used

as an approximation, but purists will want to plot the top 20 dB of the receiver's bandwidth on linear scales and integrate the area under it to find the width of a rectangle of equal area and equal height. This accounts properly for the noise in the skirt regions of the overall selectivity. (The very rectangular shape of common receiver filters tends to minimize the error of just taking the approximation.)

Switch on the test oscillator and set the attenuators to give an AF output above the noise floor and below the clipping level with the receiver peaked on the signal. Tune the receiver off to each side to find the frequencies at which the AF voltage

is half that at the peak. The difference between these is the receiver's -6 -dB bandwidth. High accuracy is not needed: 25% error in the receiver bandwidth will only cause a 1-dB error in the final result. The receiver's published selectivity specifications will be close enough. The benefit of integration is greater if the receiver has a very rounded, low-ringing or low-order filter.

3. Retune the receiver to the peak. Switch the oscillator off and note the noise-floor voltage. Turn the oscillator back on and adjust the attenuator to give an AF output voltage 1.41 times (3 dB) larger than the noise floor voltage. This means that the noise power and the test signal power at the AF output are equal—a value that's often called the *MDS (minimum discernible signal)* of a receiver. Choosing a test-oscillator level at which to do this test involves compromise. Higher levels give more accurate results where the phase noise is high, but limit the lowest level of phase noise that can be measured because better receiver oscillators require a greater input signal to produce enough noise to get the chosen AF-output level. At some point, either we've taken all the attenuation out and our measurement range is limited by the test

Table 10.1

SSB Phase Noise of ICOM IC-745 Receiver Section

Oscillator output power = -3 dBm (0.5 mW)
 Receiver bandwidth (Δf) = 1.8 kHz

1000	0	0.96			-154

*Asterisks indicate measurements possibly affected by receiver overload (see text).

oscillator's available power, or we overload the receiver's front end, spoiling the results.

Record the receiver frequency at the peak, (f_0), the attenuator setting (A_0) and the audio output voltage (V_0). These are the carrier measurements against which all the noise measurements will be compared.

4. Now you must choose the offset frequencies—the spacings from the carrier—at which you wish to make measurements. The receiver's skirt selectivity will limit how close to the carrier noise measurements can be made. (Any measurements made too close in are valid measurements of the receiver selectivity, but because the signal measured under these conditions is sinusoidal and not noise like, the corrections for noise density and noise bandwidth are not appropriate.) It is difficult to decide where the filter skirt ends and the noise begins, and what corrections to apply in the region of doubt and uncertainty. A good practical approach is to listen to the audio and tune away from the carrier until you can't distinguish a tone in the noise. The

ear is superb at spotting sine tones buried in noise, so this criterion, although subjective, errs on the conservative side.

Tune the receiver to a frequency offset from f_0 by your first chosen offset and adjust the attenuators to get an audio output voltage as close as possible to V_0 . Record the total attenuation, A_1 and the audio output voltage, V_1 . The SSB phase noise (qualified as *SSB* because we're measuring the phase noise on only one side of the carrier, whereas some other methods cannot segregate between upper and lower noise sidebands and measure their sum, giving *DSB* phase noise) is now easy to calculate:

$$L(f) = A_1 - A_0 10 \log(BW_{\text{noise}})$$

where

$$L(f) = \text{SSB phase noise in dBc/Hz}$$

$$BW_{\text{noise}} = \text{receiver noise bandwidth, Hz.}$$

5. It's important to check for overload. Decrease the attenuation by 3 dB, and record the new audio output voltage, V_2 . If all is well, the output voltage should

increase by 22% (1.8 dB); if the receiver is operating nonlinearly, the increase will be less. (An 18% increase is still acceptable for the overall accuracy we want.) Record V_2/V_1 as a check: a ratio of 1.22:1 is ideal, and anything less than 1.18:1 indicates a bad measurement.

If too many measurements are bad, you may be overdriving the receiver's AF amplifier, so try reducing the AF gain and starting again back at Step 3. If this doesn't help, reducing the RF gain and starting again at Step 3 should help if the compression is occurring late in the IF stages.

6. Repeat Steps 4 and 5 at all the other offsets you wish to measure. If measurements are made at increments of about half the receiver's bandwidth, any discrete (non-noise) spurs will be found. A noticeable tone in the audio can indicate the presence of one of these. If it is well clear of the noise, the measurement is valid, but the noise bandwidth correction should be ignored, giving a result in dBc.

Table 10.1 shows the results for an ICOM IC-745 as measured by KI6WX, and

Transmitter Phase-Noise Measurement in the ARRL Lab

Here is a brief description of the technique used in the ARRL Lab to measure transmitter phase noise. The system essentially consists of a direct-conversion receiver with very good phase-noise characteristics. As shown in Fig B, we use an attenuator after the transmitter, a Mini-Circuits ZAY-1 mixer, a Hewlett-Packard 8640B signal generator, a band-pass filter, an audio-frequency low-noise amplifier and a spectrum analyzer (HP 8563E) to make the measurements.

The transmitter signal is mixed with the output of the signal generator, and signals produced in the mixing process that are not required for the measurement process are filtered out. The spectrum analyzer then displays the transmitted phase-noise spectrum. The 100 mW output of the HP 8640B is barely enough to drive the mixer—the setup would work better with 200 mW of drive. To test the phase noise of an HP 8640B, we use a second 8640B as a reference source. It is quite important to be sure that the phase noise of the reference source is lower than that of the signal under test, because we are really measuring the combined phase-noise output of the signal generator and the transmitter. It would be quite embarrassing to publish phase-noise plots of the reference generator instead of the transmitter under test! The HP 8640B has much cleaner spectral output than most transmitters.

A sample phase-noise plot for an amateur transceiver is shown in Fig A. It was produced with the test setup shown in Fig B. Measurements from multiple passes are taken and averaged. A 3-Hz video bandwidth also helps average and smooth the plots. These plots do not necessarily reflect the phase-noise characteristics of all units of a particular model.

The log reference level (the top horizontal line on the scale in the plot) represents -60 dBc/Hz. It is common in industry to use a 0-dBc log reference, but such a refer-

ence level would not allow measurement of phase-noise levels below -80 dBc/Hz. The actual measurement bandwidth used on the spectrum analyzer is 100 Hz, but the reference is scaled for a 1-Hz bandwidth. This allows phase-noise levels to be read directly from the display in dBc/Hz. Because each vertical division represents 10 dB, the plot shows the noise level between -60 dBc/Hz (the top horizontal line) and -140 dBc/Hz (the bottom horizontal line). The horizontal scale is 2 kHz per division. The offsets shown in the plots are 2 through 20 kHz.

What Do the Phase-Noise Plots Mean?

Although they are useful for comparing different radios, plots can also be used to calculate the amount of interference you may receive from a nearby transmitter

Fig A—Sample phase noise plot for an amateur transceiver.

Fig 10.10 shows this data in graphic form. His oscillator power was only -3 dBm, which limited measurements to offsets less than 200 kHz. More power might have allowed noise measurements to lower levels, although receiver overload places a limit on this. This is not important, because the real area of interest has been thoroughly covered. When attempting phase-noise measurements at large offsets, remember that any front-end selectivity, before the first mixer, will limit the maximum offset at which LO phase-noise measurement is possible.

MEASURING OSCILLATOR AND TRANSMITTER PHASE NOISE

Measuring the composite phase noise of a receiver's LO requires a clean test oscillator. Measuring the phase noise of an incoming signal, whether from a single oscillator or an entire transmitter, requires the use of a clean receiver, with lower phase noise than the source under test. The sidebar, "Transmitter Phase-Noise Measurement in the ARRL Lab," details the

Fig 10.10—The SSB phase noise of an ICOM IC-745 transceiver (serial number 01528) as measured by KI6WX.

method used to measure composite noise (phase noise and amplitude noise, the practical effects of which are indistinguishable on the air) for *QST* Product Reviews. Although targeted at measuring high power signals from entire transmitters, this approach can be used to measure lower-level signals simply by changing the amount of input attenuation used.

At first, this method—using a low-frequency spectrum analyzer and a low-phase-noise signal generator—looks unnecessarily elaborate. A growing number of radio amateurs have acquired good-quality spectrum analyzers for their shacks since older model Tektronix and Hewlett-Packard instruments have started to appear on the surplus market at affordable prices. The obvious question is, "Why not just use one of these to view the signal and read phase-noise levels directly off the screen?" Reciprocal mixing is the problem. Very few spectrum analyzers have clean enough local oscillators not to completely swamp the noise being measured. Phase-noise measurements involve the measurement of low-level components very close to a large carrier, and that carrier will mix the noise sidebands of *the analyzer's LO* into its IF. Some way of notching out the carrier is needed, so that the analyzer need only handle the noise sidebands. A crystal filter could be designed to do the job, but this would be expensive, and one would be needed for every different oscillator

with known phase-noise characteristics. An approximation is given by

$$A_{\text{QRM}} = \text{NL} + 10 \times \log(\text{BW})$$

where

A_{QRM} = Interfering signal level, dBc

NL = noise level on the receive frequency, dBc

BW = receiver IF bandwidth, in Hz

For instance, if the noise level is -90 dBc/Hz and you are using a 2.5-kHz SSB filter, the approximate interfer-

ing signal will be -56 dBc. In other words, if the transmitted signal is 20 dB over S9, and each S unit is 6 dB, the interfering signal will be as strong as an S3 signal.

The measurements made in the ARRL Lab apply only to transmitted signals. It is reasonable to assume that the phase-noise characteristics of most transceivers are similar on transmit and receiver because the same oscillators are generally used in local-oscillator (LO) chain.

In some cases, the receiver may have better phase-noise characteristics than the transmitter. Why the possible difference? The most obvious reason is that circuits often perform less than optimally in strong RF fields, as anyone who has experienced RFI problems can tell you. A less obvious reason results from the way that many high-dynamic-range receivers work. To get good dynamic range, a sharp crystal filter is often placed immediately after the first mixer in the receive line. This filter removes all but a small slice of spectrum for further signal processing. If the desired filtered signal is a product of mixing an incoming signal with a noisy oscillator, signals far away from the desired one can end up in this slice. Once this slice of spectrum is obtained, however, unwanted signals cannot be reintroduced, no matter how noisy the oscillators used in further signal processing. As a result, some oscillators in receivers don't affect phase noise.

The difference between this situation and that in transmitters is that crystal filters are seldom used for reduction of phase noise in transmitting because of the high cost involved. Equipment designers have enough trouble getting smooth, click-free break-in operation in transceivers without having to worry about switching crystal filters in and out of circuits at 40-wpm keying speeds!—Zack Lau, W1VT, ARRL Laboratory Engineer

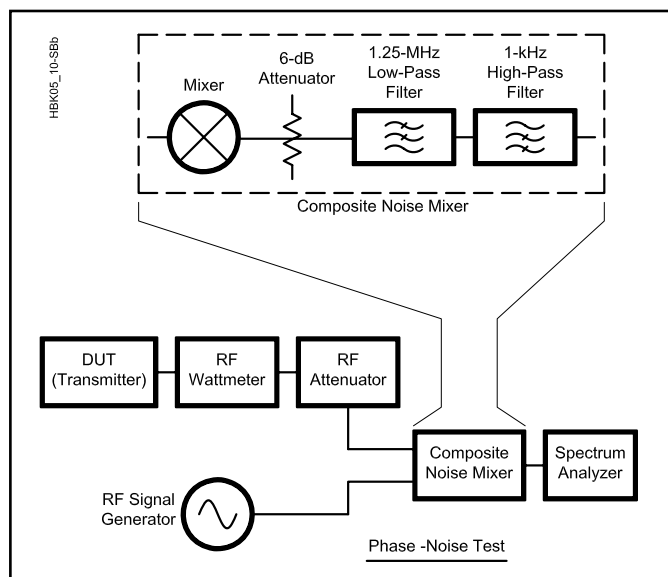

Fig B—ARRL transmitter phase-noise measurement setup.

frequency to be tested. The alternative is to build a direct-conversion receiver using a clean LO like the Hewlett-Packard HP8640B signal generator and spectrum-analyzer its “audio” output with an audio analyzer. This scheme mixes the carrier to dc; the LF analyzer is then ac-coupled, and this removes the carrier. The analyzer can be made very sensitive without overload or reciprocal mixing being a problem. The remaining problem is then keeping the LO—the HP8640B in this example—at exactly the carrier frequency. 8640s are based on a shortened-UHF-cavity oscillator and can drift a little. The oscillator under test will also drift. The task is therefore to make the 8640B track the oscillator under test. For once we get something for free: The HP8640B’s FM input is dc coupled, and we can use this as an electronic fine-tuning input. As a further bonus, the 8640B’s FM deviation control acts as a sensitivity control for this input. We also get a phase detector for free, as the mixer output’s dc component depends on the phase relationship between the 8640B and the signal under test (remember to use the dc coupled port of a diode ring mixer as the output). Taken together, the system includes everything needed to create a crude phase-locked loop that will automatically track the input signal over a small frequency range. **Fig 10.11** shows the arrangement.

The oscilloscope is not essential for operation, but it is needed to adjust the system. With the loop unlocked (8640B FM input disconnected), tune the 8640 off the signal frequency to give a beat at the mixer output. Adjust the mixer drive levels to get an undistorted sine wave on the scope. This ensures that the mixer is

not being overdriven. While the loop is off-tuned, adjust the beat to a frequency within the range of the LF spectrum analyzer and use it to measure its level, “ A_c ” in dBm. This represents the carrier level and is used as the reference for the noise measurements. Connect the FM input of the signal generator, and switch on the generator’s dc FM facility. Try a deviation range of 10 kHz to start with. When you tune the signal generator toward the input frequency, the scope will show the falling beat frequency until the loop jumps into lock. Then it will display a noisy dc level. Fine tune to get a mean level of 0 V. (This is a very-low-bandwidth, very-low-gain loop. Stability is not a problem; careful loop design is not needed. We actually want as slow a loop as possible; otherwise, the loop would track and cancel the slow components of the incoming signal’s phase noise, preventing their measurement.)

When you first take phase-noise plots, it’s a good idea to duplicate them at the generator’s next lower FM-deviation range and check for any differences in the noise level in the areas of interest. Reduce the FM deviation range until you find no further improvement. Insufficient FM deviation range makes the loop’s lock range narrow, reducing the amount of drift it can compensate. (It’s sometimes necessary to keep gently trimming the generator’s fine tune control.)

Set up the LF analyzer to show the noise. A sensitive range and 100-Hz resolution bandwidth are appropriate. Measure the noise level, “ A_n ” in dBm. We must now calculate the noise density that this represents. Spectrum-analyzer filters are normally *Gaussian*-shaped and bandwidth-

specified at their –3-dB points. To avoid using integration to find their true-noise power bandwidth, we can reasonably assume a value of $1.2 \times BW$. A spectrum analyzer logarithmically compresses its IF signal ahead of the detectors and averaging filter. This affects the statistical distribution of noise voltage and causes the analyzer to read low by 2.5 dB. To produce the same scale as the ARRL Lab photographs, the analyzer reference level must be set to –60 dBc/Hz, which can be calculated as:

$$A_{\text{ref}} = A_c - 10 \log(1.2 \times BW) + 62.5 \text{ dBm} \quad (2)$$

where

A_{ref} = analyzer reference level, dBm

A_c = carrier amplitude, dBm

This produces a scale of –60 dBc/Hz at the top of the screen, falling to –140 dBc/Hz at the bottom. The frequency scale is 0 to 20 kHz with a resolution bandwidth (BW in the above equation) of 100 Hz. This method combines the power of *both* sidebands and so measures DSB phase noise. To calculate the equivalent SSB phase noise, subtract 3 dB for noncoherent noise (the general “hash” of phase noise) and subtract 6 dB for coherent, discrete components (that is, single-frequency spurs). This can be done by setting the reference level 3 to 6 dB higher.

Low-Cost Phase Noise Testing

All that expensive equipment may seem far beyond the means of the average Amateur Radio experimenter. With careful shopping and a little more effort, alternative equipment can be put together for pocket money. (All of the things needed—parts for a VXO, a surplus spectrum analyzer and so on—have been seen on sale cheap enough to total less than \$100.) The HP8640B is good and versatile, but for use at one oscillator frequency, you can build a VXO for a few dollars. It will only cover one oscillator frequency, but a VXO can provide even better phase-noise performance than the 8640B.

As referenced at the end of this chapter, *Pontius* has also demonstrated that signal-source phase-noise measurements can be accurately obtained without the aid of expensive equipment.

OSCILLATOR CIRCUITS AND CONSTRUCTION

LC Oscillator Circuits

The LC oscillators used in radio equipment are usually arranged as *variable frequency oscillators* (VFOs). Tuning is achieved by either varying part of the capacitance of the resonator or, less

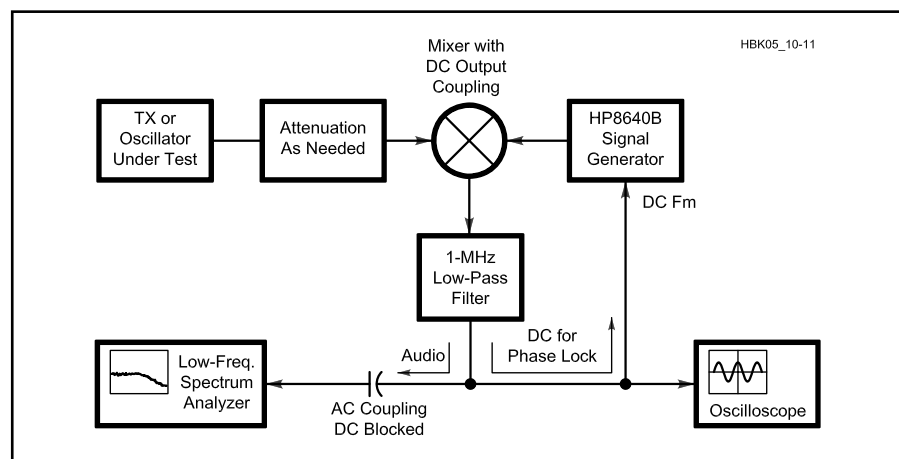

Fig 10.11—Arrangement for measuring phase noise by directly converting the signal under test to audio. The spectrum analyzer views the signal’s noise sidebands as audio; the signal’s carrier, converted to dc, provides a feedback signal to phase-lock the Hewlett-Packard HP8640B signal generator to the signal under test.

commonly, by using a movable magnetic core to vary the inductance. Since the early days of radio, there has been a huge quest for the ideal, low-drift VFO. Amateurs and professionals have spent immense effort on this pursuit. A brief search of the litera-

ture reveals a large number of designs, many accompanied by claims of high stability. The quest for stability has been solved by the development of low-cost frequency synthesizers, which can give crystal-controlled stability. Synthesizers

have other problems though, and the VFO still has much to offer in terms of signal cleanliness, cost and power consumption, making it attractive for home construction. No one VFO circuit has any overwhelming advantage over any other—component quality, mechanical design and the care taken in assembly are much more important.

Fig 10.12 shows three popular oscillator circuits stripped of any unessential frills so they can be more easily compared. The original Colpitts circuit (Fig 10.12A) is now often referred to as the *parallel-tuned Colpitts* because its series-tuned derivative (Fig 10.12B) has become common. All three of these circuits use an amplifier with a voltage gain less than unity, but large current gain. The N-channel JFET source follower shown appears to be the most popular choice nowadays. In the parallel-tuned Colpitts, C3 and C4 are large values, perhaps 10 times larger than typical values for C1 and C2. This means that only a small fraction of the total tank voltage is applied to the FET, and the FET can be considered to be only lightly coupled into the tank. The FET is driven by the sum of the voltages across C3 and C4, while it drives the voltage across C4 alone. This means that the tank operates as a resonant, voltage-step-up transformer compensating for the less-than-unity-voltage-gain amplifier. The resonant circuit consists of L, C1, C2, C3 and C4. The resonant frequency can be calculated by using the standard formulas for capacitors in series and parallel to find the resultant capacitance effectively connected across the inductor, L, and then use the standard formula for LC resonance:

$$f = \frac{1}{2\pi\sqrt{LC}} \quad (3)$$

where

- f = frequency in hertz
- L = inductance in henries
- C = capacitance in farads.

For a wide tuning range, C2 must be kept small to reduce the effect of C3 and C4 swamping the variable capacitor C1.

The series-tuned Colpitts circuit works in much the same way. The difference is that the variable capacitor, C1, is positioned so that it is well-protected from being swamped by the large values of C3 and C4. In fact, *small* values of C3, C4 would act to limit the tuning range. Fixed capacitance, C2, is often added across C1 to allow the tuning range to be reduced to that required, without interfering with C3 and C4, which set the amplifier coupling. The series-tuned Colpitts has a reputation for better stability than the parallel-tuned

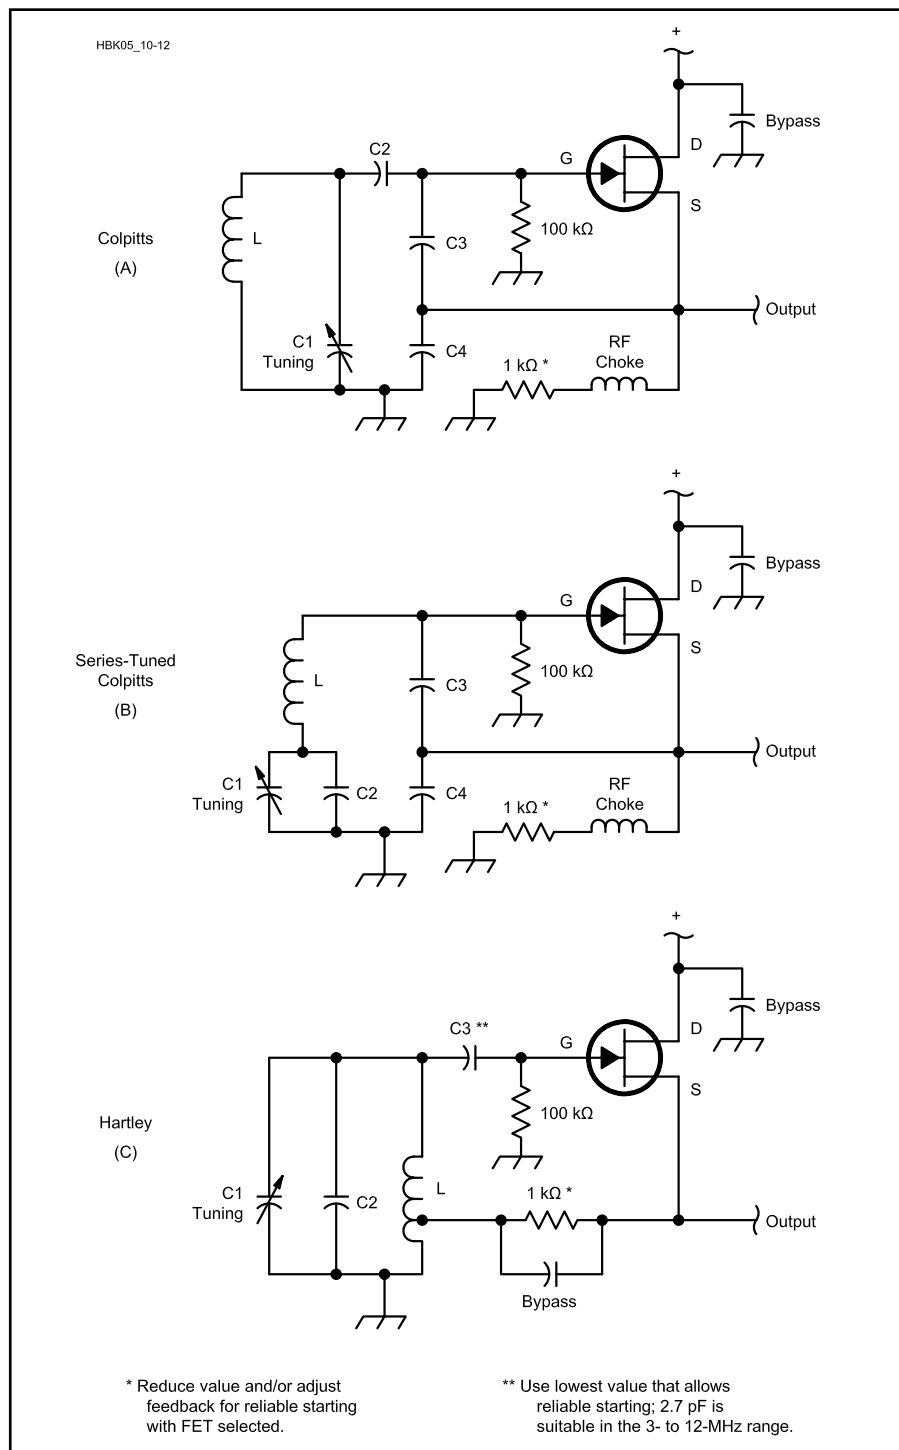

Fig 10.12—The Colpitts (A), series-tuned Colpitts (B) and Hartley (C) oscillator circuits. Rules of thumb: C3 and C4 at A and B should be equal and valued such that their $X_c = 45 \Omega$ at the operating frequency; for C2 at A, $X_c = 100 \Omega$. For best stability, use C0G or NP0 units for all capacitors associated with the FETs' gates and sources. Depending on the FET chosen, the 1-kΩ source-bias-resistor value shown may require adjustment for reliable starting.

original. Note how C3 and C4 swamp the capacitances of the amplifier in both versions.

The Hartley is similar to the parallel-tuned Colpitts, but the amplifier source is tapped up on the tank inductance instead of the tank capacitance. A typical tap placement is 10 to 20% of the total turns up from the “cold” end of the inductor. (It’s usual to refer to the lowest-signal-voltage end of an inductor as *cold* and the other, with the highest signal voltage as *hot*.) C2 limits the tuning range as required; C3 is reduced to the minimum value that allows reliable starting. This is necessary because the Hartley’s lack of the Colpitts’s capacitive divider would otherwise couple the FET’s capacitances to the tank more strongly than in the Colpitts, potentially affecting the circuit’s frequency stability.

