Columns six and seven in Table 21.3 list the maximum RMS voltage for 1500 W of RF power on the 50-Ω coax and on the 450-Ω open-wire line. The maximum RMS voltage for 1500 W on the open-wire line is extremely high, at 7640 V at 1.8 MHz. The voltage for a 100-W transmitter would be reduced by a ratio of $\sqrt{1500/100} = 3.87:1$. This is 1974 V, still high enough to cause arcing in many antenna tuners.

In general, such a nonresonant antenna is a proven, practical multiband radiator when fed with 450-Ω open-wire ladder line connected to an antenna tuner, although a longer antenna would be preferable for more efficient 160-m operation, even with open-wire line. The tuner and the line itself must be capable of handling the high RF voltages and currents involved for high-power operation. On the other hand, if such a multiband antenna is fed directly with coaxial cable, the losses on most frequencies are prohibitive. Coax is most suitable for antennas whose resonant

feed-point impedances are close to the characteristic impedance of the feed line.

The Transmission Line as Impedance Transformer

If the complex mechanics of reflections, SWR and line losses are put aside momentarily, a transmission line can very simply be considered as an impedance transformer. A certain value of load impedance, consisting of a resistance and reactance, at the end of the line is transformed into another value of impedance at the input of the line. The amount of transformation is determined by the electrical length of the line, its characteristic impedance, and by the losses inherent in the line. The input impedance of a real, lossy transmission line is computed using the following equation

$$Z_{in} = Z_0 \times \frac{Z_L \cosh(\eta\ell) + Z_0 \sinh(\eta\ell)}{Z_L \sinh(\eta\ell) + Z_0 \cosh(\eta\ell)} \quad (11)$$

where

Z_{in} = complex impedance at input of line = $R_{in} \pm j X_{in}$

Z_L = complex load impedance at end of line = $R_a \pm j X_a$

Z_0 = characteristic impedance of line = $R_0 \pm j X_0$

η = complex loss coefficient = $a + j b$

α = matched line loss attenuation

constant, in nepers/unit length
(1 neper = 8.688 dB; most cables are rated in dB/100 ft)

β = phase constant of line in radians/unit length (related to physical length of line by the fact that 2π

radians = 1 wavelength, and by Eq 1)
 ℓ = electrical length of line in same units of length measurement as α or above.

Solving this equation manually is tedious, since it incorporates hyperbolic cosines and sines of the complex loss coefficient, but it may be solved using a traditional paper Smith Chart or a computer program. *The ARRL Antenna Book* has a chapter detailing the use of the Smith Chart. *MicroSmith* is a sophisticated graphical Smith Chart program written for the IBM PC, and is available through the ARRL. *TLA* (Transmission Line) is another ARRL program that performs this transformation, but without Smith Chart graphics. *TLA.EXE* is on the CD-ROM accompanying this book.

Lines as Stubs

The impedance-transformation properties of a transmission line are useful in a number of applications. If the terminating resistance is zero (that is, a short) at the end of a low-loss transmission line which is less than $\frac{1}{4}\lambda$, the input impedance consists of a reactance, which is given by a simplification of Eq 11.

$$X_{in} \cong Z_0 \tan \ell \quad (12)$$

If the line termination is an open circuit, the input reactance is given by

$$X_{in} = Z_0 \cot \ell \quad (13)$$

The input of a short (less than $\frac{1}{4}\lambda$) length of line with a short circuit as a terminating load appears as an inductance, while an open-circuited line appears as a

Table 21.3

Modeled Data for a 100-ft Flat-Top Antenna

100-ft long, 50-ft high, center-fed dipole over average ground, using coaxial or open-wire transmission lines. Antenna impedance computed using *NEC2* computer program, with ground relative permittivity of 13, ground conductivity of 5 mS/m and Sommerfeld/Norton ground model. Note the extremely reactive impedance levels at many frequencies, but especially at 1.8 MHz. If this antenna is fed directly with RG-8A coax, the losses are unacceptably large on 160 m, and undesirably high on most other bands also. The RF voltage at 3.8 MHz for high-power operation with open-wire line is extremely high also, and would probably result in arcing either on the line itself, or more likely in the Transmatch. Each transmission line is 100 ft long.

Frequency (MHz)	Antenna Impedance (Ohms)	SWR RG-8A Coax	Loss 100 ft RG-8A Coax	Loss 100 ft 450-Ω Line	Max Volt. RG-8A 1500 W	Max Volt. 450-Ω Line 1500 W
1.8 MHz	4.5 - j 1673	1818:1	25.9 dB	12.1 dB	1640	7640
3.8 MHz	38.9 - j 362	63:1	5.7 dB	0.9 dB	1181	3188
7.1 MHz	481 + j 964	49:1	5.8 dB	0.3 dB	981	1964
10.1 MHz	2584 - j 3292	134:1	10.4 dB	0.9 dB	967	2869
14.1 MHz	85.3 - j 123.3	6.0:1	1.9 dB	0.5 dB	530	1863
18.1 MHz	2097 + j 1552	65:1	9.0 dB	0.6 dB	780	2073
21.1 MHz	345 - j 1073	73:1	9.8 dB	0.8 dB	757	2306
24.9 MHz	202 + j 367	18:1	5.2 dB	0.4 dB	630	1563
28.4 MHz	2493 - j 1375	65:1	10.1 dB	0.7 dB	690	2051

capacitance. This is a useful property of a transmission line, since it can be used as a low-loss inductor or capacitor in matching networks. Such lines are often referred to as *stubs*.

A line that is an electrical quarter wavelength is a special kind of a stub. When a quarter-wave line is short circuited at its load end, it presents an open circuit at its input. Conversely, a quarter-wave line with an open circuit at its load end presents a short circuit at its input. Such a line inverts the sense of a short or an open circuit at the frequency for which the line is a quarter-wave long. This is also true for frequencies that are odd multiples of the quarter-wave frequency. However, for frequencies where the length of the line is a half wavelength, or integer multiples thereof, the line will duplicate the termination at its end.

For example, if a shorted line is cut to be a quarter wavelength at 7.1 MHz, the impedance looking into the input of the cable will be an open circuit. The line will have no effect if placed in parallel with a transmitter's output terminal. However, at twice the frequency, 14.2 MHz, that same line is now a half wavelength, and the line looks like a short circuit. The line, often dubbed a *quarter-wave stub* in this application, will act as a trap for not only the second harmonic, but also for higher even-order harmonics, such as the fourth or sixth harmonics.

Quarter-wave stubs made of good-quality coax, such as RG-213, offer a convenient way to lower transmitter harmonic levels. Despite the fact that the exact amount of harmonic attenuation depends on the impedance (often unknown) into which they are working at the harmonic frequency, a quarter-wave stub will typically yield 20 to 25 dB of attenuation of the second harmonic when placed directly at the output of a transmitter feeding common amateur antennas. Because different manufacturing runs of coax will have slightly different velocity factors, a quarter-wave stub is usually cut a little longer than calculated, and then carefully pruned by snipping off short pieces, while monitoring the response at the fundamental