In all three circuits, there is a 1 kΩ resistor in series with the source bias choke. This resistor does a number of desirable things. It spoils the Q of the inevitable low-frequency resonance of the choke with the tank tap circuit. It reduces tuning drift due to choke impedance and winding capacitance variations. It also protects against spurious oscillation due to internal choke resonances. Less obviously, it acts to stabilize the loop gain of the built-in AGC action of this oscillator. Stable operating conditions act to reduce frequency drift. Some variations of these circuits may be found with added resistors providing a dc bias to stabilize the system quiescent current. More elaborate still are variations characterized by a constant-current source providing bias. This can be driven from a separate AGC detector system to give very tight level control. The gate-to-ground clamping diode (1N914 or similar) long used by radio amateurs as a means of avoiding gate-source conduction has been shown by Ulrich Rohde, KA2WEU, to degrade oscillator phase-noise performance, and its use is virtually unknown in professional circles.

Fig 10.13 shows some more VFOs to illustrate the use of different devices. The triode Hartley shown includes *permeability tuning*, which has no sliding contact like that to a capacitor’s rotor and can be made reasonably linear by artfully spacing the coil turns. The slow-motion drive can be done with a screw thread. The disadvantage is that special care is needed to avoid backlash and eccentric rotation of the core. If a nonrotating core is used, the slides have to be carefully designed to prevent motion in unwanted directions. The Collins Radio Company made extensive use of tube-based permeability tuners, and a semiconductor version can still

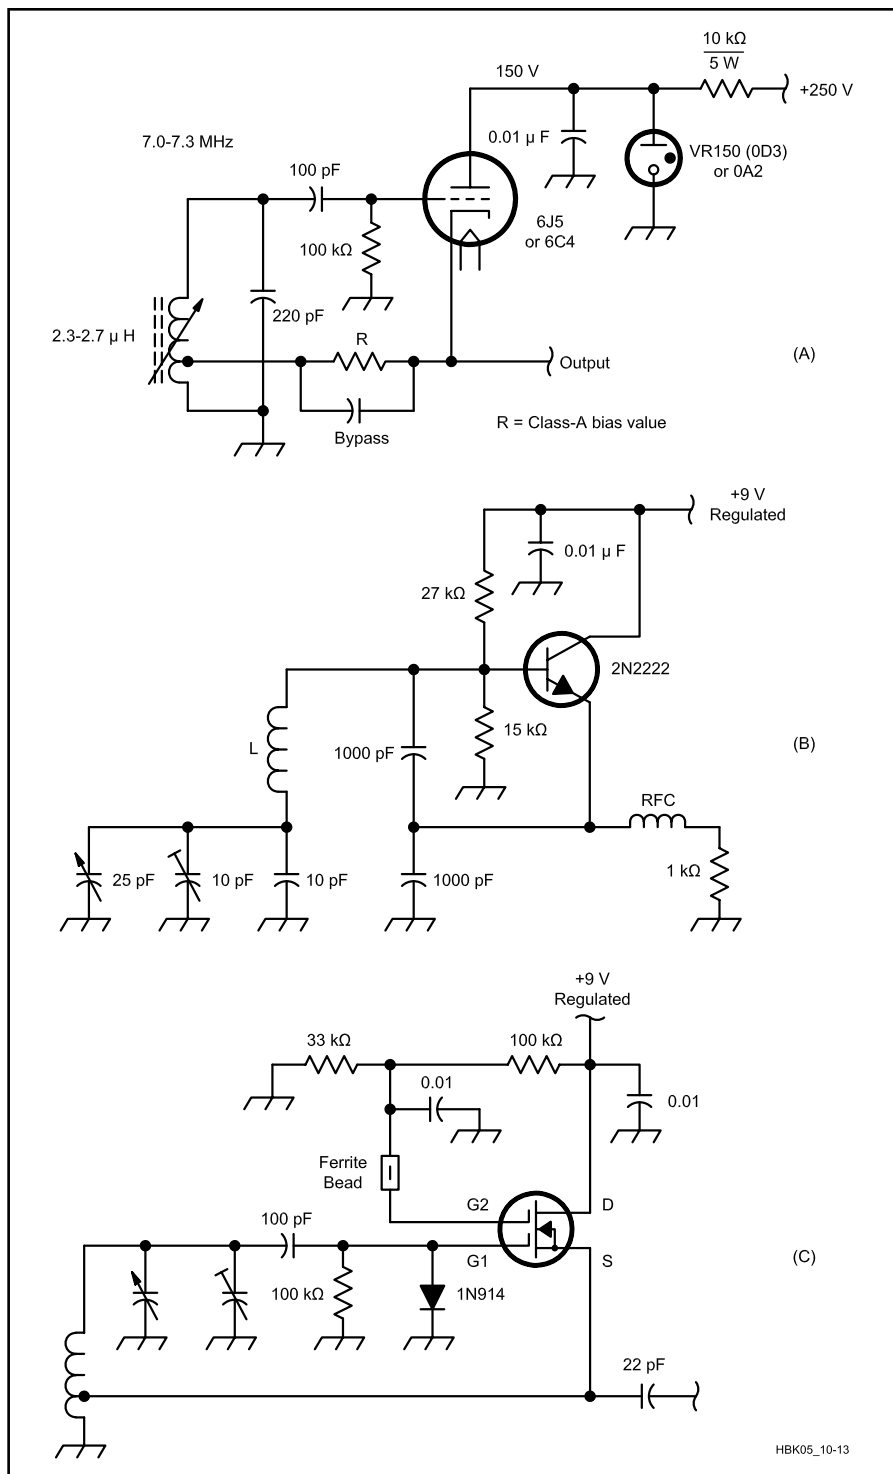

Fig 10.13—Three more oscillator examples: at A, a triode-tube Hartley; at B, a bipolar junction transistor in a series-tuned Colpitts; at C, a dual-gate MOSFET Hartley.

be found in a number of Ten-Tec radios.

Vacuum tubes cannot run as cool as competitive semiconductor circuits, so care is needed to keep the tank circuit away from the tube heat. In many amateur and commercial vacuum-tube oscillators, oscillation drives the tube into grid cur-

rent at the positive peaks, causing rectification and producing a negative grid bias. The oscillator thus runs in Class C, in which the conduction angle reduces as the signal amplitude increases until the amplitude stabilizes. As in the FET circuits of Fig 10.12, better stability and phase-

noise performance can be achieved in a vacuum-tube oscillator by moving it out of true Class C—that is, by including a bypassed cathode-bias resistor (the resistance appropriate for Class A operation is a good starting value). A small number of people still build vacuum-tube radios partly to be different, partly for fun, but the semiconductor long ago achieved dominance in VFOs.

The voltage regulator (VR) tube shown in Fig 10.13A has a potential drawback: It is a gas-discharge device with a high striking voltage at which it starts to conduct and a lower extinguishing voltage, at which it stops conducting. Between these extremes lies a region in which decreasing voltage translates to increasing current, which implies negative resistance. When the regulator strikes, it discharges any capacitance connected across it to the extinguishing voltage. The capacitance then charges through the source resistor until the tube strikes again, and the process repeats. This *relaxation oscillation* demonstrates how negative resistance can cause oscillation. The oscillator translates the resultant sawtooth modulation of its power supply into frequency and amplitude variation. Because of VR tubes' ability to support relaxation oscillation, a traditional rule of thumb is to keep the capacitance directly connected across a VR tube to 0.1 μF or less. A value much lower than this can provide sufficient bypassing in Fig 10.13A because the dropping resistor acts as a decoupler, increasing the bypass's effectiveness.

There is a related effect called *squegging*, which can be loosely defined as oscillation on more than one frequency at a time, but which may also manifest itself as RF oscillation interrupted at an AF rate, as in a superregenerative detector. One form of squegging occurs when an oscillator is fed from a power supply with a high source impedance. The power supply charges up the decoupling capacitor until oscillation starts. The oscillator draws current and pulls down the capacitor voltage, starving itself of power until oscillation stops. The oscillator stops drawing current, and the decoupling capacitor then recharges until oscillation restarts. The process, the low-frequency cycling of which is a form of relaxation oscillation, repeats indefinitely. The oscillator output can clearly be seen to be pulse modulated if an oscilloscope is used to view it at a suitable time-base setting. This fault is a well-known consequence of poor design in battery-powered radios. As dry cells become exhausted, their internal resistance rises quickly and circuits they power can begin to misbehave. In audio stages, such misbe-

havior may manifest itself in the *putt-putt* sound of the slow relaxation oscillation called *motorboating*.

Compared to the frequently used JFET, bipolar transistors, Fig 10.13B, are relatively uncommon in oscillators because their low input and output impedances are more difficult to couple into a high-Q tank without excessively loading it. Bipolar devices do tend to give better sample-to-sample amplitude uniformity for a given oscillator circuit, however, as JFETs of a given type tend to vary more in their characteristics.

The dual-gate MOSFET, Fig 10.13C, is very rarely seen in VFO circuits. It imposes the cost of the components needed to bias and suppress VHF parasitic oscillation at the second gate, and its inability to generate its own AGC through gate-source conduction forces the addition of a blocking capacitor, resistor and diode at the first gate for amplitude control.

VFO Components and Construction

Tuning Capacitors and Reduction Drives

As most commercially made radios now use frequency synthesizers, it has become increasingly difficult to find certain key components needed to construct a good VFO. The slow-motion drives, dials, gearboxes, associated with names like Millen, National, Eddystone and Jackson are no longer available. Similarly, the most suitable silver-plated variable capacitors with ball races at both ends, although still made, are not generally marketed and are expensive. Three approaches remain: Scavenge suitable parts from old equipment; use tuning diodes instead of variable capacitors—an approach that, if uncorrected through phase locking, generally degrades stability and phase-noise performance; or use two tuning capacitors, one with a capacitance range $1/5$ to $1/10$ that of the other, in a bandset/bandsread approach.

Assembling a variable capacitor to a chassis and its reduction drive to a front panel can result in *backlash*—an annoying tuning effect in which rotating the capacitor shaft deforms the chassis and/or panel rather than tuning the capacitor. One way of minimizing this is to use the reduction drive to support the capacitor, and use the capacitor to support the oscillator circuit board.

Fixed Capacitors

Traditionally, silver-mica fixed capacitors have been used extensively in oscillators, but their temperature coefficient is not

as low as can be achieved by other types, and some silver micas have been known to behave erratically. Polystyrene film has become a proven alternative. One warning is worth noting: Polystyrene capacitors exhibit a permanent change in value should they ever be exposed to temperatures much over 70°C; they do not return to their old value on cooling. Particularly suitable for oscillator construction are the low-temperature-coefficient ceramic capacitors, often described as *NPO* or *COG* types. These names are actually temperature-coefficient codes. Some ceramic capacitors are available with deliberate, controlled temperature coefficients so that they can be used to compensate for other causes of frequency drift with temperature. For example, the code N750 denotes a part with a temperature coefficient of -750 parts per million per degree Celsius. These parts are now somewhat difficult to obtain, so other methods are needed.

In a Colpitts circuit, the two large-value capacitors that form the voltage divider for the active device still need careful selection. It would be tempting to use any available capacitor of the right value, because the effect of these components on the tank frequency is reduced by the proportions of the capacitance values in the circuit. This reduction is not as great as the difference between the temperature stability of an NPO ceramic part and some of the low-cost, decoupling-quality X7R-dielectric ceramic capacitors. It's worth using low-temperature coefficient parts even in the seemingly less-critical parts of a VFO circuit—even as decouplers. Chasing the cause of temperature drift is more challenging than fun. Buy critical components like high-stability capacitors from trustworthy sources.

Inductors

Ceramic coil forms can give excellent results, as can self-supporting air-wound coils (Miniductor). If you use a magnetic core, make it powdered iron, never ferrite, and support it stably. Stable VFOs have been made using toroidal cores, but again, ferrite must be avoided. Micrometals mix number 6 has a low temperature coefficient and works well in conjunction with NPO ceramic capacitors. Coil forms in other materials have to be assessed on an individual basis.

A material's temperature stability will not be apparent until you try it in an oscillator, but you can apply a quick test to identify those nonmetallic materials that are lossy enough to spoil a coil's Q. Put a sample of the coil-form material into a microwave oven along with a glass of water and cook it about 10 s on low power.

Do not include any metal fittings or ferromagnetic cores. Good materials will be completely unaffected; poor ones will heat and may even melt, smoke, or burst into flame. (This operation is a fire hazard if you try more than a tiny sample of an unknown material. Observe your experiment continuously and do not leave it unattended.)

Wes Hayward, W7ZOI, suggests annealing toroidal VFO coils after winding. Roy Lewallen, W7EL reports achieving success with this method by boiling his coils in water and letting them cool in air.

Voltage Regulators

VFO circuits are often run from locally regulated power supplies, usually from resistor/Zener diode combinations. Zener diodes have some idiosyncrasies that could spoil the oscillator. They are noisy, so decoupling is needed down to audio frequencies to filter this out. Zener diodes are often run at much less than their specified optimum bias current. Although this saves power, it results in a lower output voltage than intended, and the diode's impedance is much greater, increasing its sensitivity to variations in input voltage, output current and temperature. Some common Zener types may be designed to run at as much as 20 mA; check the data sheet for your diode family to find the optimum current.

True Zener diodes are low-voltage devices; above a couple of volts, so-called Zener diodes are actually avalanche types. The temperature coefficient of these diodes depends on their breakdown voltage and crosses through zero for diodes rated at about 5 V. If you intend to use nothing fancier than a common-variety Zener, designing the oscillator to run from 5 V and using a 5.1-V Zener, will give you a free advantage in voltage-versus-temperature stability. There are some diodes available with especially low temperature coefficients, usually referred to as *reference* or *temperature-compensated diodes*. These usually consist of a series pair of diodes designed to cancel each other's temperature drift. Running at 7.5 mA, the 1N829A gives 6.2 V $\pm 5\%$ and a temperature coefficient of just ± 5 parts per million (ppm) maximum per degree Celsius. A change in bias current of 10% will shift the voltage less than 7.5 mV, but this increases rapidly for greater current variation. The 1N821A is a lower-grade version, at ± 100 ppm/ $^{\circ}\text{C}$. The LM399 is a complex IC that behaves like a superb Zener at 6.95 V, ± 0.3 ppm/ $^{\circ}\text{C}$. There are also precision, low-power, three-terminal regulators designed to be used as voltage references, some of which can provide

enough current to run a VFO. There are comprehensive tables of all these devices between pages 334 and 337 of Horowitz and Hill, *The Art of Electronics*, 2nd ed.

Oscillator Devices

The 2N3819 FET, a classic from the 1960s, has proven to work well in VFOs, but, like the MPF102 also long-popular with ham builders, it's manufactured to wide tolerances. Considering an oscillator's importance in receiver stability, you should not hesitate to spend a bit more on a better device. The 2N5484, 2N5485 and 2N5486 are worth considering; together, their transconductance ranges span that of the MPF102, but each is a better-controlled subset of that range. The 2N5245 is a more recent device with better-than-average noise performance that runs at low currents like the 2N3819. The 2N4416/A, also available as the plastic-cased PN4416, is a low-noise device, designed for VHF/UHF amplifier use, which has been featured in a number of good oscillators up to the VHF region. Its low internal capacitance contributes to low frequency drift. The J310 (plastic; the metal-cased U310 is similar) is another popular JFET in oscillators.

The 2N5179 (plastic, PN5179 or MPS5179) is a bipolar transistor capable of good performance in oscillators up to the top of the VHF region. Care is needed because its absolute-maximum collector-emitter voltage is only 12 V, and its collector current must not exceed 50 mA. Although these characteristics may seem to convey fragility, the 2N5179 is sufficient for circuits powered by stabilized 6-V power supplies.

VHF-UHF devices are not really necessary in LC VFOs because such circuits are rarely used above 10 MHz. Absolute frequency stability is progressively harder to achieve with increasing frequency, so free-running oscillators are rarely used to generate VHF-UHF signals for radio communication. Instead, VHF-UHF radios usually use voltage-tuned, phase-locked oscillators in some form of synthesizer. Bipolar devices like the BFR90 and MRF901, with f_T 's in the 5-GHz region and mounted in stripline packages, are needed at UHF.

Integrated circuits have not been mentioned until now because few specific RF-oscillator ICs exist. Some consumer ICs—the NE602, for example—include the active device(s) necessary for RF oscillators, but often this is no more than a single transistor fabricated on the chip. This works just as a single discrete device would, although using such on-chip devices may result in poor isolation from the

rest of the circuits on the chip. There is one specialized LC-oscillator IC: the Motorola MC1648. This device has been made since the early 1970s and is a surviving member of a long-obsolete family of emitter-coupled-logic (ECL) devices. Despite the MC1648's antiquity, it has no real competition and is still widely used in current military and commercial equipment. Market demand should force its continued production for some more years to come. Its circuitry is complex for an oscillator, with a multitransistor oscillator cell controlled by a detector and amplifier in an on-chip ALC system. The MC1648's first problem is that the ECL families use only about a 1-V swing between logic levels. Because the oscillator is made using the same ECL-optimized semiconductor manufacturing processes and circuit design techniques, this same limitation applies to the signal in the oscillator tuned circuit. It is possible to improve this situation by using a tapped or transformer-coupled tank circuit to give improved Q, but this risks the occurrence of the device's second problem.

Periodically, semiconductor manufacturers modernize their plants and scrap old assembly lines used to make old products. Any surviving devices then must undergo some redesign to allow their production by the new processes. One common result of this is that devices are shrunk, when possible, to fit more onto a wafer. All this increases the f_T of the transistors in the device, and such evolution has rendered today's MC1648s capable of operation at much higher frequencies than the specified 200-MHz limit. This allows higher-frequency use, but great care is needed in the layout of circuits using it to prevent spurious oscillation. A number of old designs using this part have needed reengineering because the newer parts generate spurious oscillations that the old ones didn't, using PC-board traces as parasitic tuned circuits.

The moral is that a UHF-capable device requires UHF-cognizant design and layout even if the device will be used at far lower frequencies. **Fig 10.14** shows the MC1648 in a simple circuit and with a tapped resonator. These more complex circuits have a greater risk of presenting a stray resonance within the device's operating range, risking oscillation at an unwanted frequency. This device is *not* a prime choice for an HF VFO because the physical size of the variable capacitor and the inevitable lead lengths, combined with the need to tap-couple to get sufficient Q for good noise performance, makes spurious oscillation difficult to avoid. The MC1648 is really intended for tuning-diode control in phase-locked loops operating at VHF. This

difficulty is inherent in wideband devices, especially oscillator circuits connected to their tank by a single “hot” terminal, where there is simply no isolation between the amplifier’s input and output paths. Any resonance in the associated circuitry can

control the frequency of oscillation.

The popular NE602 mixer IC has a built-in oscillator and can be found in many published circuits. This device has separate input and output pins to the tank and has proved to be quite tame. It’s still a rela-

tively new part and may not have been “improved” yet (so far, it has progressed from the NE602 to the NE602A, the A version affording somewhat higher dynamic range than the original NE602). It might be a good idea for anyone laying out a board using one to take a little extra care to keep PCB traces short in the oscillator section to build in some safety margin so that the board can be used reliably in the future. Experienced (read: “bitten”) professional designers know that their designs are going to be built for possibly more than 10 years and have learned to make allowances for the progressive improvement of semiconductor manufacture.

Three High-Performance HF VFOs The G3PDM Vackar VFO

The Vackar VFO shown in Fig 10.15 was developed over 20 years ago by Peter Martin, G3PDM, for the Mark II version of his high-dynamic-range receiver. This can be found in the Radio Society of Great Britain’s *Radio Communication Handbook*, with some further comments on the oscillator in RSGB’s *Amateur Radio Techniques*. This is a prime example of an oscillator that has been successfully optimized for maximum frequency stability. Not only does it work extremely well, but it still represents the highest stability that can be achieved. Its developer commented on a number of points, which also apply to the construction of different VFO circuits.

- Use a genuine Vackar circuit, with

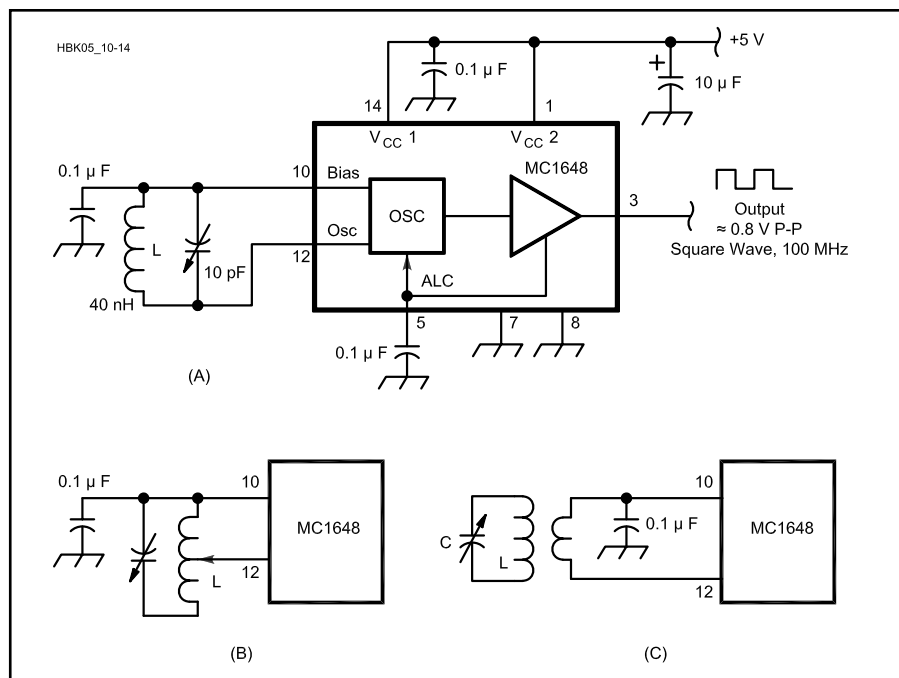

Fig 10.14—One of the few ICs ever designed solely for oscillator service, the ECL Motorola MC1648 (A) requires careful design to avoid VHF parasitics when operating at HF. Keeping its tank Q high is another challenge; B and C show means of coupling the IC’s low-impedance oscillator terminals to the tank by tapping up on the tank coil (B) or with a link (C).

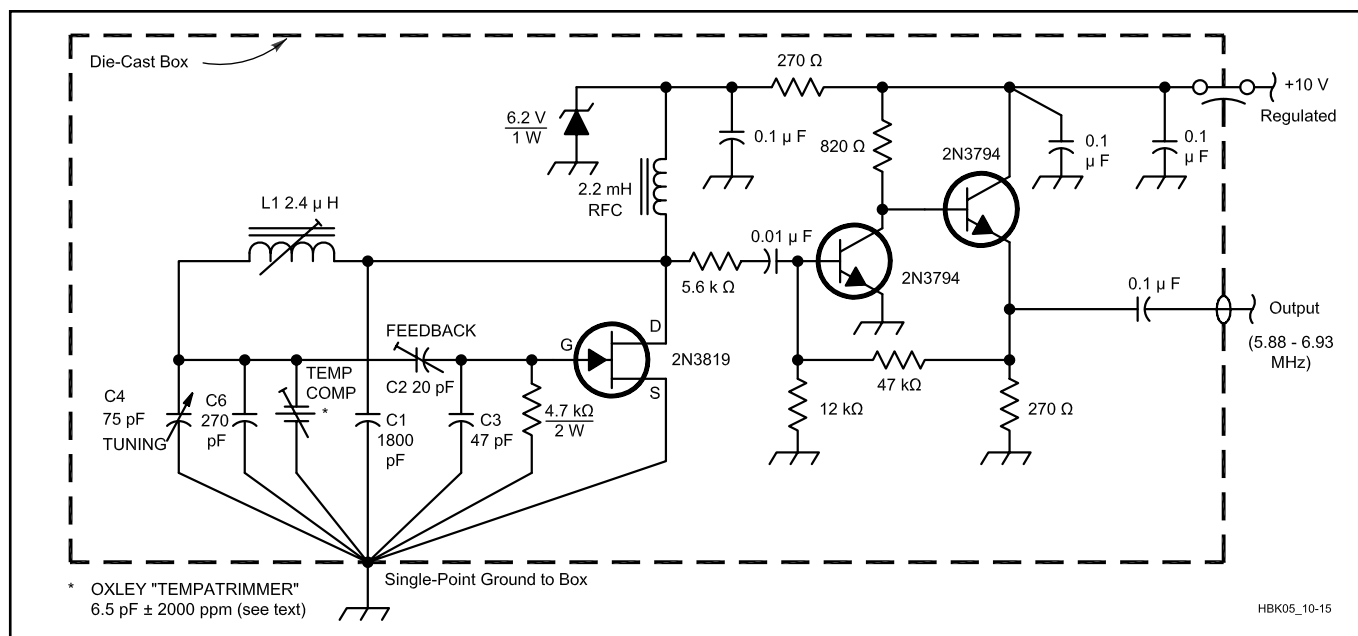

Fig 10.15—G3PDM’s Vackar VFO has proved popular and successful for two decades. The MPF102 can be used as a substitute for the 2N3819. Generally, VFOs can be adapted to work at other frequencies (within the limits of the active device). To do so, compute an adjustment factor: f_{old} / f_{new} . Multiply the value of each frequency determining or feedback L or C by the factor. As frequency increases, it may help to increase feedback even more than indicated by the factor.

$C1/(C4+C6)$ and $C3/C2 = 6$.

- Use a strong box, die-cast or milled from solid metal.
- Use a high-quality variable capacitor (double ball bearings, silver plated).
- Adjust feedback control C2, an air-dielectric trimmer, so the circuit just oscillates.
- Thoroughly clean all variable capacitors in an ultrasonic bath.
- Use an Oxley “Tempatrimmer,” a fixed capacitor whose temperature coefficient is variable over a wide range, for adjustable temperature compensation. (The “Thermatrimmer” is a lower cost, smaller range alternative.)
- C1, C3 and C6 are silver-mica types glued to a solid support to reduce sensitivity to mechanical shock.
- The gate resistor is a 4.7-k Ω , 2-W carbon-composition type to minimize self-heating.
- The buffer amplifier is essential.
- Circuits using an added gate-ground diode seem to suffer increased drift.
- Its power supply should be well-regulated. Make liberal use of decoupling capacitors to prevent unintentional feedback via supply rails.
- Single-point grounding for the tank and FET is important. This usually means using one mounting screw of the tuning capacitor.
- The inductor used a ceramic form with a powdered-iron core mounted on a spring-steel screw.
- Short leads and thick solid wire (#16 to #18 gauge) are essential for mechanical stability.

Operating in the 6-MHz region, this oscillator drifted 500 Hz during the first minute as it warmed up and then drifted at 2 Hz in 30 minutes. It must be stressed that such performance does not indicate a wonderful circuit so much as care in construction, skillful choice of components, artful mechanical layout and diligence in adjustment. The 2-W gate resistor may seem strange, but 20 years ago many components were not as good as they are today. A modern, low-inductance component of low temperature coefficient and more modest power rating should be fine.

The buffer amplifier is an important part of a good oscillator system as it serves to prevent the oscillator seeing any impedance changes in the circuit being driven. This could otherwise affect the frequency.

The Oxley Tempatrimmer used by G3PDM was a rare and expensive component, used commercially only in very high-quality equipment, and it may no longer be made. An alternative temperature compensator can be constructed from currently available components, as will be

described shortly. G3PDM also referred to his “standard mallet test,” where a thump with a wooden hammer produced an average shift of 6 Hz, as an illustration of the benefits of solid mechanical design.

The K7HFD Low-Noise Oscillator

The other high performance oscillator example, shown in Fig 10.16, was designed for low-noise performance by Linley Gumm, K7HFD, and appears on page 126 of ARRL’s *Solid State Design for the Radio Amateur*. Despite its publication in the homebrewer’s bible, this circuit seems to have been overlooked by many builders. It uses no unusual components and looks simple, yet it is a subtle and sophisticated circuit. It represents the antithesis of G3PDM’s VFO: In the pursuit of low noise sidebands, a number of design choices have been made that will degrade the stability of frequency over temperature.

The effects of oscillator noise have already been covered, and Fig 10.7 shows the effect of limiting on the signal from a noisy oscillator. Because AM noise sidebands can get translated into PM noise sidebands by imperfect limiting, there is an advantage to stripping off the AM as early as possible, in the oscillator itself. An ALC system in the oscillator will counteract and cancel only the AM components within its

bandwidth, but an oscillator based on a limiter will do this over a broad bandwidth. K7HFD’s oscillator uses a differential pair of bipolar transistors as a limiting amplifier. The dc bias voltage at the bases and the resistor in the common emitter path to ground establishes a controlled dc bias current. The ac voltage between the bases switches this current between the two collectors. This applies a rectangular pulse of current into link winding L2, which drives the tank. The output impedance of the collector is high in both the current on and current off states. Allied with the small number of turns of the link winding, this presents a very high impedance to the tank circuit, which minimizes the damping of the tank Q. The input impedance of the limiter is also quite high and is applied across only a one-turn tap of L1, which similarly minimizes the effect on the tank Q. The input transistor base is driven into conduction only on one peak of the tank waveform. The output transformer has the inverse of the current pulse applied to it, so the output is not a low distortion sine wave, although the output harmonics will not be as extensive as simple theory would suggest because the circuit’s high output impedance allows stray capacitances to attenuate high-frequency components. The low-frequency transistors used also act to reduce the harmonic power.

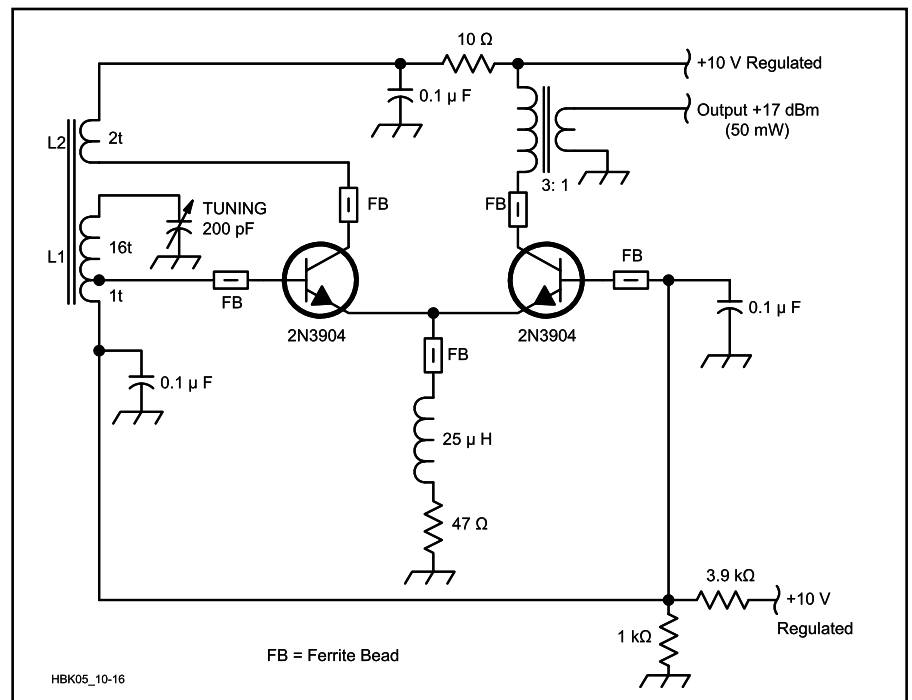

Fig 10.16—This low-noise oscillator design by K7HFD operates at an unusually high power level to achieve a high C/N (carrier-to-noise) ratio. Need other frequencies? See Fig 10.15 (caption) for a frequency-scaling technique.

With an output of +17 dBm, this is a power oscillator, running with a large dc input power, so appreciable heating results that can cause temperature-induced drift. The circuit's high-power operation is a deliberate ploy to create a high signal-to-noise ratio by having as high a signal power as possible. This also reduces the problem of the oscillator's broadband noise output. The limitation on the signal level in the tank is the transistors' base-emitter-junction breakdown voltage. The circuit runs with a few volts peak-to-peak across the one-turn tap, so the full tank is running at over 50 V P-P. The single easiest way to damage a bipolar transistor is to reverse bias the base-emitter junction until it avalanches. Most devices are only rated to withstand 5 V applied this way, the current needed to do damage is small, and very little power is needed. If the avalanche current is limited to less than that needed to perform immediate destruction of the transistor, it is likely that there will be some degradation of the device, a reduction in its bandwidth and gain along with an increase in its noise. These changes are irreversible and cumulative. Small, fast signal diodes have breakdown voltages of over 30 V and less capacitance than the transistor bases, so one possible experiment would be to try the effect of adding a diode in series with the base of each transistor and running the circuit at even higher levels.

The amplitude must be controlled by the drive current limit. The voltage on L2 must never allow the collector of the transistor driving it to go into saturation, if this happens, the transistor presents a very low impedance to L2 and badly loads the tank, wrecking the Q and the noise performance. The circuit can be checked to verify the margin from saturation by probing the hot end of L2 and the emitter with an oscilloscope. Another, less obvious, test is to vary the power-supply voltage and monitor the output power. While the circuit is under current control, there is very little change in output power, but if the supply is low enough to allow saturation, the output power will change significantly.

The use of the 2N3904 is interesting, as it is not normally associated with RF oscillators. It is a cheap, plain, general-purpose type more often used at dc or audio frequencies. There is evidence that suggests some transistors that have good noise performance at RF have worse noise performance at low frequencies, and that the low-frequency noise they create can modulate an oscillator, creating noise sidebands. Experiments with low-noise audio transistors may be worthwhile, but many such devices have very low f_T and high junction capacitances. In the description of this cir-

cuit in *Solid State Design for the Radio Amateur*, the results of a phase-noise test made using a spectrum analyzer with a crystal filter as a preselector are given. Ten kilohertz out from the carrier, in a 3-kHz measurement bandwidth, the noise was over 120 dB below the carrier level. This translates into better than $-120 - 10 \log(3000)$, which equals -154.8 dBc/Hz, SSB. At this offset, -140 dBc is usually considered to be excellent. This is state-of-the-art performance by today's standards—in a 1977 publication.

A JFET Hartley VFO

Fig 10.17 shows an 11.1-MHz version of a VFO and buffer closely patterned after that used in 7-MHz transceiver designs published by Roger Hayward, KA7EXM, and Wes Hayward, W7ZOI (The Ugly Weekender) and Roy Lewallen, W7EL (the Optimized QRP Transceiver). In it, a 2N5486 JFET Hartley oscillator drives the two-2N3904 buffer attributed to Lewallen. This version diverges from the originals in that its JFET uses source bias (the bypassed 910- Ω resistor) instead of a gate-clamping diode and is powered from a low-current 7-V regulator IC instead of a Zener diode and dropping resistor. The 5-dB pad sets the buffer's output to a level appropriate for "Level 7" (+7-dBm-LO) diode ring mixers.

The circuit shown was originally built with a gate-clamping diode, no source bias and a 3-dB output pad. Rebiasing the oscillator as shown increased its output by 2 dB without degrading its frequency stability (200 to 300-Hz drift at power up, stability within ± 20 Hz thereafter at a constant room temperature).

Temperature Compensation

The general principle for creating a high-stability VFO is to use components with minimal temperature coefficients in circuits that are as insensitive as possible to changes in components' secondary characteristics. Even after careful minimization of the causes of temperature sensitivity, further improvement can still be desirable. The traditional method was to split one of the capacitors in the tank so that it could be apportioned between low-temperature-coefficient parts and parts with deliberate temperature dependency. Only a limited number of different, controlled temperature coefficients are available, so the proportioning between low coefficient and controlled coefficient parts was varied to "dilute" the temperature sensitivity of a part more sensitive than needed. This was a tedious process, involving much trial and error, an undertaking made more complicated by the dif-

ficulty of arranging means of heating and cooling the unit being compensated. (Hayward described such a means in December 1993 *QST*.) As commercial and military equipment have been based on frequency synthesizers for some time, supplies of capacitors with controlled temperature sensitivity are drying up. An alternative approach is needed.

A temperature-compensated crystal oscillator (TCXO) is an improved-stability version of a crystal oscillator that is used widely in industry. Instead of using controlled-temperature coefficient capacitors, most TCXOs use a network of thermistors and normal resistors to control the bias of a tuning diode. See Fig 10.18. Manufacturers measure the temperature vs frequency characteristic of sample oscillators, and use a computer program to calculate the optimum normal resistor values for production. This can reliably achieve at least a tenfold improvement in stability. We are not interested in mass manufacture, but the idea of a thermistor tuning a varactor is worth stealing. The parts involved are likely to be available for a long time.

Browsing through component suppliers' catalogs shows ready availability of 4.5- to 5-k Ω -bead thermistors intended for temperature-compensation purposes, at less than a dollar each. Fig 10.19 shows a circuit based on this form of temperature compensation. Fig 10.20 illustrates a practical VCO using a tuning diode. Commonly available thermistors have negative temperature coefficients, so as temperature rises, the voltage at the counterclockwise (ccw) end of R8 increases, while that at the clockwise (cw) end drops. Somewhere near the center, there is no change. Increasing the voltage on the tuning diode decreases its capacitance, so settings toward R8's ccw end simulate a negative-temperature-coefficient capacitor; toward its clockwise end, a positive-temperature-coefficient part. Choose R1 to pass 8.5 mA from whatever supply voltage is available to the 6.2-V reference diode, D1. The 1N821A/1N829A-family diode used has a very low temperature coefficient and needs 7.5 mA bias for best performance; the bridge takes 1 mA. R7 and R8 should be good-quality multiturn trimmers. D2 and C1 are best determined by trial and error. Practical components aren't known well enough to rely on analytical models. Choose the least capacitance that provides enough compensation range. This reduces the noise added to the oscillator. (It is possible, though tedious, to solve for the differential varactor voltage with respect to R2 and R5, via differential calculus and circuit theory. The equations in Hayward's 1993 article can then be

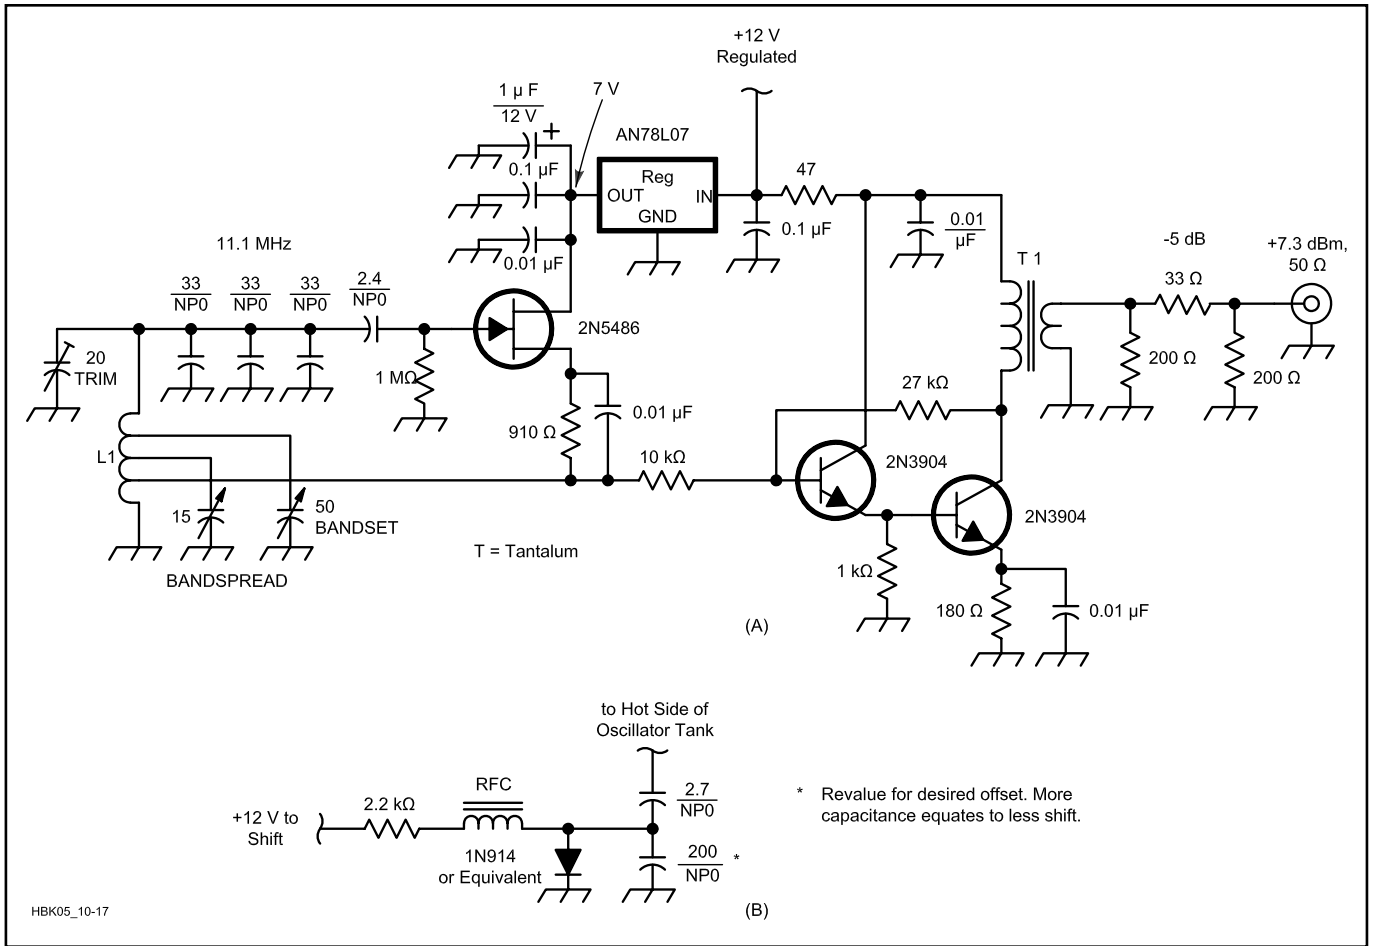

Fig 10.17—Incorporating ideas from KA2WEU, KA7EXM, W7ZOI and W7EL, the oscillator at A achieves excellent stability and output at 11.1 MHz without the use of a gate-clamping diode, as well as end-running the shrinking availability of reduction drives through the use of bandset and bandspread capacitors. L1 consists of 10 turns of B & W #3041 Miniductor (#22 tinned wire, 5/8 inch in diameter, 24 turns per inch). The source tap is 2½ turns above ground; the tuning-capacitor taps are positioned as necessary for bandset and bandspread ranges required. T1's primary consists of 15 turns of #28 enameled wire on an FT-37-72 ferrite core; its secondary, 3 turns over the primary. B shows a system for adding fixed TR offset that can be applied to any LC oscillator. The RF choke consists of 20 turns of #26 enameled wire on an FT-37-43 core. Need other frequencies? See Fig 10.15 (caption) for a frequency-scaling technique.

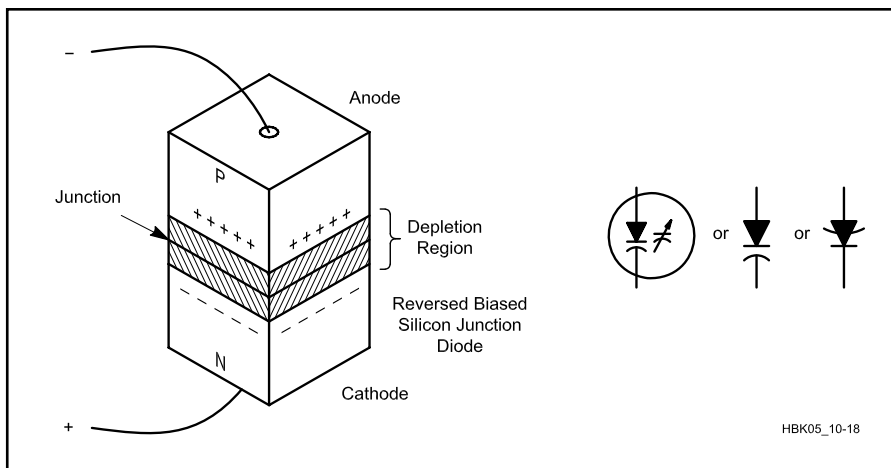

Fig 10.18—A modern voltage-controlled oscillator (VCO) uses the voltage-variable characteristic of a diode PN junction for tuning.

modified to accommodate the additional capacitors formed by D2 and C1.) Use a single ground point near D2 to reduce the influence of ground currents from other circuits. Use good-quality metal-film components for the circuit's fixed resistors.

The circuit requires two adjustments, one at each of two different temperatures, and achieving them requires a stable frequency counter that can be kept far enough from the radio so that the radio, not the counter, is subjected to the temperature extremes. (Using a receiver to listen to the oscillator under test can speed the adjustments.) After connecting the counter to the oscillator to be corrected, run the radio containing the oscillator and compensator in a room-temperature, draft-free environment until the oscillator's frequency

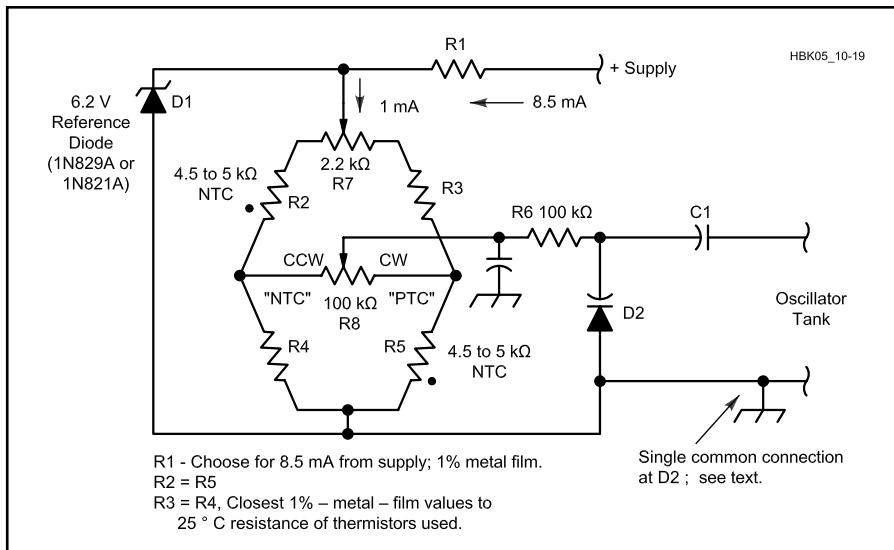

Fig 10.19—Oscillator temperature compensation has become more difficult because of the scarcity of negative-temperature-coefficient capacitors. This circuit, by GM4ZNX, uses a bridge containing two identical thermistors to steer a tuning diode for drift correction. The 6.2-V Zener diode used (a 1N821A or 1N829A) is a temperature-compensated part; just any 6.2-V Zener will not do.

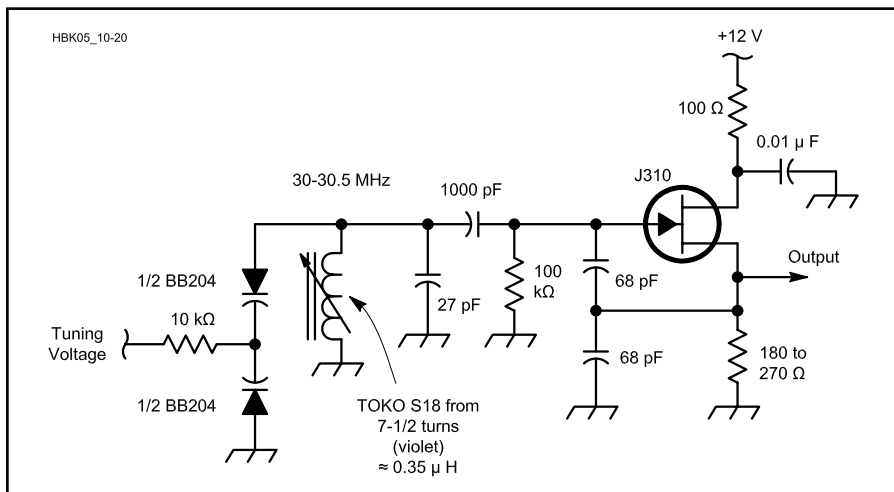

Fig 10.20—A practical VCO. The tuning diodes are halves of a BB204 dual, common-cathode tuning diode (capacitance per section at 3 V, 39 pF) or equivalent. The ECG617, NTE617 and MV104 are suitable dual-diode substitutes, or use pairs of 1N5451s (39 pF at 4 V) or MV2109s (33 pF at 4 V).

reaches its stable operating temperature rise over ambient. Lock its tuning, if possible. Adjust R7 to balance the bridge. This causes a drop of 0 V across R8, a condition you can reach by winding R8 back and forth across its range while slowly adjusting R7. When the bridge is balanced and 0 V appears across R8, adjusting R8 causes no frequency shift. When you've found this R7 setting, leave it there, set R8 is to the exact center of its range and record the oscillator frequency.

Run the radio in a hot environment and allow its frequency to stabilize. Adjust R8

to restore the frequency to the recorded value. The sensitivity of the oscillator to temperature should now be significantly reduced between the temperatures at which you performed the adjustments. You will also have somewhat improved the oscillator's stability outside this range.

For best results with any temperature-compensation scheme, it's important to group all the oscillator and compensator components in the same box, avoiding differences in airflow over components. A good oscillator should not dissipate much power, so it's feasible, even advisable, to

mount all of the oscillator components in an unventilated box. In the real world, temperatures change, and if the components being compensated and the components doing the compensating have different thermal time constants, a change in temperature can cause a temporary change in frequency until the slower components have caught up. One cure for this is to build the oscillator in a thick-walled metal box that's slow to heat or cool, and so dominates and reduces the possible rate of change of temperature of the circuits inside. This is sometimes called a *cold oven*.

Shielding and Isolation

Oscillators contain inductors running at moderate power levels and so can radiate strong enough signals to cause interference with other parts of a radio, or with other radios. Oscillators are also sensitive to radiated signals. Effective shielding is therefore important. A VFO used to drive a power amplifier and antenna (to form a simple CW transmitter) can prove surprisingly difficult to shield well enough. Any leakage of the power amplifier's high-level signal back into the oscillator can affect its frequency, resulting in a poor transmitted note. If the radio gear is in the station antenna's near field, sufficient shielding may be even more difficult. The following rules of thumb continue to serve ham builders well:

- Use a complete metal box, with as few holes as possible drilled in it, with good contact around surface(s) where its lid(s) fit(s) on.
- Use feedthrough capacitors on power and control lines that pass in and out of the VFO enclosure, and on the transmitter or transceiver enclosure as well.
- Use *buffer amplifier* circuitry that amplifies the signal by the desired amount and provide sufficient attenuation of signal energy flowing in the reverse direction. This is known as *reverse isolation* and is a frequently overlooked loophole in shielding. Figs 10.15 and 10.17 include buffer circuitry of proven performance. As another (and higher-cost) option, consider using a high-speed buffer-amplifier IC (such as the LM6321N by National Semiconductor, a part that combines the high input impedance of an op amp with the ability to drive 50-Ω loads directly up into the VHF range).
- Use a mixing-based frequency-generation scheme instead of one that operates straight through or by means of multiplication. Such a system's oscillator stages can operate on frequencies with no direct frequency relationship to its output frequency.

- Use the time-tested technique of running your VFO at a *subharmonic* of the output signal desired—say, 3.5 MHz in a 7-MHz transmitter—and *multiply* its output frequency in a suitably nonlinear stage for further amplification at the desired frequency.

Quartz Crystals in Oscillators

Because crystals afford Q values and frequency stabilities that are orders of magnitude better than those achievable with LC circuits, fixed-frequency oscillators usually use quartz-crystal resonators. Master references for frequency counters and synthesizers are always based on crystal oscillators.

So glowing is the executive summary of the crystal's reputation for stability that newcomers to radio experimentation naturally believe that the presence of a crystal in an oscillator will force oscillation at the frequency stamped on the can. This impression is usually revised after the first few experiences to the contrary! There is no sure-fire crystal oscillator circuit (although some are better than others); reading and experience soon provide a learner with plenty of anecdotes to the effect that:

- Some circuits have a reputation of being temperamental, even to the point of not always starting.
- Crystals sometimes mysteriously oscillate on unexpected frequencies.

Even crystal manufacturers have these problems, so don't be discouraged from building crystal oscillators. The occasional uncooperative oscillator is a nuisance, not a disaster, and it just needs a little individual attention. Knowing how a crystal behaves is the key to a cure.

Quartz and the Piezoelectric Effect

Quartz is a crystalline material with a regular atomic structure that can be distorted by the simple application of force. Remove the force, and the distorted structure springs back to its original form with very little energy loss. This property allows *acoustic waves*—sound—to propagate rapidly through quartz with very little attenuation, because the velocity of an acoustic wave depends on the elasticity and density (mass/volume) of the medium through which the wave travels.

If you heat a material, it expands. Heating may cause other characteristics of a material to change—such as elasticity, which affects the speed of sound in the material. In quartz, however, expansion and change in the speed of sound are very small and tend to cancel, which means that the transit time for sound to pass through a piece of quartz is very stable.

The third property of this wonder material is that it is *piezoelectric*. Apply an electric field to a piece of quartz and the crystal lattice distorts just as if a force had been applied. The electric field applies a force to electrical charges locked in the lattice structure. These charges are captive and cannot move around in the lattice as they can in a semiconductor, for quartz is an insulator. A capacitor's dielectric stores energy by creating physical distortion on an atomic or molecular scale. In a piezoelectric crystal's lattice, the distortion affects the entire structure. In some piezoelectric materials, this effect is sufficiently pronounced that special shapes can be made that bend *visibly* when a field is applied.

Consider a rod made of quartz. Any sound wave propagating along it eventually hits an end, where there is a large and abrupt change in acoustic impedance. Just as when an RF wave hits the end of an unterminated transmission line, a strong reflection occurs. The rod's other end similarly reflects the wave. At some frequency, the phase shift of a round trip will be such that waves from successive round trips exactly coincide in phase and reinforce each other, dramatically increasing the wave's amplitude. This is *resonance*.

The passage of waves in opposite directions forms a standing wave with antinodes at the rod ends. Here we encounter a seeming ambiguity: not just one, but a *family* of different frequencies, causes standing waves—a family fitting the pattern of $1/2, 2/3, 5/2, 7/2$ and so on, wavelengths into the length of the rod. And this *is* the case: A quartz rod *can* resonate at any and all of these frequencies.

The lowest of these frequencies, where the crystal is $1/2$ wavelength long, is called the *fundamental mode*. The others are named the third, fifth, seventh and so on, *overtones*. There is a small phase-shift error during reflection at the ends, which causes the frequencies of the overtone modes to differ slightly from odd integer multiples of the fundamental. Thus, a crystal's third overtone is very close to, but not exactly, three times, its fundamental frequency. Many people are confused by overtones and harmonics. Harmonics are additional signals at *exact* integer multiples of the fundamental frequency. Overtones are not signals at all; they are additional resonances that can be exploited if a circuit is configured to excite them.

The crystals we use most often resonate in the 1- to 30-MHz region and are of the *AT cut*, *thickness shear* type, although these last two characteristics are rarely mentioned. A 15-MHz-fundamental crystal of this type is about 0.15 mm thick.

Because of the widespread use of reprocessed war-surplus, pressure-mounted *FT-243* crystals, you may think of crystals as small rectangles on the order of a half inch in size. The crystals we commonly use today are discs, etched and/or doped to their final dimensions, with metal electrodes deposited directly on the quartz. A crystal's diameter does not directly affect its frequency; diameters of 8 to 15 mm are typical.

AT cut is one of a number of possible standard designations for the orientation at which a crystal disc is sawed from the original quartz crystal. The crystal lattice atomic structure is asymmetric, and the orientation of this with respect to the faces of the disc influences the crystal's performance. *Thickness shear* is one of a number of possible orientations of the crystal's mechanical vibration with respect to the disc. In this case, the crystal vibrates perpendicularly to its thickness. This is not easy to visualize, and diagrams don't help much, but **Fig 10.21** is an attempt at illustrating this. Place a moist bathroom sponge between the palms of your hands, move one hand up and down, and you'll see thickness shear in action.

There is a limit to how thin a disc can be made, given requirements of accuracy and price. Traditionally, fundamental-mode crystals have been made up to 20 MHz, although 30 MHz is now common at a

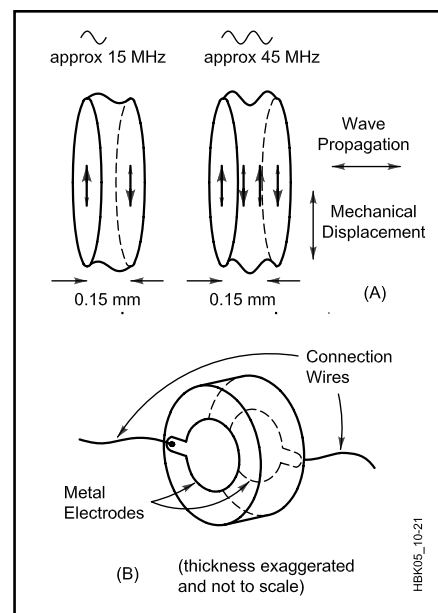

Fig 10.21—Thickness-shear vibration at a crystal's fundamental and third overtone (A); B shows how the modern crystals commonly used by radio amateurs consist of etched quartz discs with electrodes deposited directly on the crystal surface.

moderately raised price. Using techniques pioneered in the semiconductor industry, crystals have been made with a central region etched down to a thin membrane, surrounded by a thick ring for robustness. This approach can push fundamental resonances to over 100 MHz, but these are more lab curiosities than parts for everyday use. The easy solution for higher frequencies is to use a nice, manufacturably thick crystal on an overtone mode. All crystals have all modes, so if you order a 28.060-MHz, third-overtone unit for a little QRP transmitter, you'll get a crystal with a fundamental resonance somewhere near 9.353333 MHz, but its manufacturer will have adjusted the thickness to plant the third overtone exactly on the ordered frequency. An accomplished manufacturer can do tricks with the flatness of the disc faces to make the wanted overtone mode a little more active and the other modes a little less active. (As some builders discover, however, this does not *guarantee* that the wanted mode is the most active!)

Quartz's piezoelectric property provides a simple way of driving the crystal electrically. Early crystals were placed between a pair of electrodes in a case. This gave amateurs the opportunity to buy surplus crystals, open them and grind them a little to reduce their thickness, thus moving them to higher frequencies. The frequency could be reduced very slightly by loading the face with extra mass, such as by blackening it with a soft pencil. Modern crystals have metal electrodes deposited directly onto their surfaces (Fig 10.21B), and such tricks no longer work.

The piezoelectric effect works both ways. Deformation of the crystal produces voltage across its electrodes, so the mechanical energy in the resonating crystal can also be extracted electrically by the same electrodes. Seen electrically, at the electrodes, the mechanical resonances look like electrical resonances. Their Q is very high. A Q of 10,000 would characterize a *poor* crystal nowadays; 100,000 is often reached by high-quality parts. For comparison, a Q of over 200 for an LC tank is considered good.

Accuracy

A crystal's frequency accuracy is as outstanding as its Q. Several factors determine a crystal's frequency accuracy. First, the manufacturer makes parts with certain tolerances: ± 200 ppm for a low-quality crystal for use as in a microprocessor clock oscillator, ± 10 ppm for a good-quality part for professional radio use. Anything much better than this starts to get expensive! A crystal's resonant frequency is influenced

by the impedance presented to its terminals, and manufacturers assume that once a crystal is brought within several parts per million of the nominal frequency, its user will perform fine adjustments electrically.

Second, a crystal ages after manufacture. Aging could give increasing or decreasing frequency; whichever, a given crystal usually keeps aging in the same direction. Aging is rapid at first and then slows down. Aging is influenced by the care in polishing the surface of the crystal (time and money) and by its holder style. The cheapest holder is a soldered-together, two-part metal can with glass bead insulation for the connection pins. Soldering debris lands on the crystal and affects its frequency. Alternatively, a two-part metal can be made with flanges that are pressed together until they fuse, a process called *cold-welding*. This is much cleaner and improves aging rates roughly fivefold compared to soldered cans. An all-glass case can be made in two parts and fused together by heating in a vacuum. The vacuum raises the Q, and the cleanliness results in aging that's roughly ten times slower than that achievable with a soldered can. The best crystal holders borrow from vacuum-tube assembly processes and have a *getter*, a highly reactive chemical substance that traps remaining gas molecules, but such crystals are used only for special purposes.

Third, temperature influences a crystal. A reasonable, professional quality part might be specified to shift not more than ± 10 ppm over 0 to 70°C. An AT-cut crystal has an S-shaped frequency-versus-temperature characteristic, which can be varied by slightly changing the crystal cut's orientation. **Fig 10.22** shows the general shape and the effect of changing the cut angle by only a few seconds of arc. Notice how all the curves converge at 25°C. This is because this temperature is normally chosen as the reference for specifying a crystal. The temperature stability specification sets how accurate the manufacturer

Fig 10.22—Slight changes in a crystal cut's orientation shift its frequency-versus-temperature curve.

must make the cut. Better stability may be needed for a crystal used as a receiver frequency standard, frequency counter clock and so on. A crystal's temperature characteristic shows a little hysteresis. In other words, there's a bit of offset to the curve depending on whether temperature is increasing or decreasing. This is usually of no consequence except in the highest-precision circuits.

It is the temperature of the quartz that is important, and as the usual holders for crystals all give effective thermal insulation, only a couple of milliwatts dissipation by the crystal itself can be tolerated before self-heating becomes troublesome. Because such heating occurs in the quartz itself and does not come from the surrounding environment, it defeats the effects of temperature compensators and ovens.

The techniques shown earlier for VFO for temperature compensation can also be applied to crystal oscillators. An after-compensation drift of 1 ppm is routine and 0.5 ppm is good. The result is a *temperature-compensated crystal oscillator (TCXO)*. Recently, oscillators have appeared with built-in digital thermometers, microprocessors and ROM look-up tables customized on a unit-by-unit basis to control a tuning diode via a digital-to-analog converter (DAC) for temperature compensation. These *digitally temperature-compensated oscillators (DTCXOs)* can reach 0.1 ppm over the temperature range. With automated production and adjustment, they promise to become the cheapest way to achieve this level of stability.

Oscillators have long been placed in temperature-controlled *ovens*, which are typically held at 80°C. Stability of several parts per billion can be achieved over temperature, but this is a limited benefit as aging can easily dominate the accuracy. These are usually called *oven-controlled crystal oscillators (OCXOs)*.

Fourth, the crystal is influenced by the impedance presented to it by the circuit in which it is used. This means that care is needed to make the rest of an oscillator circuit stable, in terms of impedance and phase shift.

Gravity can slightly affect crystal resonance. Turning an oscillator upside down usually produces a small frequency shift, usually much less than 1 ppm; turning the oscillator back over reverses this. This effect is quantified for the highest-quality reference oscillators.

The Equivalent Circuit of a Crystal

Because a crystal is a passive, two-terminal device, its electrical appearance is that of an impedance that varies with

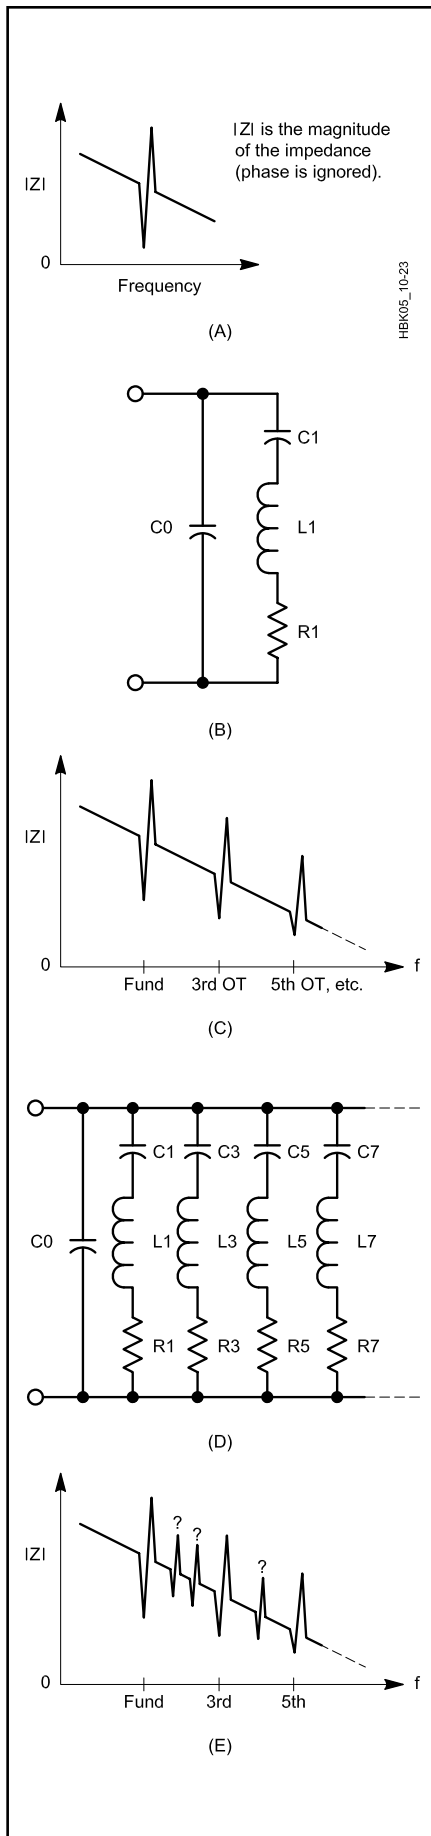

Fig 10.23—Exploring a crystal's impedance (A) and equivalent circuit (B) through simplified diagrams. C and D extend the investigation to include overtones; E, to spurious responses not easily predictable by theory or controllable through manufacture. A crystal may oscillate on any of its resonances under the right conditions.

frequency. Fig 10.23A shows a very simplified sketch of the magnitude (phase is ignored) of the impedance of a quartz crystal. The general trend of dropping impedance with increasing frequency implies capacitance across the crystal. The sharp fall to a low value resembles a series-tuned tank, and the sharp peak resembles a parallel-tuned tank. These are referred to as series and parallel resonances. Fig 10.23B shows a simple circuit that will produce this impedance characteristic. The impedance looks purely resistive at the exact centers of both resonances, and the region between them has impedance increasing with frequency, which looks inductive.

C_1 (sometimes called *motional capacitance*, C_m , to distinguish it from the lumped capacitance it approximates) and L_1 (*motional inductance*, L_m) create the series resonance, and as C_0 and R_1 are both fairly small, the impedance at the bottom of the dip is very close to R_1 . At parallel resonance, L_1 is resonating with C_1 and C_0 in series, hence the higher frequency. The impedance of the parallel tank is immense, the terminals are connected to a capacitive tap, which causes them to see only a small fraction of this, which is still a very large impedance. The overtones should not be neglected, so Figs 10.23C and 10.23D include them. Each overtone has series and parallel resonances and so appears as a series tank in the equivalent circuit. C_0 again provides the shifted parallel resonance.

This is still simplified, because real-life crystals have a number of spurious, unwanted modes that add yet more resonances, as shown in Fig 10.23E. These are not well controlled and may vary a lot even between crystals made to the same speci-

fication. Crystal manufacturers work hard to suppress these spurs and have evolved a number of recipes for shaping crystals to minimize them. Just where they switch from one design to another varies from manufacturer to manufacturer.

Always remember that the equivalent circuit is just a representation of crystal behavior and does not represent circuit components actually present. Its only use is as an aid in designing and analyzing circuits using crystals. Table 10.2 lists typical equivalent-circuit values for a variety of crystals. It is impossible to build a circuit with 0.026 to 0.0006-pF capacitors; such values would simply be swamped by strays. Similarly, the inductor must have a Q orders of magnitude better than is practically achievable, and impossibly low stray C in its winding.

The values given in Table 10.2 are nothing more than rough guides. A crystal's frequency is tightly specified, but this still allows inductance to be traded for capacitance. A good manufacturer could hold these characteristics within a $\pm 25\%$ band or could vary them over a 5:1 range by special design. Similarly marked parts from different sources vary widely in motional inductance and capacitance.

Quartz is not the only material that behaves in this way, but it is the best. Resonators can be made out of lithium tantalate and a group of similar materials that have lower Q, allowing them to be pulled over a larger frequency range in VCXOs. Much more common, however, are ceramic resonators based on the technology of the well-known ceramic IF filters. These have much lower Q than quartz and much poorer frequency precision. They serve mainly as clock resonators for cheap microprocessor systems in which every last cent must be saved. A ceramic resonator could be used as the basis of a wide range, cheap VXO, but its frequency stability would not be as good as a good LC VFO.

Crystal Oscillator Circuits

Crystal oscillator circuits are usually categorized as series- or parallel-mode types, depending on whether the crystal's low- or high-impedance resonance comes

Table 10.2
Typical Equivalent Circuit Values for a Variety of Crystals

Crystal Type	Series L	Series C (pF)	Series R (Ω)	Shunt C (pF)
1-MHz fundamental	3.5 H	0.007	340	3.0
10-MHz fundamental	9.8 mH	0.026	7	6.3
30-MHz third overtone	14.9 mH	0.0018	27	6.2
100-MHz fifth overtone	4.28 mH	0.0006	45	7.0

into play at the operating frequency. The series mode is now the most common; parallel-mode operation was more often used with vacuum tubes. Fig 10.24 shows a basic series-mode oscillator. Some people would say that it is an overtone circuit, used to run a crystal on one of its overtones, but this is not necessarily true. The tank (L-C1-C2) tunes the collector of the common-base amplifier. C1 is larger than C2, so the tank is tapped in a way that transforms to a lower impedance, decreasing signal voltage, but increasing current. The current is fed back into the emitter via the crystal. The common-base stage provides a current gain of less than unity, so the transformer in the form of the tapped tank is essential to give loop gain. There are two tuned circuits, the obvious collector tank and the series-mode one "in" the crystal. The tank kills the amplifier's gain away from its tuned frequency, and the crystal will only pass current at the series resonant frequencies of its many modes. The tank resonance is much broader than any of the crystal's modes, so it can be thought of as the crystal setting the frequency, but the tank selecting which of the crystal's modes is active. The tank could be tuned to the crystal's fundamental, or one of its overtones.

Fundamental oscillators can be built without a tank quite successfully, but there is always the occasional one that starts up on an overtone or spurious mode. Some simple oscillators have been known to change modes while running (an effect triggered by changes in temperature or loading) or to not always start in the same

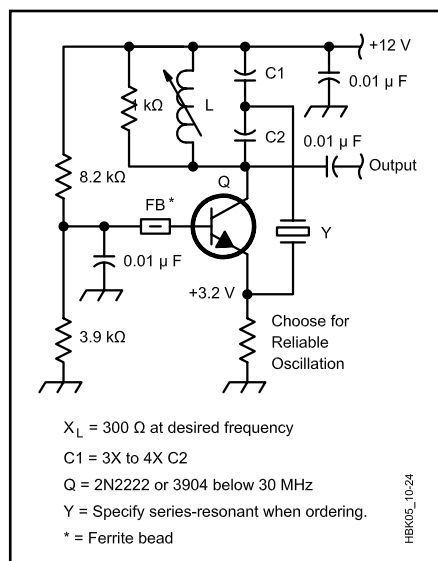

Fig 10.24—A basic series-mode crystal oscillator. A 2N5179 can be used in this circuit if a lower supply voltage is used; see text.

mode! A series-mode oscillator should present a low impedance to the crystal at the operating frequency. In Fig 10.24, the tapped collector tank presents a transformed fraction of the 1-k- Ω collector load resistor to one end of the crystal, and the emitter presents a low impedance to the other. To build a practical oscillator from this circuit, choose an inductor with a reactance of about 300Ω at the wanted frequency and calculate C1 in series with C2 to resonate with it. Choose C1 to be 3 to 4 times larger than C2. The amplifier's quiescent ("idling") current sets the gain and hence the operating level. This is not easily calculable, but can be found by experiment. Too little quiescent current and the oscillator will not start reliably; too much and the transistor can drive itself into saturation. If an oscilloscope is available, it can be used to check the collector waveform; otherwise, some form of RF voltmeter can be used to allow the collector voltage to be set to 2 to 3 V RMS. $3.3 \text{ k}\Omega$ would be a suitable starting point for the emitter bias resistor. The transistor type is not critical; 2N2222A or 2N3904 would be fine up to 30 MHz; a 2N5179 would

allow operation as an overtone oscillator to over 100 MHz (because of the low collector voltage rating of the 2N5179, a supply voltage lower than 12 V is required). The ferrite bead on the base gives some protection against parasitic oscillation at UHF.

If the crystal is shorted, this circuit should still oscillate. This gives an easy way of adjusting the tank; it is even better to temporarily replace the crystal with a small-value (tens of ohms) resistor to simulate its *equivalent series resistance* (ESR), and adjust L until the circuit oscillates close to the wanted frequency. Then restore the crystal and set the quiescent current. If a lot of these oscillators were built, it would sometimes be necessary to adjust the current individually due to the different equivalent series resistance of individual crystals. One variant of this circuit has the emitter connected directly to the C1/C2 junction, while the crystal is a decoupler for the transistor base (the existing capacitor and ferrite bead not being used). This works, but with a greater risk of parasitic oscillation.

We commonly want to trim a crystal

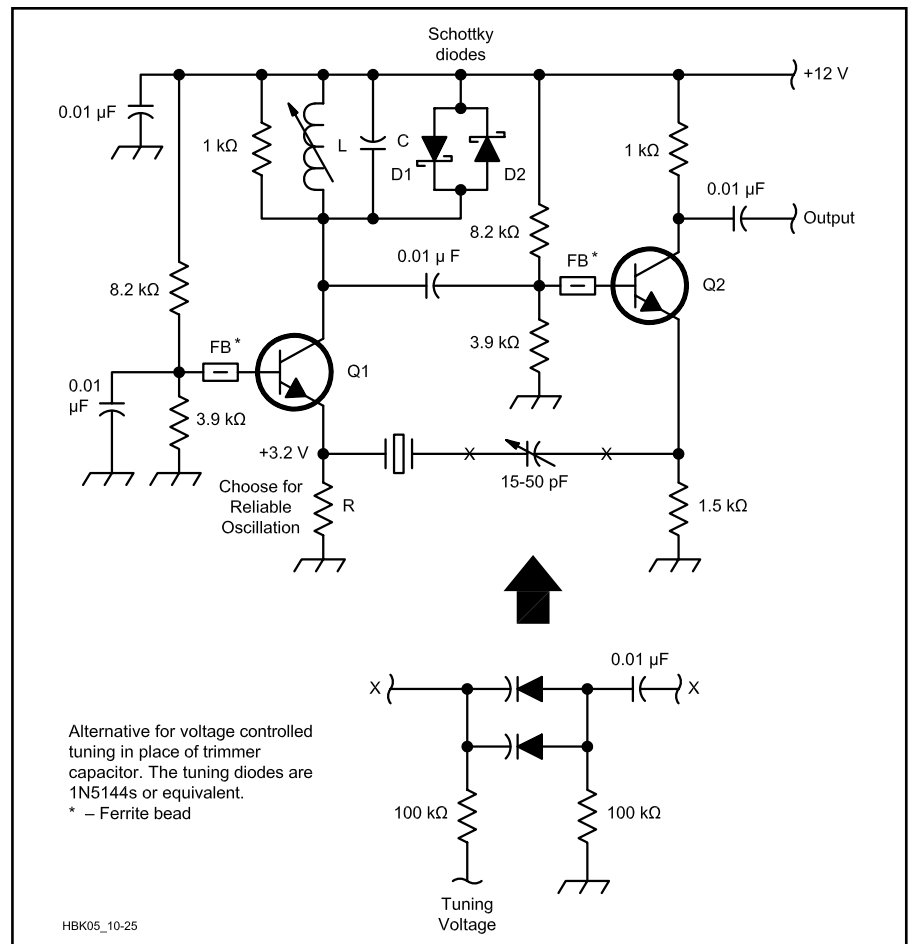

Fig 10.25—A Butler crystal oscillator.

oscillator's frequency. While off-tuning the tank a little will pull the frequency slightly, too much detuning spoils the mode control and can stop oscillation (or worse, make the circuit unreliable). The answer to this is to add a trimmer capacitor, which will act as part of the equivalent series tuned circuit, in series with the crystal. This will shift the frequency in one way only, so the crystal frequency must be respecified to allow the frequency to be varying around the required value. It is common to specify

a crystal's frequency with a standard load (30 pF is commonly specified), so that the manufacturer grinds the crystal such that the series resonance of the specified mode is accurate when measured with a capacitor of this value in series. A 15- to 50-pF trimmer can be used in series with the crystal to give fine frequency adjustment. Too little capacitance can stop oscillation or prevent reliable starting. The Q of crystals is so high that marginal oscillators can take several seconds to start!

This circuit can be improved by reducing the crystal's driving impedance with an emitter follower as in Fig 10.25. This is the *Butler* oscillator. Again the tank controls the mode to either force the wanted overtone or protect the fundamental mode. The tank need not be tapped because Q2 provides current gain, although the circuit is sometimes seen with C split, driving Q2 from a tap. The position between the emitters offers a good, low-impedance environment to keep the crystal's in-circuit Q

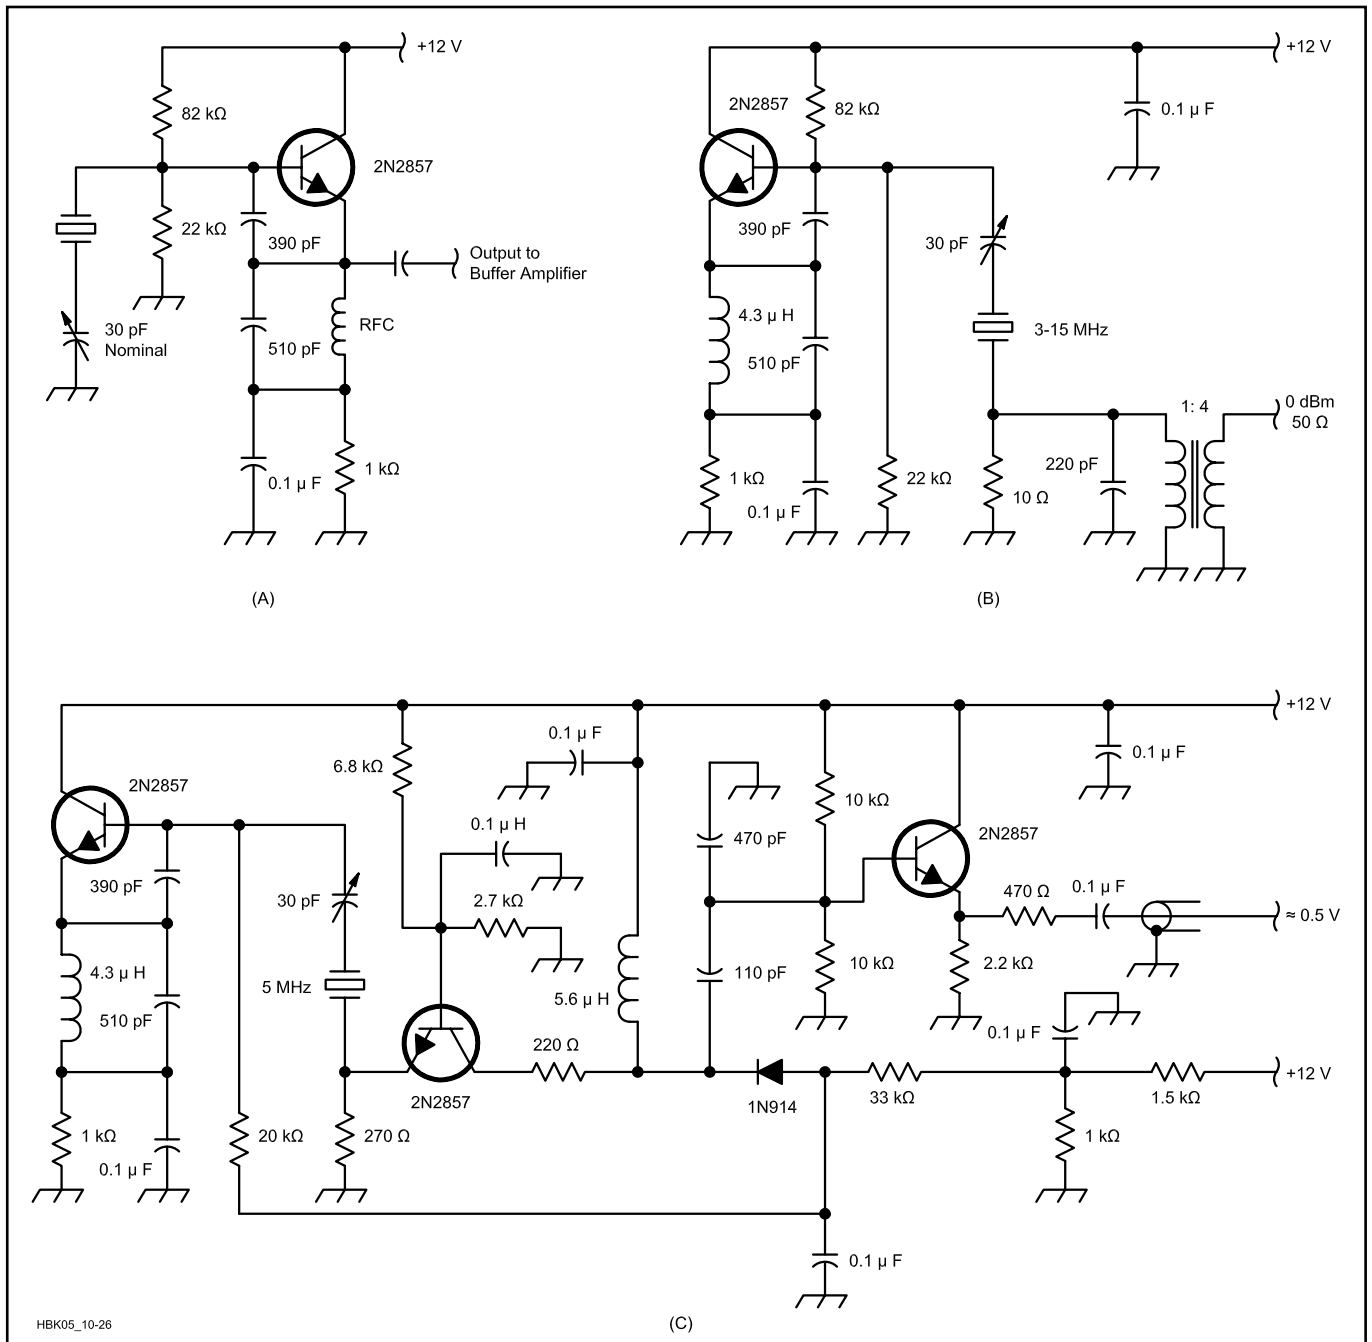

Fig 10.26—The crystal in the series-tuned Colpitts oscillator at A operates in its series-resonant mode. B shows KA2WEU's low-noise version, which uses the crystal as a filter and features high harmonic suppression. The circuit at C builds on the B version by adding a common-base output amplifier and ALC loop.

high. R, in the emitter of Q1, is again selected to give reliable oscillation. The circuit has been shown with a capacitive load for the crystal, to suit a unit specified for a 30-pF load. An alternative circuit to give electrical fine tuning is also shown. The diodes across the tank act as limiters to stabilize the operating amplitude and limit the power dissipated in the crystal by clipping the drive voltage to Q2. The tank should be adjusted to peak at the operating frequency, not used to trim the frequency. The capacitance in series with the crystal is the proper frequency trimmer.

The Butler circuit works well, and has been used in critical applications to 140 MHz (seventh-overtone crystal, 2N5179 transistor). Although the component count is high, the extra parts are cheap ones. Increasing the capacitance in series with the crystal reduces the oscillation frequency but has a progressively diminishing effect. Decreasing the capacitance pulls the frequency higher, to a point at which oscillation stops; before this point is reached, start-up will become unreliable. The possible amount of adjustment, called *pulling range*, depends on the crystal; it can range from less than ten to several hundred parts per million. Overtone crystals have much less pulling range than fundamental crystals on the same frequency; the reduction in pulling is roughly proportional to the square of the overtone number.

Low-Noise Crystal Oscillators

Fig 10.26A shows a crystal operating in its series mode in a series-tuned Colpitts circuit. Because it does not include an LC tank to prevent operation on unwanted modes, this circuit is intended for fundamental mode operation only and relies on that mode being the most active. If the crystal is ordered for 30-pF loading, the frequency trimming capacitor can be adjusted to compensate for the loading of the capacitive divider of the Colpitts circuit. An unloaded crystal without a trimmer would operate slightly off the exact series resonant frequency in order to create an inductive impedance to resonate with the divider capacitors. Ulrich Rohde, KA2WEU, in Fig 4-47 of his book *Digital PLL Frequency Synthesizers—Theory and Design*, published an elegant alternative method of extracting an output signal from this type of circuit, shown in Fig 10.26B. This taps off a signal from the current in the crystal itself. This can be thought of as using the crystal as a band-pass filter for the oscillator output. The RF choke in the emitter keeps the emitter bias resistor from loading the tank and degrading the Q. In this case (3-MHz operation), it has been chosen to resonate close to 3 MHz with the

parallel capacitor (510 pF) as a means of forcing operation on the wanted mode. The 10-Ω resistor and the transformed load impedance will reduce the in-circuit Q of the crystal, so a further development substituted a common base amplifier for the resistor and transformer. This is shown in Fig 10.26C. The common-base amplifier is run at a large quiescent current to give a very low input impedance. Its collector is tuned to give an output with low harmonic content and an emitter follower is used to buffer this from the load. This oscillator sports a simple ALC system, in which the amplified and rectified signal is used to reduce the bias voltage on the oscillator transistor's base. This circuit is described as achieving a phase noise level of -168 dBc/Hz a few kilohertz out from the carrier. This may seem far beyond what may ever be needed, but frequency multiplication to high frequencies, whether by classic multipliers or by frequency synthesizers, multiplies the deviation of any FM/PM sidebands as well as the carrier frequency. This means that phase noise worsens by 20 dB for each tenfold multiplication of frequency. A clean crystal oscillator and a multiplier chain is still the best way of generating clean microwave signals for use with narrow-band modulation schemes.

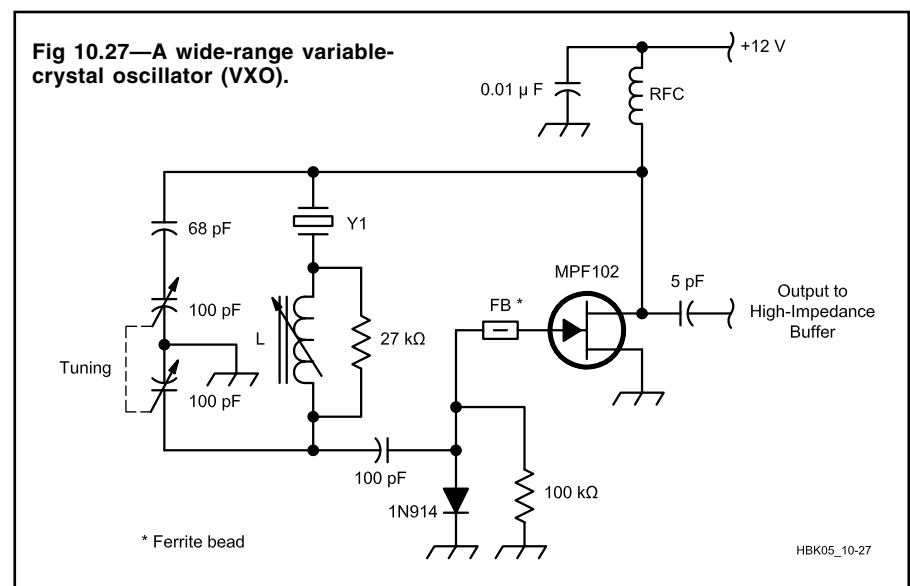

It has already been mentioned that overtone crystals are much harder to pull than fundamental ones. This is another way of saying that overtone crystals are less influenced by their surrounding circuit, which is helpful in a frequency-standard oscillator like this one. Even though 5 MHz is in the main range of fundamental-mode crystals and this circuit will work well with them, an overtone crystal has been used. To fur-

ther help stability, the power dissipated in the crystal is kept to about 50 μW. The common-base stage is effectively driven from a higher impedance than its own input impedance, under which conditions it gives a very low noise figure.

VXOs

Some crystal oscillators have frequency trimmers. If the trimmer is replaced by a variable capacitor as a front-panel control, we have a *variable crystal oscillator (VXO)*: a crystal-based VFO with a narrow tuning range, but good stability and noise performance. VXOs are often used in small, simple QRP transmitters to tune a few kilohertz around common calling frequencies. Artful constructors, using optimized circuits and components, have achieved 1000-ppm tuning ranges. Poor-quality “soft” crystals are more pullable than high-Q ones. Overtone crystals are not suited to VXOs. For frequencies beyond the usual limit for fundamental mode crystals, use a fundamental unit and frequency multipliers.

ICOM and Mizuho made some 2-m SSB transceivers based on multiplied VXO local oscillators. This system is simple and can yield better performance than many expensive synthesized radios. SSB filters are available at 9 or 10.7 MHz, to yield sufficient image rejection with a single conversion. Choice of VXO frequency depends on whether the LO is to be above or below signal frequency and how much multiplication can be tolerated. Below 8 MHz multiplier filtering is difficult. Above 15 MHz, the tuning range per crystal narrows. A 50-200 kHz range per crystal should work with a modern front-end design feeding a good 9-MHz IF, for a

contest quality 2-m SSB Receiver.

The circuit in **Fig 10.27** is a JFET VXO from Wes Hayward, W7ZOI, and Doug DeMaw, W1FB, optimized for wide-range pulling. Published in *Solid State Design for the Radio Amateur*, many have been built and its ability to pull crystals as far as possible has been proven. Ulrich Rohde, KA2WEU, has shown that the diode arrangement as used here to make signal-dependent negative bias for the gate confers a phase-noise disadvantage, but oscillators like this that pull crystals as far as possible need any available means to stabilize their amplitude and aid start-up. In this case, the noise penalty is worth paying. This circuit can achieve a 2000-ppm tuning range with amenable crystals. If you have some overtone crystals in your junk

box whose fundamental frequency is close to the wanted value, they are worth trying.

This sort of circuit doesn't necessarily stop pulling at the extremes of the possible tuning range, sometimes the range is set by the onset of undesirable behavior such as jumping mode or simply stopping oscillating. L was a 16- μ H slug-tuned inductor for 10-MHz operation. It is important to minimize the stray and interwinding capacitance of L since this dilutes the range of impedance presented to the crystal.

One trick that can be used to aid the pulling range of oscillators is to tune out the C0 of the equivalent circuit with an added inductor. **Fig 10.28** shows how. L is chosen to resonate with C0 for the individual crystal, turning it into a high-impedance parallel-tuned circuit. The Q of this circuit is orders of magnitude less than the Q of the true series resonance of the crystal, so its tuning is much broader. The value of C0 is usually just a few picofarads, so L has to be a fairly large value considering the frequency it is resonated at. This means that L has to have low stray capacitance or else it will self-resonate at a lower frequency. The tolerance on C0 and the variations of the stray C of the inductor means that individual adjustment is needed. This technique can also work wonders in crystal ladder filters.

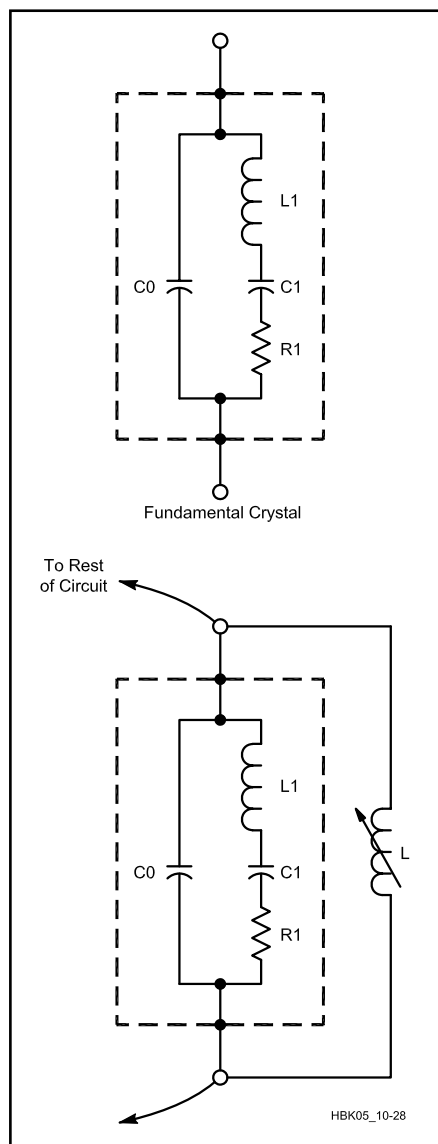

Fig 10.28—Using an inductor to “tune out” C0 can increase a crystal oscillator’s pulling range.

clock oscillators for digital systems. Fig 10.29D shows this minimalist Pierce, using a logic inverter as the amplifier. R_{bias} provides dc negative feedback to bias the gate into its linear region. At first sight it appears that this arrangement should not oscillate, but the crystal is a resonator (not a simple resistor) and oscillation occurs offset from the series resonance, where the crystal appears inductive, which makes up the missing phase shift. This is one circuit that *cannot* oscillate exactly on the crystal’s series resonance. This circuit is included in many microprocessors and other digital ICs that need a clock. It is also the usual circuit inside the miniature clock oscillator cans. It is not a very reliable circuit, as operation is dependent on the crystal’s equivalent series resistance and the output impedance of the logic gate, occasionally the logic device or the crystal needs to be changed to start oscillation, sometimes playing with the capacitor values is necessary. It is doubtful whether these circuits are ever designed—values (the two capacitors) seem to be arrived at by experiment. Once going, the circuit is reliable, but its drift and noise are moderate, not good—acceptable for a clock oscillator. The commercial packaged oscillators are the same, but the manufacturers have handled the production foibles on a batch-by-batch basis.

RC Oscillators

Plenty of RC oscillators are capable of operating to several megahertz. Some of these are really constant-current-into-capacitor circuits, which are easier to make in silicon. Like the phase-shift oscillator above, the timing circuit Q is less than one, giving very poor noise performance that’s unsuitable even to the least demanding radio application. One example is the oscillator section of the CD4046 phase-locked-loop IC. This oscillator has poor stability over temperature, large batch-to-batch variation and a wide variation in its voltage-to-frequency relationship. It is not recommended that this sort of oscillator is used at RF in radio systems. (The ’4046 phase detector section is very useful, however, as we’ll see later.) These oscillators are best suited to audio applications.

VHF AND UHF OSCILLATORS

A traditional way to make signals at higher frequencies is to make a signal at a lower frequency (where oscillators are easier) and multiply it up to the wanted range. Multipliers are still one of the easiest ways of making a clean UHF/microwave signal. The design of a multiplier depends on whether the multiplication factor is an odd or even number. For odd

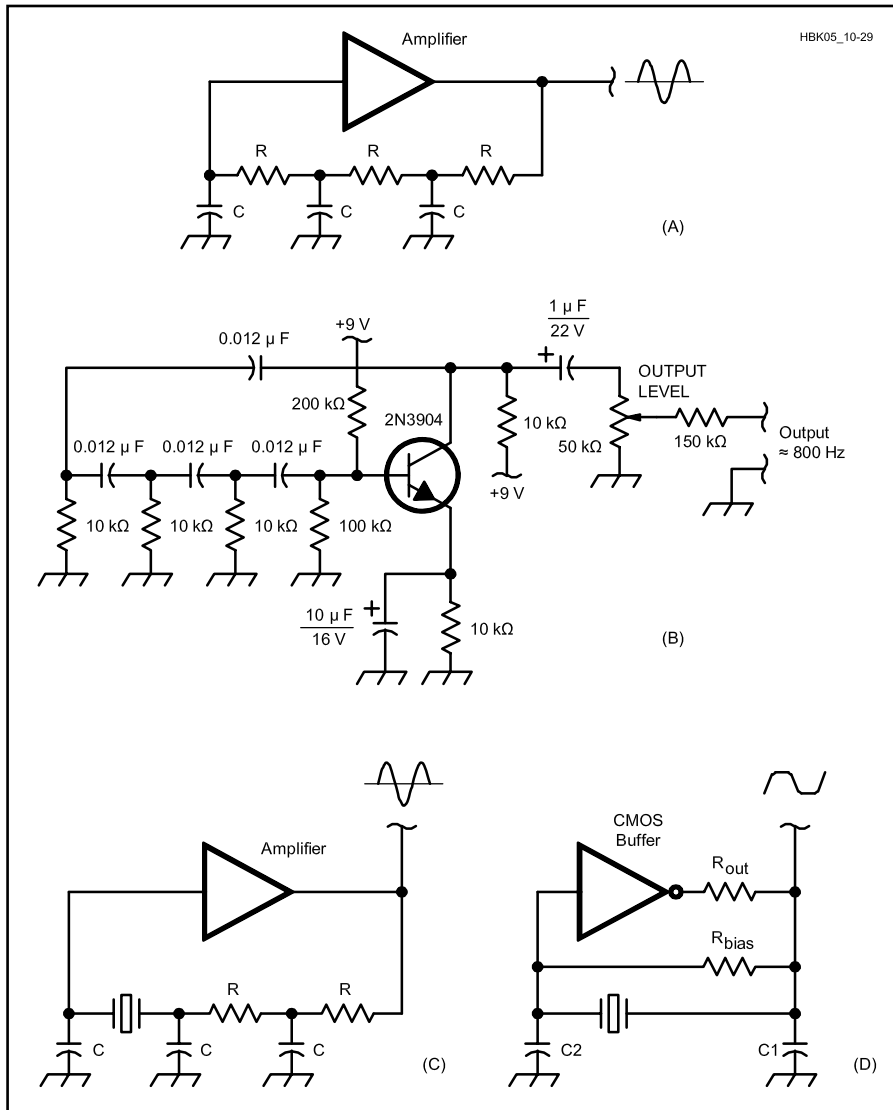

Fig 10.29—In a phase-shift oscillator (A) based on logic gates, a chain of RC networks—three or more—provide the feedback and phase shift necessary for oscillation, at the cost of low Q and considerable loop loss. Many commercial Amateur Radio transceivers have used a phase-lead oscillator similar to that shown at B as a sidetone generator. Replacing one of the resistors in A with a crystal produces a Pierce oscillator (C), a cut-down version of which (D) has become the most common clock oscillator configuration in digital systems.

multiplication, a Class-C biased amplifier can be used to create a series of harmonics; a filter selects the one wanted. For even multiplication factors, a full-wave-rectifier arrangement of distorting devices can be used to create a series of harmonics with strong even-order components, with a filter selecting the wanted component. At higher frequencies, diode-based passive circuits are commonly used. Oscillators using some of the LC circuits already described can be used in the VHF range. At UHF different approaches become necessary.

Fig 10.30 shows a pair of oscillators based on a resonant length of line. The first one is a return to basics: a resonator, an

amplifier and a pair of coupling loops. The amplifier can be a single bipolar or FET device or one of the monolithic microwave integrated circuit (MMIC) amplifiers. The second circuit is really a Hartley, and one was made as a test oscillator for the 70-cm band from a 10-cm length of wire suspended 10 mm over an unetched PC board as a ground plane, bent down and soldered at one end, with a trimmer at the other end. The FET was a BF981 dual-gate device used as a source follower.

No free-running oscillator will be stable enough on these bands except for use with wideband FM or video modulation and AFC at the receiver. Oscillators in this range are almost invariably tuned with

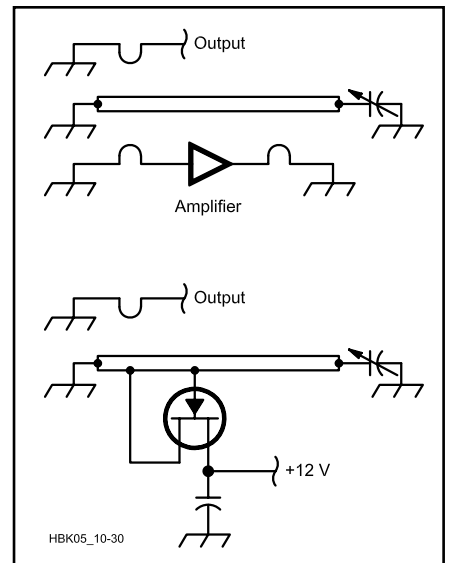

Fig 10.30—Oscillators that use transmission-line segments as resonators. Such oscillators are more common than many of us may think, as Fig 10.31 reveals.

tuning diodes controlled by phase-locked-loop synthesizers, which are themselves controlled by a crystal oscillator.

There is one extremely common UHF oscillator that is rarely applied intentionally. The answer to this riddle is a configuration that is sometimes deliberately built as a useful wide-tuning oscillator covering say, 500 MHz to 1 GHz—and is also the modus operandi of a very common form of *spurious* VHF/UHF oscillation in circuitry intended to process lower-frequency signals! This oscillator has no generally accepted name. It relies on the creation of a small negative resistance in series with a series resonant LC tank.

Fig 10.31A shows the circuit in its simplest form. This circuit is well-suited to construction with printed-circuit inductors. Common FR4 glass-epoxy board is lossy at these frequencies; better performance can be achieved by using the much more expensive glass-Teflon board. If you can get surplus offcuts of this type of material, it has many uses at UHF and microwave, but it is difficult to use, as the adhesion between the copper and the substrate can be poor. A high-UHF transistor with a 5-GHz f_T like the BFR90 is suitable; the base inductor can be 30 mm of 1-mm trace folded into a hairpin shape (inductance, less than 10 nH). Analyzing this circuit using a comprehensive model of the UHF transistor reveals that the emitter presents an impedance that is small, resistive and negative to the outside world. If this is large enough to more than cancel the effective series resistance of the emitter

tank, oscillation will occur. Fig 10.31B shows a very basic emitter-follower circuit with some capacitance to ground on both the input and output. If the capacitor shunting the input is a distance away from the transistor, the trace can look like an inductor—and small capacitors at audio and low RF can look like very good decouplers at hundreds of MHz. The length to the capacitor shunting the output will behave as a series resonator at a frequency where it is a $1/4$ wavelength long. This circuit is the same as in Fig 10.31A; it, too, can oscillate. The semiconductor manufacturers have steadily improved their small-signal transistors to give better gain and bandwidth so that any transistor circuit where all three electrodes find themselves decoupled to ground at UHF may oscillate at several hundred megahertz. The upshot of this is that there is no longer any branch of electronics where RF design and layout techniques can be safely ignored. A circuit must not just be designed to do what it *should* do, it must also be designed so that it cannot do what it *should not* do.

There are three ways of taming such a circuit; adding a small resistor, perhaps 50 to 100 Ω in the collector lead, close to the transistor, or adding a similar resistor in the base lead, or by fitting a ferrite bead over the base lead under the transistor. The resistors can disturb dc conditions, depending on the circuit and its operating currents. Ferrite beads have the advantage that they can be easily added to existing equipment and have no effect at dc and low frequencies. Beware of some electrically conductive ferrite materials that can short transistor leads. If an HF oscillator uses beads to prevent any risk of spurs (Fig 10.16), the beads should be anchored with a spot of adhesive to prevent movement that can cause small frequency shifts. Ferrite beads of Fair-Rite no. 43 material are especially suitable for this purpose; they are specified in terms of impedance, not inductance. Ferrites at frequencies above their normal usable range become very lossy and can make a lead look not inductive, but like a few tens of ohms, resistive.

Microwave Oscillators

Low-noise microwave signals are still best made by multiplying a very-low-noise HF crystal oscillator, but there are a number of oscillators that work directly at microwave frequencies. Such oscillators can be based on resonant lengths of stripline or microstrip, and are simply scaled-down versions of UHF oscillators, using microwave transistors and printed striplines on a low-loss substrate, like alumina. Techniques for printing metal traces

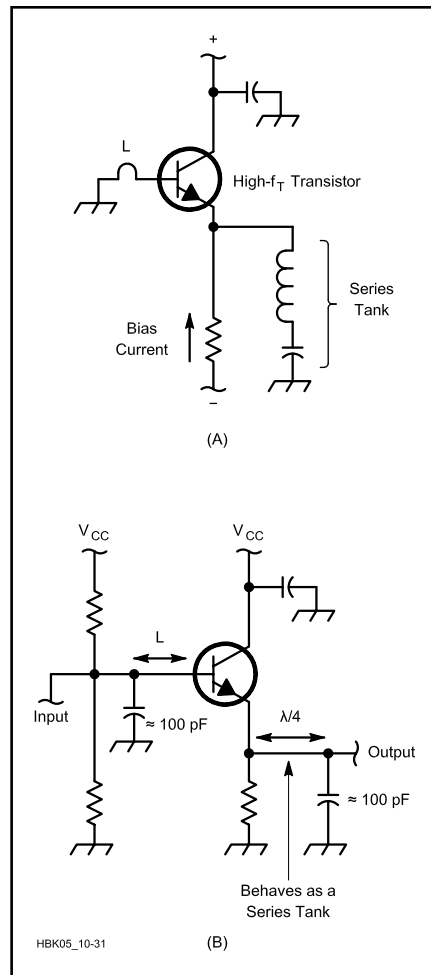

Fig 10.31—High device gain at UHF and resonances in circuit board traces can result in spurious oscillations even in non-RF equipment.

Fig 10.32—Evolution of the cavity resonator.

on substrates to form filters, couplers, matching networks and so on, have been intensively developed over the past two decades. Much of the professional microwave community has moved away from waveguide and now uses low-loss coaxial cable with a solid-copper shield—*semi-rigid cable*—to connect circuits made flat on ceramic or Teflon based substrates. Semiconductors are often bonded on as unpackaged chips, with their bond-wire connections made directly to the traces on the substrate. At lower microwave frequencies, they may be used in standard surface-mount packages. From an Amateur Radio viewpoint, many of the processes involved are not feasible without access to specialized furnaces and materials. Using ordinary PC-board techniques with surface-mount components allows the construction of circuits up to 4 GHz or so. Above this, structures get smaller and accuracy becomes critical; also PC-board materials quickly become very lossy.

Older than stripline techniques and far more amenable to home construction, cavity-based oscillators can give the highest possible performance. The dielectric constant of the substrate causes stripline structures to be much smaller than they would be in free air, and the lowest-loss substrates tend to have very high dielectric constants. Air is a very low-loss dielectric with a dielectric constant of 1, so it gives high Q and does not force excessive miniaturization. Fig 10.32 shows a series of structures used by G. R. Jessup, G6JP, to illustrate the evolution of a cavity from a tank made of lumped components. All cavities have a number of different modes of resonance, the orientation of the currents and fields are shown in Fig 10.33. The cavity can take different shapes, but that shown has proven to suppress unwanted modes well. The gap need not be central and is often right at the top. A screw can be fitted through the top, protruding into the gap, to adjust the frequency.

To make an oscillator out of a cavity, an amplifier is needed. Gunn and tunnel diodes have regions in their characteristics where their current *falls* with increasing bias voltage. This is negative resistance. If such a device is mounted in a loop in a cavity and bias applied, the negative resistance can more than cancel the effective loss resistance of the cavity, causing oscillation. These diodes are capable of operating at extremely high frequencies and were discovered long before transistors were developed that had any gain at microwave frequencies.

A *Gunn-diode* cavity oscillator is the basis of many of the Doppler-radar

modules used to detect traffic or intruders. **Fig 10.34** shows a common configuration. The coupling loop and coax output connector could be replaced with a simple aperture to couple into waveguide or a mixer cavity. **Fig 10.35** shows a transistor cavity oscillator version using a modern microwave transistor. FET or bipolar devices can be used. The two coupling loops

Fig 10.33—Currents and fields in a cavity.

Fig 10.34—A Gunn diode oscillator uses negative resistance and a cavity resonator to produce radio energy.

are completed by the capacitance of the feedthroughs.

The *dielectric-resonator oscillator* (DRO) may soon become the most common microwave oscillator of all, as it is used in the downconverter of satellite TV receivers. The dielectric resonator itself is a ceramic cylinder, like a miniature hockey puck, several millimeters in diameter. The ceramic has a very high dielectric constant, so the surface (where ceramic meets air in an abrupt mismatch) reflects electromagnetic waves and makes the ceramic body act as a resonant cavity. It is mounted on a substrate and coupled to the active device of the oscillator by a stripline that runs past it. At 10 GHz, a FET made of gallium arsenide (GaAsFET), rather than silicon, is normally used. The dielectric resonator elements are made at frequencies appropriate to mass applications like satellite TV. The set-up charge to manufacture small quantities at special frequencies is likely to be prohibitive for the foreseeable future. The challenge with these devices is to devise new ways of using oscillators on industry standard frequencies. Their chief attraction is their low cost in large quantities and compatibility with microwave stripline (microstrip) techniques. Frequency stability and Q are competitive with good cavities, but are inferior to that achievable with a crystal oscillator and chain of frequency multipliers. Satellite TV downconverters need free running oscillators with less than 1 MHz of drift at 10 GHz.

There are a number of thermionic (vacuum-tube) microwave sources, klystrons, magnetrons and *backwards wave oscillators* (BWOs). Available devices are either very old or designed for very high power.

The *yttrium-iron garnet* (YIG) oscillator was developed for a wide tuning range as a solid-state replacement for the BWO, and many of them can be tuned over more

Fig 10.35—A transistor can also directly excite a cavity resonator.

than an octave. They are complete, packaged units that appear to be a heavy block of metal with low-frequency connections for power supplies and tuning, and an SMA connector for the RF output. The manufacturer's label usually states the tuning range and often the power supply voltages. This is very helpful because, with new units priced in the kilodollar range, it is important to be able to identify surplus units. The majority of YIGs are in the 2- to 18-GHz region, although units down to 500 MHz and up to 40 GHz are occasionally found. In this part of the spectrum there is no octave-tunable device that can equal their cleanliness and stability. A 3-GHz unit drifting less than 1 kHz per second gives an idea of typical stability. This seems very poor—until we realize that this is 0.33 ppm per second. Nevertheless, any YIG application involving narrow-band modulation will usually require some form of frequency stabilizer.

Good quality, but elderly, RF spectrum analyzers have found their way into the workshops of a number of dedicated constructors. A 0- to 1500-MHz analyzer usually uses a 2- to 3.5-GHz YIG as its first local oscillator, and its tuning circuits are designed around it. A reasonable understanding of YIG oscillators will help in troubleshooting and repair.

YIG spheres are resonant at a frequency controlled not only by their physical dimensions, but also by any applied magnetic field. A YIG sphere is carefully oriented within a coupling loop connected to a negative-resistance device and the whole assembly is placed between the poles of an electromagnet. Negative-resistance diodes have been used, but transistor circuits are now common. The support for the YIG sphere often contains a thermostatically controlled heater to reduce temperature sensitivity.

The first problem with a magnetically tuned oscillator is that magnetic fields, especially at low frequencies, are extremely difficult to shield; the tuning will be influenced by any local fields. Varying fields will cause frequency modulation. The magnetic core must be carefully designed to be all-enclosing in an attempt at self-shielding and then one or more nested mu-metal cans are fitted around everything. It is still important to site the unit away from obvious sources of magnetic noise, like power transformers. Cooling fans are less obvious sources of fluctuating magnetic fields, since some are 20 dB worse than a well designed 200-W 50/60-Hz transformer.

The second problem is that the oscillator's internal tuning coils need significant current from the power supply to

create strong fields. This can be eased by adding a permanent magnet as a fixed “bias” field, but the bias will shift as the magnet ages. The only solution is to have a coil with many turns, hence high inductance, which will require a high supply voltage to permit rapid tuning, thus increasing the power consumption. The usual compromise is to have dual coils: One with many turns allows slow tuning over a wide range; a second with much fewer turns allows fast tuning or FM over a limited range. The main coil can have a sensitivity in the 20 MHz/mA range; and the “FM” coil, perhaps 500 kHz/mA.

The frequency/current relationship can have excellent linearity. Fig 10.36 shows the construction of a YIG oscillator.

For some insight into present and future trends in oscillator applications, see the sidebar beginning on page 52.

Fig 10.36—A yttrium-iron-garnet (YIG) sphere serves as the resonator in the sweep oscillators used in many spectrum analyzers.

Frequency Synthesizers

Like many of our modern technologies, the origins of Frequency Synthesis can be traced back to WW II. The driving force was the desire for stable, rapidly switchable and accurate frequency control technology to meet the demands of narrow-band, frequency-agile HF communications systems without resorting to large banks of switched crystals. Early synthesizers were cumbersome and expensive, and therefore their use was limited to the most sophisticated communications systems. With the help of the same technologies that have taken computers from “rooms” to the palms of our hands, the role of frequency synthesis has gone far beyond its original purpose and has become one of the most enabling technologies in modern communications equipment.

Just about every communications device manufactured today, be it a handheld trans-

ceiver, cell phone, pager, AM/FM entertainment radio, scanner, television, HF communications equipment, or test equipment contains a synthesizer. Synthesis is the technology that allows an easy interface with both computers and microprocessors. It provides amateurs with many desirable features, such as the feel of an analog knob with 10-Hz frequency increments, accuracy and stability determined by a single precision crystal oscillator, frequency memories, and continuously variable splits. Now reduced in size to only a few small integrated circuits, frequency synthesizers have also replaced the cumbersome chains of frequency multipliers and filters in VHF, UHF and microwave equipment, giving rise to many of the highly portable communications devices we use today. Frequency synthesis has also had a major impact in lowering the cost of

modern equipment, as well as reducing manufacturing complexity.

Frequency synthesizers have been categorized in two general types, *direct synthesizers* (not to be confused with direct digital synthesis) and *indirect synthesizers*. The architecture of the direct types consists mainly of multipliers, dividers, mixers, filters and copious amounts of shielding. They are also cumbersome and expensive, and have all but disappeared from the market. The indirect varieties make use of programmable dividers and phase-lock loops, thereby considerably reducing their complexity. There are a number of variations on the indirect theme. They include programmable division, variable or dual modulus division, and fractional N. Other techniques that have been developed since the direct/indirect classification are direct digital

synthesis (DDS) and rate multiplier synthesis. Synthesizers used in equipment today are usually a hybrid of the indirect technique and some of the latter developments. There are entire textbooks devoted to treating these various methods in depth, and as such it is not practical to discuss each one in detail in this handbook. We will focus on the indirect approach, based on phase-locked loops. This approach came to dominate frequency synthesis long ago, and is still dominant today.

Phase-Locked Loops

To understand the indirect synthesizer, we need to understand the phase-locked loop. The principle of the *phase-locked loop (PLL)* synthesizer is very simple. An oscillator can be built to cover the required frequency range, so what is needed is a system to keep its tuning correct. This is done by continuously comparing the phase of the oscillator to a stable reference, such as a crystal oscillator and using the result to steer the tuning. If the oscillator frequency is too high, the phase of its output will start to lead that of the reference by an increasing amount. This is detected and is used to decrease the frequency of the oscillator. Too low a frequency causes an increasing phase lag, which is detected and used to increase the frequency of the oscillator. In this way, the oscillator is locked into a fixed-phase relationship with the reference, which means that their frequencies are held exactly equal.

The oscillator is now under control, but is locked to a fixed frequency. **Fig 10.37** shows the next step. The phase detector

does not simply compare the oscillator frequency with the reference oscillator; both signals have now been passed through frequency dividers. Advances in digital integrated circuits have made frequency dividers up to microwave frequencies (over 10 GHz) commonplace. The divider on the reference path has a fixed division factor, but that in the VCO path is programmable, the factor being entered digitally as a (usually) binary word. The phase detector is now operating at a lower frequency, which is a submultiple of both the reference and output frequencies.

The phase detector, via the loop amplifier, steers the oscillator to keep both its inputs equal in frequency. The reference frequency, divided by M , is equal to the output frequency divided by N . The output frequency equals the reference frequency $\times N/M$. N is programmable (and an integer), so this synthesizer is capable of tuning in steps of F_{ref}/M .

As an example, to make a 2-m radio covering 144 to 148 MHz with a 10.7-MHz IF, we need a local oscillator covering 154.7-158.7 MHz. If the channel spacing is 20 kHz, then F_{ref}/M is 20 kHz, so N is 7735 to 7935. There is a free choice of F_{ref} or M , but division by a round binary number is easiest. Crystals are readily available for 10.24 MHz, and one of these (divided by 512) will give 20 kHz at low cost. ICs are readily available containing most of the circuitry necessary for the reference oscillator (less the crystal), with the programmable divider and the phase detector.

The phase detector in this example com-

pares the relative timing of 5-V pulses (CMOS logic level) at 20 kHz. Inevitably, the phase detector output will contain strong components at 20 kHz and its harmonics in addition to the wanted “steering” signal. The loop filter must block these unwanted signals; otherwise the loop amplifier will amplify them and apply them to the VCO, generating unwanted FM. No filtering can be perfect and the VCO is very sensitive, so most synthesizers have measurable sidebands spaced at the phase detector operating frequency (and harmonics) away from the carrier. These are called *reference-frequency sidebands*. (Exactly which is the reference frequency is ambiguous: Do we mean the frequency of the reference oscillator, or the frequency applied to the reference input of the phase detector? You must look carefully at context whenever *reference frequency* is mentioned.)

The loop filter is not usually built as a single block of circuitry, it is often made up of three areas: Some components directly after the phase detector, a shaped frequency response in the loop amplifier and some more components between the loop amplifier and the VCO.

The PLL is like a feedback amplifier, although the “signal” around its loop is represented by frequency in some places, by phase in others and by voltage in others. Like any feedback amplifier, there is the risk of instability and oscillations traveling around the loop, which can be seen as massive FM on the output and a strong ac signal on the tuning line to the VCO. The loop’s filtering and gain has to be designed to prevent this.

The following example illustrates the loop action: Imagine that we shift the reference oscillator by 1 Hz. The reference applied to the phase detector would shift $1/M$ Hz, and the loop would respond by shifting the output frequency to produce a matching shift at the other phase detector port, so the output is shifted by N/M Hz. Imagine now that we apply a very small amount of FM to the reference oscillator. The amount of deviation will be amplified by N/M —but this is only true for low modulating frequencies. If the modulating frequency is increased, eventually the loop filter starts to reduce the gain around the loop, the loop ceases to track the modulation and the deviation at the output falls. This is referred to as the *closed-loop frequency response* or *closed-loop bandwidth*. Poorly designed loops can have poor closed-loop responses. For example, the gain can have large peaks above N/M at some reference modulation frequencies, indicating marginal stability and excessively amplifying any noise at those off-

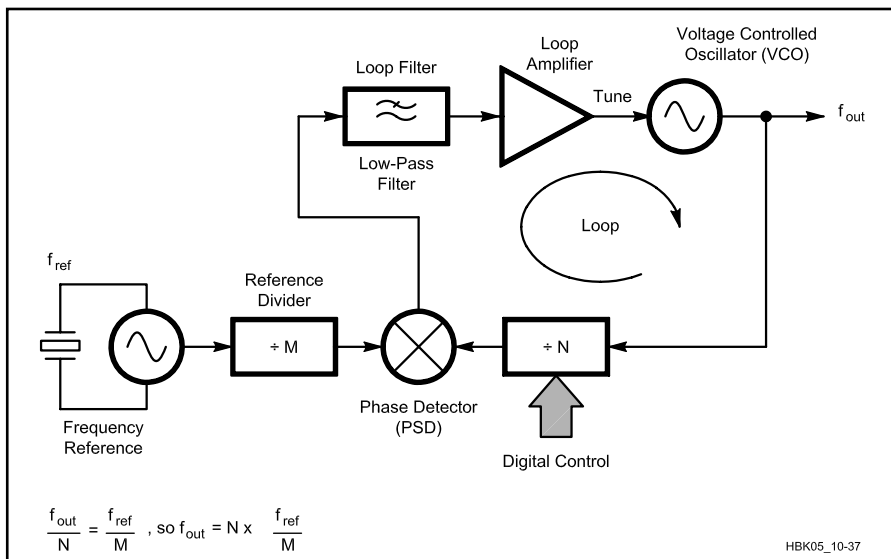

Fig 10.37—A basic phase-locked-loop (PLL) synthesizer acts to keep the divided-down signal from its voltage-controlled oscillator (VCO) phase-locked to the divided-down signal from its reference oscillator. Fine tuning steps are therefore possible without the complication of direct synthesis.

sets from the carrier. The design of the loop filtering and the gain around the loop sets the closed-loop performance.

In a single-loop synthesizer, there is a trade-off between how fine the step size can be versus the performance of the loop. A loop with a very fine step size runs the phase detector at a very low frequency, so the loop bandwidth has to be kept very, very low to keep the reference-frequency sidebands low. Also, the reference oscillator usually has much better phase-noise performance than the VCO, and (within the loop bandwidth) the loop acts to oppose the low-frequency components of the VCO phase-noise sidebands. This very useful cleanup activity is lost when loops have to be narrowed in bandwidth to allow narrow steps. Low-bandwidth loops are slow to respond—they exhibit overly long *settling times*—to the changes in N necessary to change channels. Absolutely everything seems to become impossible in any attempt to get fine resolution from a phase-locked loop.

Single-loop synthesizers are okay for the 2-m FM example for a number of reasons: Channel spacings in this band are not too small, FM is not as critical of phase noise as other modes, 2-m FM is rarely used for weak-signal DXing and the channelization involved does away with the desirability of simulating fast, smooth, continuous tuning. None of these excuses apply to MF/HF radios, however, and ways to circumvent the problems are needed.

A clue was given earlier, by carefully referring to *single-loop synthesizers*. It's possible to use *several* PLLs, or for that matter, some of the other mentioned techniques such as DDS, fractional N , variable- or dual-modulus etc, as components in a larger structure, dividing the frequency of one loop and adding it to the frequency of another that has not been divided. This represents a form of hybrid between the old direct synthesizer and the PLL. A form of PLL containing a mixer in place of the programmable divider can be used to perform the frequency addition.

Let us continue our discussion of phase-lock loop synthesizers by examining the role of each of the component pieces of the system. They are, the VCO, the dividers, prescalers, the phase detector and the loop-compensation amplifier.

Voltage-Controlled Oscillators

Voltage-controlled oscillators are commonly referred to as *VCOs*. (Voltage-tuned oscillator, VTO, more accurately describes the circuitry most commonly used in VCOs, but tradition is tradition! An exception to this is the YIG oscillator,

described earlier as sometimes used in UHF and microwave PLLs, which is *current-tuned*.) In all the oscillators described so far, except for permeability tuning, the frequency is controlled or trimmed by a variable capacitor. These are modified for voltage tuning by using a tuning diode. The oscillator section of this chapter shows the schematic symbol and construction detail of a voltage-controlled or *varactor* (tuning) diode as is typically used in a VCO (see Fig 10.18).

When this oscillator is used in a PLL, the PLL adjusts the tuning voltage to completely cancel any drift in the oscillator (provided it does not drift further than it can be tuned) regardless of its cause, so no special care is needed to compensate a PLL VCO for temperature effects. Adjusting the inductor core will not change the frequency; the PLL will adjust the tuning voltage to hold the oscillator on frequency. This adjustment is important, though. It's set so that the tuning voltage neither gets too close to the maximum available, nor too low for acceptable Q , as the PLL is tuned across its full range.

In a high-performance, low noise synthesizer, the VCO may be replaced by a bank of switched VCOs, each covering a section of the total range needed, each VCO having better Q and lower noise because the lossy diodes constitute only a smaller part of the total tank capacity than they would in a single, full-range oscillator. Another method uses tuning diodes for only part of the tuning range and switches in other capacitors (or inductor taps) to extend the range. The performance of wide-range VCOs can be improved by using a large number of varactors in parallel in a high- C , low- L tank.

Programmable Dividers

Designing your own programmable divider is now a thing of the past, as complete systems have been made as single ICs for over 10 years. The only remaining reason to do so is when an ultra-low-noise synthesizer is being designed.

It may seem strange to think of a digital counter as a source of random noise, but digital circuits have propagation delays caused by analog effects, such as the charging of stray capacitances. Digital circuits are composed of the same sorts of components as analog circuits; there are no such things as digital and analog electrons! Signals are made of voltages and currents. The prime difference between analog and digital electronics lies in the different ways meaning is assigned to the magnitude of a signal. The differences in circuit design are consequences of this, not causes.

Thermal noise in the components of a digital circuit, added to the signal voltage will slightly change the times at which thresholds are crossed. As a result, the output of a digital circuit will have picked up some timing *jitter*. Jitter in one or both of the signals applied to a phase detector can be viewed as low-level random phase modulation. Within the loop bandwidth, the phase detector steers the VCO so as to oppose and cancel it, so phase jitter or noise is applied to the VCO in order to cancel out the jitter added by the divider. This makes the VCO noisier. The noise performance of the high-speed CMOS logic normally used in programmable dividers is good. For ultra-low-noise dividers, ECL devices are sometimes used.

As shown in **Fig 10.38A**, a programmable divider consists of a loadable counter and some control circuitry. The counter is designed to count downward. The programmed division factor is loaded into the counter, and the incoming frequency clocks the downward counting. When the count reaches zero, the counter is quickly reloaded with the division factor before the next clock edge. The maximum frequency of operation is limited by the minimum time needed to reliably perform the loading operation. One improvement is to have a circuit to recognize a state a few clock cycles before the zero count is reached, so the reload can be performed at a more leisurely pace during those cycles. This imposes a minimum division ratio, but that is rarely a problem. An output pulse is given during the loading cycle. In this way a frequency is divided by the number loaded.

The maximum input frequency that can be handled is set by the speed of available logic. The synchronous reset cycle forces the entire divider to be made of equally fast logic. Just adding a fast *prescaler*—a fixed-ratio divider ahead of the programmable one—will increase the maximum frequency that can be used, but it also scales up the loop step size. Equal division has to be added to the reference input of the phase detector to restore the step size, reducing the phase detector's operating frequency. The loop bandwidth has to be reduced to restore the filtering needed to suppress reference frequency sidebands. This makes the loop much slower to change frequency and degrades the noise performance.

Variable or Dual-Modulus Prescalers

A plain programmable divider for VHF use would need to be built from ECL devices. It would be expensive, hot and power-hungry. The idea of a fast front end

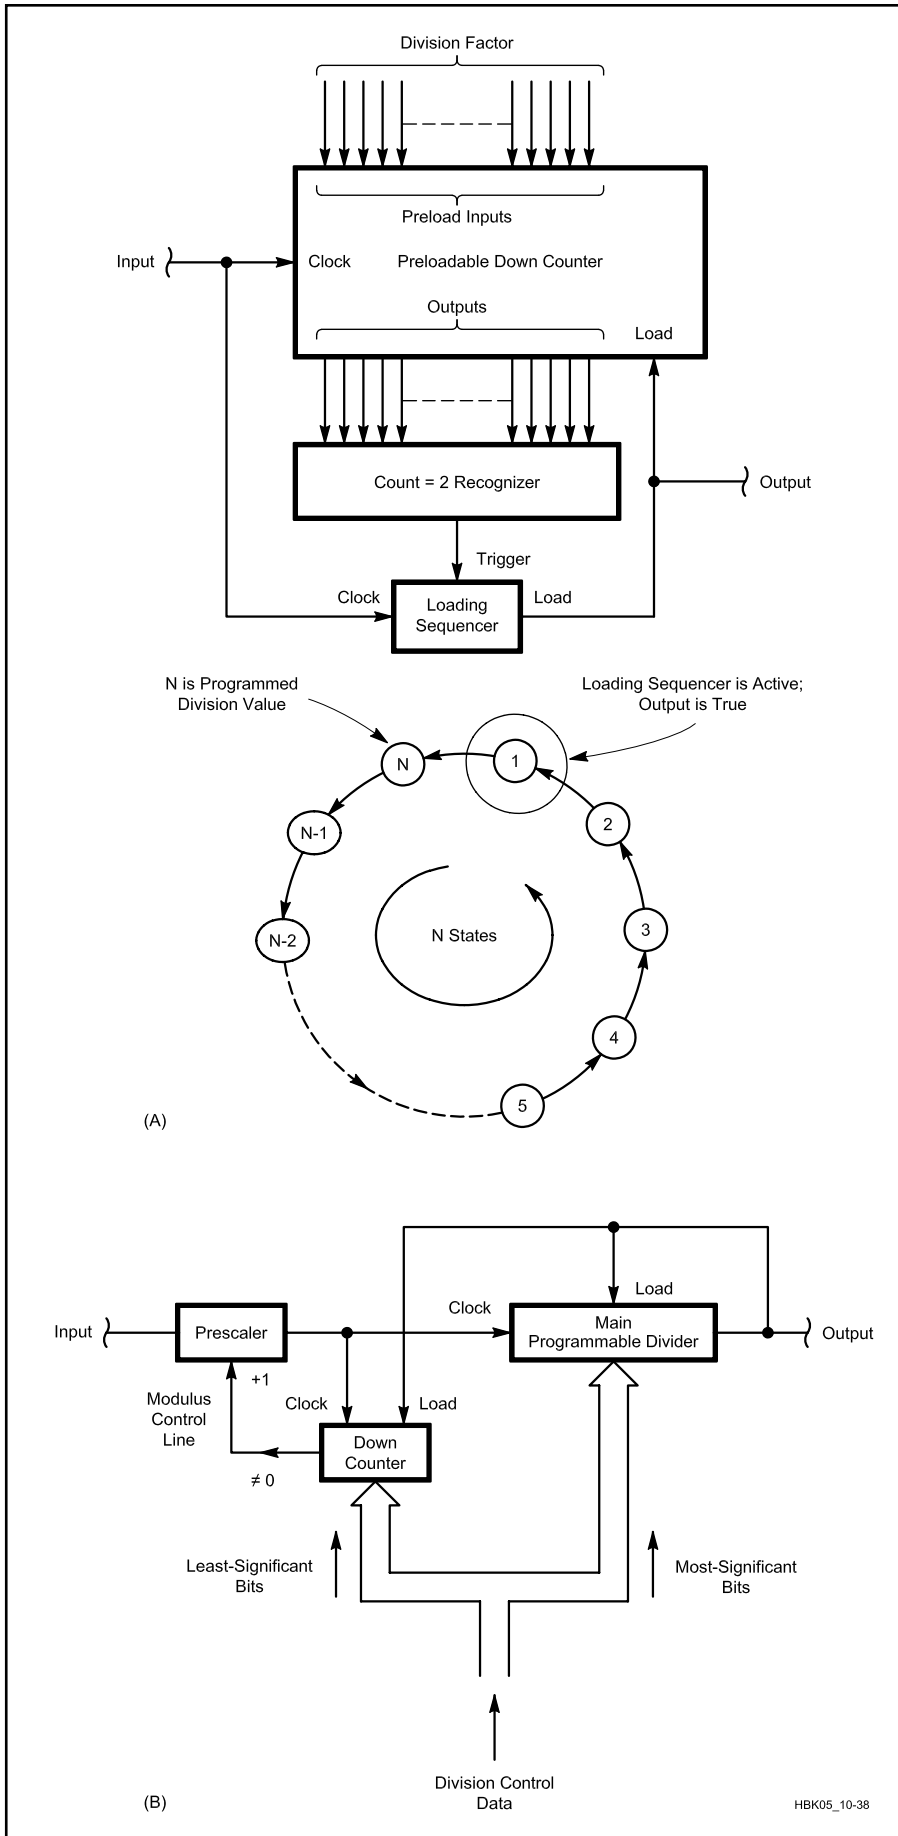

Fig 10.38—(A) Shows the mechanism of a programmable frequency divider. (B) shows the function of a dual-modulus prescaler. The counter is reloaded with N when the count reaches 0 or 1, depending on the sequencer action.

ahead of a CMOS programmable divider would be perfect if these problems could be circumvented. Consider a fast divide-by-ten prescaler ahead of a programmable divider where division by 947 is required. If the main divider is set to divide by 94, the overall division ratio is 940. The prescaler goes through its cycle 94 times and the main divider goes through its cycle once, for every output pulse. If the prescaler is changed to divide by 11 for 7 of its cycles for every cycle of the entire divider system, the overall division ratio is now $[(7 \times 11) + (87 \times 10)] = 947$. At the cost of a more elaborate prescaler and the addition of a slower programmable counter to control it, this prescaler does not multiply the step size and avoids all the problems of fixed prescaling.

Fig 10.38B shows the general block diagram of a dual-modulus prescaled divider. The down counter controls the modulus of the prescaler. The numerical example, just given, used decimal arithmetic, although binary is now usual. Each cycle of the system begins with the last output pulse having loaded the frequency control word, into both the main divider and the prescaler controller. If the part of the word loaded into the prescaler controller is not zero, the prescaler is set to divide by 1 greater than its normal ratio. Each cycle of the prescaler clocks the down counter. Eventually, it reaches zero, and two things happen: The counter is designed to freeze at zero (and it will remain frozen until it is next reloaded) and the prescaler is switched back to its normal ratio, at which it will remain until the next reload. One way of visualizing this is to think of the prescaler as just being a divider of its normal ratio, but with the ability to “steal” a number of input pulses controlled by the data loaded into its companion down counter. Note that a dual-modulus prescaler system has a *minimum* division ratio, needed to ensure there are enough cycles of the prescaler to allow enough input pulses to be stolen.

Dual-modulus prescaler ICs are widely used and widely available. Devices for use to a few hundred megahertz are cheap, and devices in the 2.5-GHz region are commonly available. Common prescaler IC division ratio pairs are: 8-9, 10-11, 16-17, 32-33, 64-65 and so on. Many ICs containing programmable dividers are

available in versions with and without built-in prescaler controllers.

Phase Detectors

A phase detector (PSD) produces an output voltage that depends on the phase relationship between its two input signals. If two signals, *in phase on exactly the same frequency*, are mixed together in a conventional diode-ring mixer with a decoupled output port, one of the products is direct current (0 Hertz). If the phase relationship between the signals changes, the

mixer's dc output voltage changes. With both signals in phase, the output is at its most positive; with the signals 180° out of phase, the output is at its most negative. When the phase difference is 90° (the signals are said to be *in quadrature*), the output is 0 V.

Applying sinusoidal signals to a phase detector causes the detector's output voltage to vary sinusoidally with phase angle, as in **Fig 10.39A**. This nonlinearity is not a problem, as the loop is usually arranged to run with phase differences close to 90° .

What might seem to be a more serious complication is that the detector's phase-voltage characteristic repeats every 180° , not 360° . Two possible input phase differences can therefore produce a given output voltage. This turns out not to be a problem, because the two identical voltage points lie on opposing slopes on the detector's output-voltage curve. One direction of slope gives positive feedback (making the loop unstable and driving the VCO away from what otherwise would be the lock angle) over to the other slope, to the true and stable lock condition.

MD108, SBL-1 and other diode mixers can be used as phase detectors, as can active mixers like the MC1496. Mixer manufacturers make some parts (Mini-Circuits RPD-1 and so on) that are specially optimized for phase-detector service. All these devices can make excellent, low-noise phase detectors but are not commonly used in ham equipment. A high-speed sample-and-hold circuit, based on a Schottky-diode bridge, can form a very low-noise phase detector and is sometimes used in specialized instruments. This is just a variant on the basic mixer; it produces a similar result, as shown in Fig 10.39B.

The most commonly used simple phase detector is just a single exclusive-OR (XOR) logic gate. This circuit gives a logic 1 output only when *one* of its inputs is at logic 1; if both inputs are the same, the output is a logic 0. If inputs A and B in Fig 10.39C are almost in phase, the output will be low most of the time, and its average filtered value will be close to the logic 0 level. If A and B are almost in opposite phase, the output will be high most of the time, and its average voltage will be close to logic 1. This circuit is very similar to the mixer. In fact, the internal circuit of ECL XOR gates is the same transistor tree as found in the MC1496 and similar mixers, with some added level shifting. Like the other simple phase detectors, it produces a cyclic output, but because of the square-wave input signals, produces a triangular output signal. To achieve this circuit's full output-voltage range, it's important that the reference and VCO signals applied operate at a 50% duty cycle.

Phase-Frequency Detectors

All the simple phase detectors described so far are really specialized mixers. If the loop is out of lock and the VCO is far off frequency, such phase detectors give a high-frequency output midway between zero and maximum. This provides no information to steer the VCO towards lock, so the loop remains unlocked. Various solutions to this problem, such as crude relaxation oscillators that start up to sweep

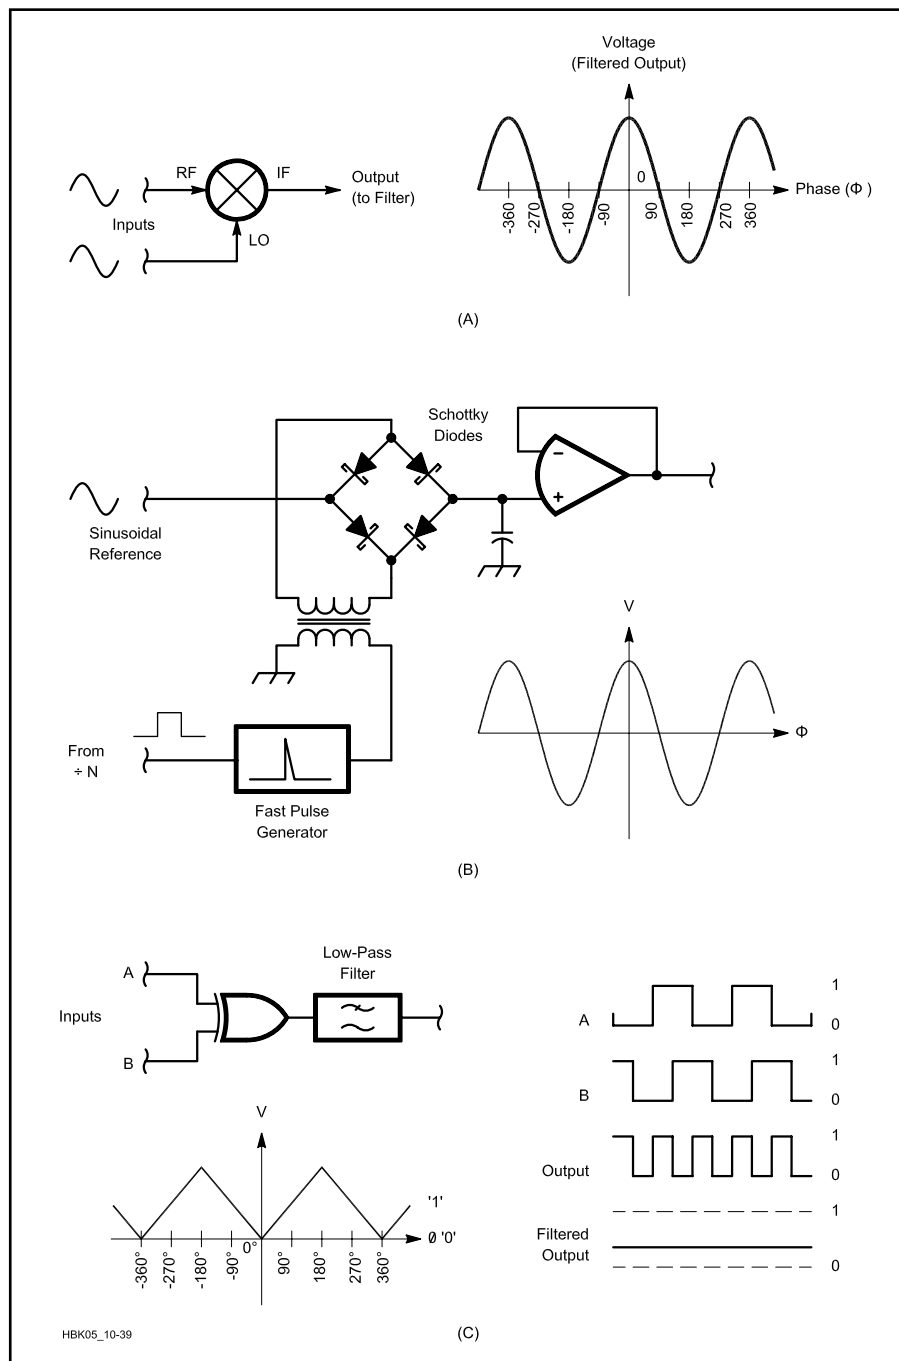

Fig 10.39—Simple phase detectors: a mixer (A), a sampler (B) and an exclusive-OR gate (C).

the VCO tuning until lock is acquired, or laboriously adjusted “pretune” systems in which a DAC, driven from the divider control data, is used to coarse tune the VCO to within locking range, have been used in the past. Many of these solutions have been superseded, although pretune systems are still used in synthesizers that must change frequency very rapidly.

The *phase-frequency detector* is the usual solution to lock-acquisition problems. It behaves like a simple phase detector over an extended phase range, but its characteristic is not repetitive. Because its output voltage stays high or low, depending on which input is higher in frequency, this PSD can steer a loop towards lock from anywhere in its tuning range. **Fig 10.40** shows the internal logic of the phase-frequency detector in the CD4046 PLL chip. (The CD4046 also contains an XOR PSD). When the phase of one input leads that of the other, one of the output MOSFETs is pulsed on with a duty cycle proportional

to the phase difference. Which MOSFET receives drive depends on which input is leading. If both inputs are in phase, the output will include small pulses due to noise, but their effects on the average output voltage will cancel. If one signal is at a higher frequency than the other, its phase will lead by an increasing amount, and the detector’s output will be held close to either V_{DD} or ground, depending on which input signal is higher in frequency. To get a usable voltage output, the MOSFET outputs can be terminated in a high-value resistor to $V_{DD}/2$, but the CD4046’s output stage was really designed to drive current pulses into a capacitive load, with pulses of one polarity charging the capacitor and pulses of the other discharging it. The capacitor integrates the pulses. Simple phase detectors are normally used to lock their inputs in quadrature, but phase-frequency detectors are used to lock their input signals in phase.

Traditional textbooks and logic-design

courses give extensive coverage to avoiding *race hazards* caused by near-simultaneous signals racing through parallel paths in a structure to control a single output. Avoiding such situations is important in many circuits because the outcome is strongly dependent on slight differences in gate speed. The phase-frequency detector is the one circuit whose entire function depends on its built-in ability to *make* both its inputs race. Consequently, it’s not easy to home-brew a phase-frequency detector from ordinary logic parts. Fortunately, they are available in IC form, usually combined with other functions. The MC4044 is an old stand-alone TTL phase-frequency detector; the MC12040 is an ECL derivative, and the much faster and compatible MCH 12140 can be used to over 600 MHz. The Hittite HMC403S8G can be used to 1.3 GHz. CMOS versions can be found in the CD4046 PLL chip and in almost all current divider-PLL synthesizer chips.

The race-hazard tendency does cause one problem in phase-frequency detectors: A device’s delays and noise, rather than its input signals, control its phase-voltage characteristic in the zero-phase-difference region. This degrades the loop’s noise performance and makes its phase-to-voltage coefficient uncertain and variable in a small region, a “dead zone”—unfortunately, in the detector’s normal operating range! It’s therefore normal to bias operation slightly away from *exact* phase equality to avoid this problem. Fortunately, the newer, faster phase detectors like the MCH 12140 and HMC403S8G tend to minimize this “dead zone” problem.

The Loop Compensation Amplifier

Phase-locked loops have acquired a troublesome reputation for a variety of reasons. In the past, a number of commercially made radios have included poorly designed synthesizers that produced excessive noise sidebands, or wouldn’t lock reliably. Some un-producible designs have been published for home construction that could not be made to work. Many experimenters have toiled over an unstable loop, desperately trying anything to get it to lock stably. So the PLL has earned a shady reputation. Because of all of this aversion therapy, very few amateurs are now prepared to attempt to build a PLL.

Luckily, things are not as bad as they used to be. The proliferation of synthesis and PLLs in contemporary equipment have lead to a number of excellent integrated circuits, as well as fine application notes to support them.

The **first** task is to take action to ensure that all previously discussed components

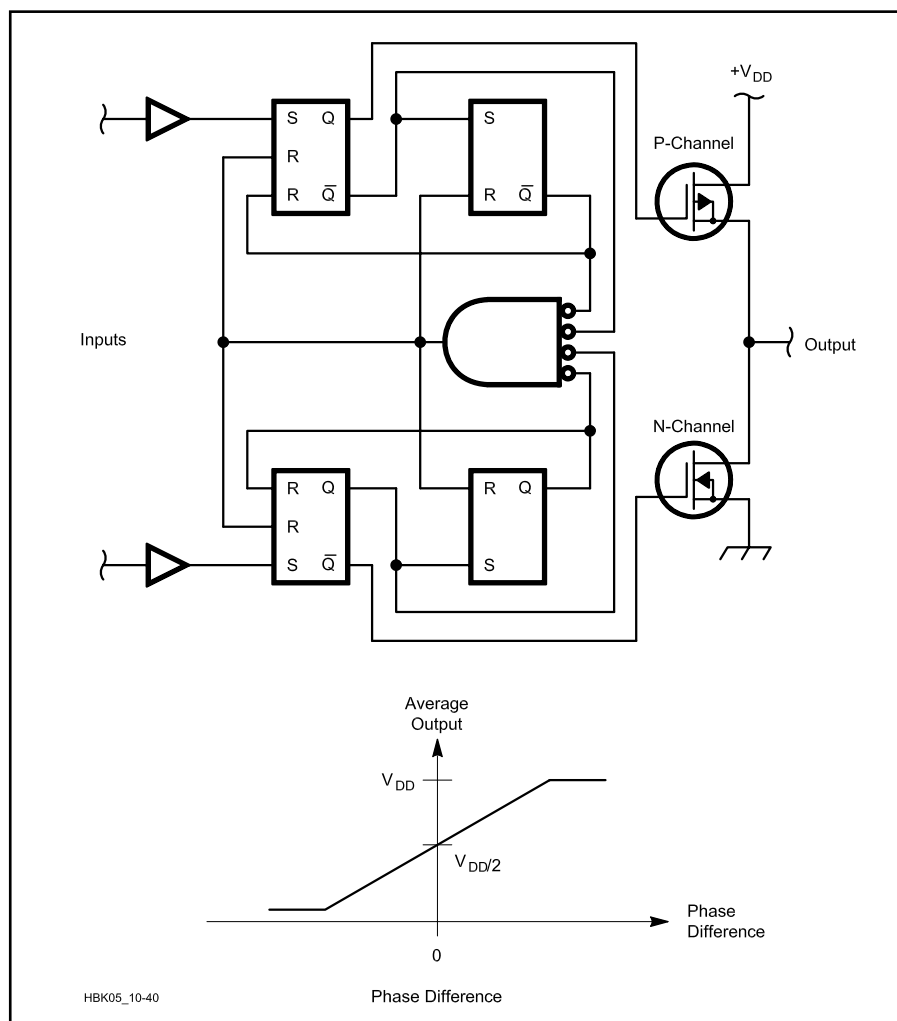

Fig 10.40—Input signals very far off frequency can confuse a simple phase-detector; a phase-frequency detector solves this problem.

of the loop are functioning properly and stably before attempting to close the loop. This means that the oscillators, dividers and amplifiers must all be unconditionally stable. Any instability or squegging in these components must be dealt with prior to attempting to close the loop.

The **second** task is to produce a closed-loop characteristic that best suits the application. Herein is where the greatest difficulty frequently lies. The selection of the closed-loop bandwidth and phase margin or peaking is usually one of great compromise and thought. The process frequently begins with an educated approximation that is then evaluated and modified. There are many factors to consider, including the degree of reference frequency suppression, switching speed, noise, microphonics and modulation, if any. Once the optimum loop characteristic is established, the next problem is to maintain it with respect to variations of the division resulting from the synthesis, and also gain variations associated with the nonlinear tuning curve of the VCO. While not always required in amateur applications, loops in sophisticated synthesizers frequently employ programmable multiplying DACs to maintain constant loop bandwidths and phase margin. In an example later in this chapter, we will actually describe the process for establishing the loop bandwidth for a simple synthesizer.

The **third** task is to design a loop compensation amplifier (filter) that will ensure stable operation when the loop is closed. The design of this compensation network or filter requires knowledge of the VCO gain and linearity, the phase-detector gain, and the effective division ratio and its variation in the loop. The foregoing requirements imply the necessity for measurement and calculation to have any reasonable hope of producing a successful outcome.

Note carefully that we are designing a *loop*. Trial and error, intuitive component choice, or “reusing” a loop amplifier design from a different synthesizer may lead to a low probability of success. All oscillators are loops, and any loop will oscillate when certain conditions are met. Look again at the RC phase-shift oscillator from which the “Pierce” crystal oscillator is derived (Fig 10.29A). Our PLL is a loop, containing an amplifier and a number of RC sections. It has all the parts needed to make an oscillator. If a loop is unstable and oscillates, there will be an oscillatory voltage superimposed on the VCO tuning voltage. This will produce massive unwanted FM on the output of the PLL, which is absolutely undesirable.

Before you turn to a less demanding chapter, consider this: It’s one of nature’s jokes that easy procedures often hide behind a terror-inducing facade. The math you need to design a good PLL may look weird when you see it for the first time and seem to involve some obviously impossible concepts, but it ends in a very simple procedure that allows you to calculate the response and stability of a loop. Professional designers must handle these things daily, and because they like differential equations no more than anyone else does, they use a graphical method based on the work of the mathematician, Laplace, to generate PLL designs. (We’ll leave proofs in the textbooks, where they belong! Incidentally, if you can get the math required for PLL design under control, as a free gift you will also be ready to do modern filter synthesis and design beam antennas, since the math they require is essentially the same.)

The easy solutions to PLL problems can only be performed during the design phase. We must deliberately design loops with sufficient stability safety margins so that all foreseeable variations in component tolerances, from part-to-part, over temperature and across the tuning range, cannot take the loop anywhere near the threshold of oscillation. More than this, it is important to have adequate stability margin because loops with lesser margins will exhibit amplified phase-noise sidebands, and that is another PLL problem that can be designed out.

At the beginning of this chapter (following the text cite of Fig 10.4A), the criterion for stability/oscillation of a loop was mentioned: Barkhausen’s for oscillation or Nyquist’s for stability. This time Harry Nyquist is our hero.

A PLL is a negative feedback system, with the feedback opposing the input, this opposition or inversion around the loop amounts to a 180° phase shift. This is the frequency-*independent* phase shift round the loop, but there are also frequency-*dependent* shifts that will add in. These will inevitably give an increasing, lagging phase with increasing frequency. Eventually an extra 180° phase shift will have occurred, giving a total of 360° around the loop at some frequency. We are in trouble if the gain around the loop has not dropped below unity (0 dB) by this frequency.

Note that we are not concerned only with the loop operating frequency. Consider a 30-MHz low-pass filter passing a 21-MHz signal. Just because there is no signal at 30 MHz, our filter is no less a 30-MHz circuit. Here we use the concept of frequency to describe “what would happen if a signal was applied at that frequency.”

The next sections show us how to use the graphical concepts of poles and zeros to calculate the gain and phase response around a loop. The graphical concepts are quite useful in that they provide insight into the effect of various component choices on the loop performance.

Poles and Zeros

Let’s define some terms first. We all think of frequency as stretching from zero to infinity, but let’s imagine that additional numbers could be used. This is pure imagination—we can’t make signals at *complex* values (with *real* and *imaginary* components) of hertz—but if we try using complex numbers for frequency, some “impossible” things happen. For example, take a simple RC low-pass network shown in Fig 10.41. The frequency response of such a network is well known, but its phase response is *not* so well known. The equation shown for the *transfer function*, the “gain” of this simple circuit, is pretty standard, although the *j* is included to make it complete and accurately describe the output in phase as well as magnitude (*j* is an impossible number, the square root of -1 , usually called an *imaginary* number and used to represent a 90° phase shift).

Although the equation shown in Fig 10.41 was constructed to show the behavior of the circuit at real-world frequencies, there is nothing to stop us from using it to explore how the circuit would behave at impossible frequencies, just out of curiosity. At one such frequency, the circuit goes crazy. At $f = -j 2\pi RC$, the denominator of the equation is zero, and the gain is infinite! Infinite gain is a pretty amazing thing to achieve with a passive circuit—but because this can only happen at an impossible frequency, it cannot happen in the real world. This frequency is equal to the network’s -3 dB frequency multiplied by *j*; it is called a *pole*. Other circuits, which produce real amplitude responses that start to *rise* with frequency, act similarly, but their crazy effect is called a *zero*—an imaginary frequency at which gain goes to zero. The frequency of a circuit’s zero is again *j* times its -3 -dB frequency (+3 dB in this case).

These things are clearly impossible, but we can map all the poles and zeros of a complex circuit and look at the patterns to determine if the circuit possesses unwanted gain and/or phase bumps across a frequency range of interest. Poles are associated with -3 -dB roll-off frequencies and 45° phase lags, zeros are associated with -3 -dB “roll-up” frequencies and 45° phase leads. We can plot the poles and zeros on a two-dimensional chart of real and imaginary frequency. (The names of this chart and its

Fig 10.41—A simple RC filter is a “pole.”

axes are results of its origins in *Laplace transforms*, which we don't need to touch in this discussion.) The traditional names for the axes are used, but we can add labels with clearer meanings.

What is a Pole?—A pole is associated with a bend in a frequency response plot where attenuation with increasing frequency increases by 6 dB per octave (20 dB per decade; an octave is a 2:1 frequency ratio, a decade is a 10:1 frequency ratio).

There are four ways to identify the existence and frequency of a pole:

1. A downward bend in a gain vs frequency plot, the pole is at the -3 dB point for a single pole. If the bend is more than 6 dB/octave, there must be multiple poles at this frequency.

2. A 90° change in a phase vs frequency plot, where lag increases with frequency. The pole is at the point of 45° added lag.

Multiple poles will add their lags, as above.

3. On a circuit diagram, a single pole looks like a simple RC low-pass filter. The pole is at the -3 dB frequency ($1/(2\pi RC)$ Hz). Any other circuit that gives the same response will produce a pole at the same frequency.

4. In an equation for the transfer function of a circuit, a pole is a theoretical value of frequency, which would make the equation predict infinite gain. This is clearly impossible, but as the value of frequency will either be absolute zero, or will have an imaginary component, it is impossible to make a signal at a pole frequency.

What is a Zero?—A zero is the complement of a pole. Each zero is associated with an upward bend of 6 dB per octave in a gain vs frequency plot. The zero is at the +3 dB point. Each zero is associated with

a transition on a phase-versus-frequency plot that *reduces* the lag by 90°. The zero is at the 45° point of this S-shaped transition.

In math, it is a frequency at which the transfer-function equation of a circuit predicts zero gain. This is not impossible in real life (unlike the pole), so zeros can be found at real-number frequencies as well as complex-number frequencies.

On a circuit diagram, a pure zero would need gain that increases with frequency forevermore above the zero frequency. This implies active circuitry that would inevitably run out of gain at some frequency, which implies one or more poles up there. In real-world circuits, zeros are usually not found making gain go up, but rather in conjunction with a pole, giving a gain slope between two frequencies and flat gain beyond them. Real-world zeros are only found chaperoned by a greater or equal number of poles.

Consider a classic RC high-pass filter. The gain increases at 6 dB per octave from 0 Hz (so there must be a zero at 0 Hz) and then levels off at $1/(2\pi RC)$ Hz. This leveling off is really a pole, it adds a 6 dB per octave roll off to cancel the roll-up of the zero.

Poles and Zeros in the Loop Amplifier—The loop-amplifier circuit used in the example loop has a blocking capacitor in its feedback path. This means there is no dc feedback. At higher frequencies the reactance of this capacitor falls, increasing the feedback and so reducing the gain. This is an *integrator*. The gain is immense at 0 Hz (dc) and falls at 6 dB per octave. This points to a pole at 0 Hz. This is true whatever the value of the series resistance feeding the signal into the amplifier inverting input and whatever the value of the feedback capacitor. The values of these components scale the gain rather than shape it. The shape of the integrator gain is fixed at -6 dB per octave, but these components allow us to move it to achieve some wanted gain at some wanted frequency.

At high frequencies, the feedback capacitor in an ordinary integrator will have very low reactance, giving the circuit very low gain. In our loop amplifier, there is a resistor in series with the capacitor. This limits how low the gain can go, in other words the integrator's downward (with increasing frequency) slope is leveled off. This resistor and capacitor make a zero, and its +6 dB per octave slope cancels the -6 dB per octave slope created by the pole at 0 Hz.

Recipe for A PLL Pole-Zero Diagram

We can choose a well-tried loop-amplifier circuit and calculate values for

Fig 10.42—A common loop-amplifier/filter arrangement.

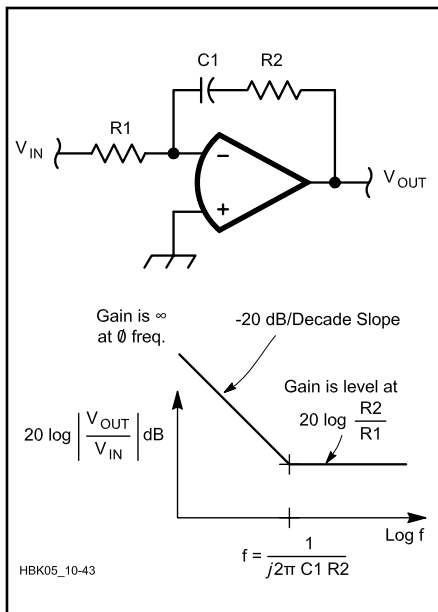

Fig 10.43—Loop-amplifier detail.

Fig 10.44—The loop's resulting pole-zero "constellation."

switched between 10 and 11 MHz on alternate Tuesdays. Imagine that we divide its output by 10. The output of the divider will change between 1 and 1.1 MHz, still on alternate Tuesdays. The divider divides the deviation of the frequency (or phase) modulated signal, but it cannot affect the modulating frequency.

A possible test signal passing around the example loop is in the form of frequency modulation as it passes through the divider, so it is simply attenuated. A divide by N circuit will give $20 \log_{10}(N)$ dB of attenuation (reduction of loop gain). This completes the loop. We can plot all this information on one *s-plane*, Fig 10.44, a plot sometimes referred to as a PLL system's *pole-zero constellation*.

Open-Loop Gain and Phase

Just putting together the characteristics of the blocks around the loop, without allowing for the loop itself, gives us the system's *open-loop* characteristic, which is all we really need.

What Is Stability?—Here "open-loop response" means the gain around the loop that would be experienced by a signal at some frequency *if* such a signal were inserted. We do not insert such signals in the actual circuit, but the concept of frequency-dependent gain is still valid. We need to ensure that there is insufficient gain, at *all* frequencies, to ensure that the loop cannot create a signal and begin oscillating. More than this, we want a good safety margin to allow for component variations and because loops that are *close* to instability perform poorly.

The loop gain and phase are doing interesting things on our plots at frequencies in the AF part of the spectrum. This does not mean that there is visible operation at those frequencies. Imagine a bad, unstable loop. It will have a little too much loop gain at some frequency, and unavoidable noise will build up until a strong signal is created. The amplitude will increase until nonlinearities limit it. A 'scope view of the tuning voltage input to the VCO will show a big signal, often in the hertz to tens of kilohertz region, often large enough to drive the loop amplifier to the limits of its output swing, close to its supply voltages. As this big signal is applied to the tuning voltage input to the VCO, it will modulate the VCO frequency across a wide range. The output will look like that of a sweep generator on a spectrum analyzer. What is wrong? How can we fix this loop? Well, the problem may be excessive loop gain, or improper loop time constants. Rather than work directly with the loop time constants, it is far easier to work with the pole and zero frequencies of the loop response. It's

its components to make it suit our loop. Fig 10.42 shows a common synthesizer loop arrangement. The op amp operates as an integrator, with R2 added to level off its falling gain. An integrator converts a dc voltage at its input to a ramping voltage at its output. Greater input voltages yield faster ramps. Reversing the input polarity reverses the direction of the ramp.

The system's phase-frequency detector (connected to work in the right sense) steers the integrator to ramp in the direction that tunes the VCO toward lock. As the VCO approaches lock, the phase detector reduces the drive to the integrator, and the ramping output slows and settles on the right voltage to give the exact, locked output frequency. Once lock is achieved, the phase detector outputs short pulses that "nudge" the integrator to keep the divided VCO frequency exactly locked in phase with the reference. Now we'll take a look around the entire loop and find the poles and zeros of the circuits.

The integrator produces a -20 dB per decade roll off from 0 Hz, so it has a pole at 0 Hz. It also includes R2 to cancel this slope, which is the same as adding a rising slope that exactly offsets the falling one. This implies a zero at $f = 1/(2\pi C1 R2)$ Hz, as Fig 10.43 shows. R3 and C2 make another pole at $f = 1/(2\pi C2 R3)$ Hz. A VCO usually includes a series resistor that conveys the control voltage to the tuning diode, which also is loaded by various capacitors. This creates another pole.

The VCO generates frequency, while the phase detector responds to phase. Phase is the integral of frequency, so together they act as another integrator and add another pole at 0 Hz.

What About the Frequency Divider?—The frequency divider is like a simple attenuator in its effect on loop response. Imagine a signal generator that is

Fig 10.45—Calculating loop gain and phase characteristics from a pole-zero diagram.

just a different view of the same things.

Now imagine a good, stable loop, with an adequate stability safety margin. There will be some activity around the loop: the PSD (phase detector) will demodulate the phase noise of the VCO and feed the demodulated noise through the loop amplifier in such a way as to cancel the phase noise. This is how a good PLL should give *less* phase noise than the VCO alone would suggest. In a good loop, this noise will be such a small voltage that a 'scope will not show it. In fact, connecting test equipment in an attempt to measure it can usually *add* more noise than is normally there.

Finally, imagine a poor loop that is only just stable. With an inadequate safety margin, the action will be like that of a Q multiplier or a regenerative receiver close to the point of oscillation: There will be an amplified noise peak at some frequency. This spoils the effect of the phase detector trying to combat the VCO phase noise and gives the opposite effect. The output spectrum will show prominent bumps of exaggerated phase noise, as the excess noise

frequency modulates the VCO.

Now, let's use the pole-zero diagram as a graphic tool to find the system open-loop gain and phase. As we do so, we need to keep in mind that the frequency we have been discussing in designing a loop response is the frequency of a theoretical test signal passing around the loop. In a real PLL, the loop signal exists *in two forms*: As sinusoidal voltage between the output of the phase detector and the input of the VCO, and as a sinusoidal modulation of the VCO frequency in the remainder of the loop.

With our loop's pole-zero diagram in hand, we can pick a frequency at which we want to know the system's open-loop gain and phase. We plot this value on the graph's vertical (Real Frequency) axis and draw lines between it and each of the poles and zeros, as shown in **Fig 10.45**. Next, we measure the lengths of the lines and the "angles of elevation" of the lines. The loop gain is proportional to the product of the lengths of all the lines to zeros *divided by* the product of all the lengths of the lines to the poles. The phase shift around the loop

(lagging phase equates to a positive phase shift) is equal to the sum of the pole angles minus the sum of the zero angles. We can repeat this calculation for a number of different frequencies and draw graphs of the loop gain and phase versus frequency.

All the lines to poles and zeros are hypotenuses of right triangles, so we can use Pythagoras's rule and the tangents of angles to eliminate the need for scale drawings. Much tedious calculation is involved because we need to repeat the whole business for each point on our open-loop response plots. This much tedious calculation is an ideal application for a computer.

The procedure we've followed so far gives only *proportional* changes in loop gain, so we need to calculate the loop gain's *absolute* value at some (chosen to be easy) frequency and then relate everything to this. Let's choose 1 Hz as our reference. (Note that it's usual to express angles in radians, not degrees, in these calculations and that this normally renders frequency in peculiar units of *radians per second*. We can keep frequencies in hertz if we remember to include factors of 2π in the right places. A frequency of 1 Hz = 2π radians/second, because 2π radians = 360° .)

We must then calculate the loop's proportional gain at 1 Hz from the pole-zero diagram, so that the constant of proportion can be found. For starters, we need a reasonable estimate of the VCO's *voltage-to-frequency gain*—how much it changes frequency per unit change of tuning voltage. As we are primarily interested in stability, we can just take this number as the slope, in Hertz per volt, at the steepest part of voltage-versus-frequency tuning characteristic, which is usually at the low-frequency end of the VCO tuning range. (You can characterize a VCO's voltage-versus-frequency gain by varying the bias on its tuning diode with an adjustable power supply and measuring its tuning characteristic with a voltmeter and frequency counter.)

The loop divide-by-N stage divides our theoretical modulation—the tuning corrections provided through the phase detector,

$$\text{Open loop gain (dB)} = 20 \log \left[\frac{\sqrt{P_1^2 + 1} \sqrt{P_2^2 + 1} \sqrt{P_3^2 + 1} \sqrt{P_4^2 + 1} \sqrt{Z^2 + f^2}}{\sqrt{P_1^2 + f^2} \sqrt{P_2^2 + f^2} \sqrt{P_3^2 + f^2} \sqrt{P_4^2 + f^2} \sqrt{Z^2 + 1}} \times 10 \frac{\text{unity freq gain}}{20} \right]$$

$$\text{Phase (lead)} = \tan^{-1} \left(\frac{f}{Z} \right) - \tan^{-1} \left(\frac{f}{P_2} \right) - \tan^{-1} \left(\frac{f}{P_3} \right) - \tan^{-1} \left(\frac{f}{P_4} \right)$$

f is the frequency of the point to be characterized. P₁, P₂, P₃, P₄, Z are the frequencies of the poles and zero (all in the same units!)

Fig 10.46—Pole-zero frequency-response equations capable of handling up to four poles and one zero.

loop amplifier and the VCO tuning diode—by its programmed ratio. The worst case for stability occurs at the divider’s lowest N value, where the divider’s “attenuation” is least. The divider’s voltage-versus-frequency gain is therefore $1/N$, which, in decibels, equates to $-20 \log(N)$.

The change from frequency to phase has a voltage gain of one at the frequency of 1 radian/second, $1/(2\pi)$, which equates to -16 dB, at 1 Hz. The phase detector will have a specified “gain” in volts per radian. To finish off, we then calculate the gain of the loop amplifier, including its feedback network, at 1 Hz.

There is no need even to draw the pole-zero diagram. **Fig 10.46** gives the equations needed to compute the gain and phase of a system with up to four poles and one zero. They can be extended to more singularities and put into a simple computer program. Alternatively, you can type them into your favorite spreadsheet and get printed plots. The computational power needed is trivial, and a listing to run these equations on a Hewlett-Packard HP11C (or similar pocket calculator, using RPN) is available from ARRL HQ for an SASE. (Contact the Technical Department Secretary and ask for the 1995 *Handbook* PLL design program.)

Fig 10.47 shows the sort of gain- and phase-versus-frequency plots obtained from a “recipe” loop design. We want to know where the loop’s phase shift equals, or becomes more negative than, -180° . Added to the -180° shift inherent in the loop’s feedback (the polarity of which must be negative to ensure that the phase detector drives the VCO toward lock instead of away from it), this will be the

Fig 10.47—An open-loop gain/phase plot.

point at which the loop itself oscillates—if any loop gain remains at this point. The game is to position the poles and zero, and set the unit frequency gain, so that the loop gain falls to below 0 dB before the -180° line is crossed.

At the low-frequency end of the Fig 10.47 plots, the two poles have had their effect, so the gain falls at 40 dB/decade, and the phase remains just infinitesimally on the safe side of -180° . The next influence is the zero, which throttles the gain’s fall back to 20 dB/decade and peels the phase line away from the -180° line. The zero would eventually bring the phase back to 90° of lag, but the next pole bends it back before that and returns the gain slope back to a fall of 20 dB/decade. The last pole, that attributable to the VCO, pushes the phase over the -180° line.

It’s essential that there not be a pole between the 0-Hz pair and the zero, or else the phase will cross the line early. In this example, the R3-C2 pole and the zero do all the work in setting this critical portion of the loop’s response. Their frequency spacing should create a phase bump of 30 to 45° , and their particular frequency positions are constrained as a compromise between sufficient loop bandwidth and sufficient suppression of reference-frequency sidebands. We know the frequency of the loop amplifier zero (that contributed by R1 and C1), so all we need to do now is design the loop amplifier to exhibit a frequency response such that the open-loop gain passes through 0 dB at a frequency close to that of the phase-plot bump.

This loop-design description may have been hard to follow, but a loop amplifier can be designed in under 30 minutes with a pocket calculator and a little practice. The high output impedance of commonly used CMOS phase detectors favors loop amplifiers based on FET-input op amps and allows the use of high-impedance RC networks (large capacitors can therefore be avoided in their design). LF356 and TL071 op amps have proven successful in loop-amplifier service and have noise characteristics suited to this environment.

To sum up, the recipe gives a proven pole zero pattern (listed in order of increasing frequency):

1. Two poles at 0 Hz (one is the integrator, the other is implicit in all PLLs)
2. A zero controlled by the RC series in the loop amplifier feedback path
3. A simple RC low-pass pole
4. A second RC low-pass pole formed by the resistor driving the capacitive load of the tuning voltage inputs of the VCO

To design a loop: Design the VCO,

divider, PSD and find their coefficients to get the loop gain at unit frequency (1 Hz), then, keeping the poles and zeros in the above order, move them about until you get the same 45° phase bump at a frequency close to your desired bandwidth. Work out how much loop-amplifier unit-frequency gain is needed to shift the gain-frequency-frequency plot so that 0-dB loop gain occurs at the center of the phase bump. Then calculate R and C values to position the poles and zero and the feedback-RC values to get the required loop amplifier gain at 1 Hz.

To Cheat—You can scale the example loop to other frequencies: Just take the reactance values at the zero and pole frequencies and use them to scale the components, you get the nice phase plot bump at a scaled frequency. Even so, you still must do the loop-gain design.

Don’t forget to do this for your lowest division factor, as this is usually the least stable condition because there is less attenuation. Also, VCOs are usually most sensitive at the low end of their tuning range.

Noise in Phase-Locked Loops

Differences in Q usually make the phase-noise sidebands of a loop’s reference oscillator much smaller than those of the VCO. Within its loop bandwidth, a PLL acts to correct the phase-noise components of its VCO and impose those of the reference. Dividing the reference oscillator to produce the reference signal applied to the phase detector also divides the deviation of the reference oscillator’s phase-noise sidebands, translating to a 20-dB reduction in phase noise per decade of division, a factor of $20 \log(M)$ dB, where M is the reference divisor. Offsetting this, within its loop bandwidth the PLL acts as a frequency *multiplier*, and this multiplies the deviation, again by 20 dB per decade, a factor of $20 \log(N)$ dB, where N is the loop divider’s divisor. Overall, the reference sidebands are increased by $20 \log(N/M)$ dB. Noise in the dividers is, in effect, present at the phase detector input, and so is increased by $20 \log(N)$ dB. Similarly, op-amp noise can be calculated into an equivalent phase value at the input to the phase detector, and this can be increased by $20 \log(N)$ to arrive at the effect it has on the output.

Phase noise can be introduced into a PLL by other means. Any amplifier stages between the VCO and the circuits that follow it (such as the loop divider) will contribute some noise, as will microphonic effects in loop- and reference-filter components (such as those due to the piezoelectric properties of ceramic capacitors

Fig 10.48—A PLL’s open- and closed-loop phase-noise characteristics. The noise bumps at the crossover between open- and closed-loop characteristics are typical of PLLs; the severity of the bumps reflects the quality of the system’s design.

and the crystal filters sometimes used for reference-oscillator filtering). Noise on the power supply to the system’s active components can modulate the loop. The fundamental and harmonics of the system’s ac line supply can be coupled into the VCO directly or by means of ground loops.

Fig 10.48 shows the general shape of the PLL’s phase noise output. The dashed curve shows the VCO’s noise performance when unlocked; the solid curve shows how much locking the VCO to a cleaner reference improves its noise performance. The two noise bumps are a classic characteristic of a phase-locked loop. If the loop is poorly designed and has a low stability margin, the bumps may be exaggerated—a sign of noise amplification due to an overly peaky loop response.

Exaggerated noise bumps can also occur if the loop bandwidth is less than optimum. Increasing the loop bandwidth in such a case would widen the band over which the PLL acts, allowing it to do a better job of purifying the VCO—but this might cause other problems in a loop that’s deliberately bandwidth-limited for better suppression of reference-frequency sidebands. Immense loop bandwidth is not desirable, either: Farther away from the carrier, the VCO may be so quiet on its own that widening the loop would make it worse.

A BASIC DESIGN EXAMPLE

In this section, we will explore the application of the design principles previously covered, as well as some of the tradeoffs required in a practical design. We will also cover measurement tech-

niques designed to give the builder confidence that the loop design goals have been met. Finally, we will cover some common troubleshooting problems.

As our design example, a synthesized local oscillator chain for a 10-GHz Transverter will be considered. **Fig 10.49** is a simplified block diagram of a 10-GHz converter. This example was chosen as it represents a departure from the traditional multi-stage multiply and filter approach.

It permits realization of the oscillator system with two very simple loops and minimal RF hardware. It is also representative of what is achievable with current hardware, and can fit in a space of 2 to 3 square inches. This example is intended as a vehicle to explore the loop design aspects and is not offered as a “construction project.” The additional detail required would be beyond the scope of this chapter.

In this example, two synthesized frequencies, 10 GHz and 340 MHz, are required. Since 10.368 GHz is one of the popular traffic frequencies, we will mix this with the 10-GHz LO to produce an IF of 368 MHz. The 368-MHz IF signal will be subsequently mixed with a 340-MHz LO to produce a 28-MHz final IF, which can be fed into the 10-meter input of any amateur transceiver. We will focus our attention on the design of the 10-GHz synthesizer only. Once this is done, the same principles may be applied to the 340-MHz section. Our goal is to attempt to design a low-noise LO system (this implies minimum division) with a loop reference oscillator that is an integer multiple of 10 MHz. Using this technique will allow the entire system to be locked at a later time to a 10-MHz standard for precise frequency control.

Ideally, we would like to start with a low-noise 100-MHz crystal reference and a 10-GHz oscillator divided by 100. It is here that we are already confronted with

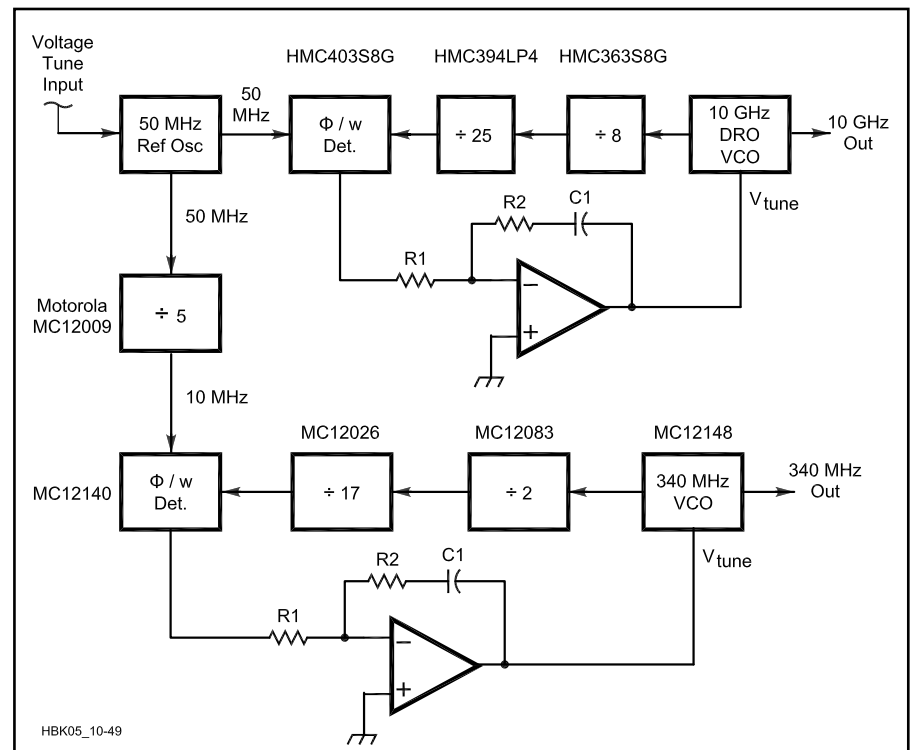

Fig 10.49—A simplified block diagram of a local oscillator, for a 10-GHz converter.

our first practical design tradeoff. We are considering using a line of microwave integrated circuits made by Hittite Microwave. These include a selection of prescalers operating to 12 GHz, a 5-bit counter that will run to 2.2 GHz and a phase/frequency detector that will run up to 1.3 GHz. The 5-bit counter presents the first problem. Our ideal scheme would be to use a divide-by-4 prescaler and enter the 5-bit counter at 2.5 GHz, subsequently dividing by 25 to 100 MHz. The problem is that the 5-bit counter is only rated to 2.2 GHz and not 2.5 GHz. This forces us to use a divide-by-8 prescaler and enter the 5-bit divider at 1.25 GHz. This is well in the range of the divider, but we can no longer use an integer division (ie, $1.25 \text{ GHz}/12.5 = 100 \text{ MHz}$) to get to 100 MHz. The next easiest option is to reduce the reference frequency to 50 MHz and to let the 5-bit divider run as a divide-by-25, giving us a total division ratio of 200.

Having already faced our first design tradeoff, a number of additional aspects must be considered to minimize the conflicts in the design. **First**, this is a “static” synthesizer—That is, it will not be required to change frequency during operation. As a result, switching time considerations are irrelevant, as are the implications that the switching time would have had on the loop bandwidth. The effects of variable division ratios are also eliminated, as well as any problems associated with nonlinear tuning of the VCOs. **Second**, the reference frequencies (50 MHz and 10 MHz) are very large with respect to any practically desirable loop bandwidths. This makes the requirement of the loop filter to eliminate reference sidebands quite easy to achieve. In fact, reference sideband suppression will more likely be a function of board layout

and shielding effectiveness rather than suppression in the loop filter. This also allows placement of the reference suppression poles far out in the pole zero constellation and well outside the loop bandwidth (about $10 \times \text{BW}_3$ of the loop). This placement of the reference suppression poles will give us the option of using a “type 2, 2nd order” loop approximation, which will greatly simplify the calculation process. **Third**, based on all of the foregoing tradeoffs, the loop bandwidth can be chosen almost exclusively on the basis of noise performance.

Before we can proceed with the loop calculations we need some additional information: specifically VCO gain, VCO noise performance, divider noise performance, phase detector gain, phase detector noise performance and finally reference noise performance. The phase detector and divider information is available from specification sheets. Now we need to select the 50-MHz reference and the 10-GHz VCO. An excellent choice for a low noise reference is the one described by John Stephensen on page 13 in Nov/Dec 1999 *QEX*. The noise performance of this VCXO is in the order of -160 dBc/Hz at 10-kHz offset at the fundamental frequency. For the 10-GHz VCO, there are many possibilities, including cavity oscillators, YIG oscillators and dielectric resonator oscillators. Always looking for parts that are easily available, useable and economical, salvaging a dielectric resonator from a Ku band LNB (see Jan-Feb 2002 *QEX*, p 3) appears promising. These high-Q oscillators can be fitted with a varactor and tuned over a limited range with good results. The tuning sensitivity of our dielectric resonator VCO is about 10 MHz per volt and the phase noise at 10-kHz offset is

-87 dBc/Hz . We are now in a position to plot the phase noise of the reference, the dividers, the division effect (46 dB) and the VCO. The phase noise plots are shown in **Fig 10.50**. The noise of the reference is uniformly about 25 dB below the divider and phase detector noise floor. This means that the noise of the phase detector and dividers will be the dominant contribution within the loop bandwidth. The cross over point is at approximately 9 kHz. At frequencies lower than 9 kHz, the loop will reduce the noise of the VCO (eg, at 1 kHz the reduction will be about 20 dB). At frequencies above 9 kHz, the natural noise roll off of the VCO will dominate. At this point, we can also see the effect of having chosen a reference frequency of 50 MHz. Had we been able to use a 100-MHz reference instead of 50 MHz and reduce the division factor from 200 to 100, we could have put the loop bandwidth at about 30 kHz and picked up an additional 6-dB improvement in close-in noise performance. Nevertheless, even with the 6-dB penalty, this will be quite a respectable 10-GHz LO. It should be apparent that a fair amount of thought and effort was required to be able to determine an applicable bandwidth for this loop.

Now that we have some estimate of the noise performance and the required loop bandwidth, it is time to design the loop. The second consideration cited above enabling the application of the “type-2, 2nd order” approximation is now going to pay off. The math for this loop is really quite simple. There are two main variables, the “natural frequency” of the loop, ω_n (omega-n in radians/second) and the “damping factor” D (delta is dimensionless). The closed-loop bandwidth of the loop is a function of ω_n and D . **Fig 10.51**

Fig 10.50—Phase noise plots of the 10-GHz transverter design example.

Fig 10.51—Closed-loop frequency response of a second-order loop as a function of the loop’s natural frequency and damping factor (ω_n).

shows loop response as a function of ω_n and D. Values of D less than 0.5 are not desirable, as they tend towards instability and poor phase margin. A value for D of 0.707 is referred to as “critically damped” and is favored in applications where settling time is critical (see Gardner). For our application, we will choose a D of 1.0. This will give acceptable phase margin and further simplify the math. For a D of 1, $\omega_n = (6.28 \times BW3) / 2.48$. Substituting the 9-kHz loop bandwidth for BW3 yields 22790 radians per second for ω_n . Our loop filter will take the basic form shown in Fig 10.43. We can compute values for R1, R2 and C1 as follows.

$$R1 = (Kpd \times Kvc0) / (N \times \omega_n^2 \times C1)$$

where Kpd is the phase detector gain, 1/6.28 volts/radian in this case, Kvc0 is the VCO gain in radians/Hz, 6.28×10^7 radians/volt in this case, N is the division factor, 200 in this case. C1 is the feedback capacitor value in Farads. To proceed, we need to start with an estimate for C1. Practically speaking, since odd values of capacitors are more difficult to obtain, let us try a value for C1 of 0.01 μ F.

$$R2 = 2 \times D / (\omega_n \times C1)$$

R1 computes as 9626 Ω and R2 is 8775 Ω . Since we will be using a phase/frequency detector with differential outputs, we will have to modify the circuit of Fig 10.43 to become a differential amplifier. We will also add a passive input filter to keep the inputs of the op amp from being stressed by the very fast and short pulses emanating from the phase/frequency detector. We will also add a passive “hash filter” at the output of the op amp to limit the amount of out of band noise delivered to the VCO tuning port. Both of these filters will be designed for a cutoff frequency of 90 kHz (ie, 10 times the 9-kHz closed-loop bandwidth, as cited above in the second consideration. Both of these filters will also aid in the rejection of reference frequency sidebands. For the input filter, we simply divide the input resistor in half and add a capacitor to ground. The value of this capacitor is determined as follows:

$$C2 = 4 / (62.8 \times BW3 \times R1)$$

$$C2 = 735 \text{ pF}$$
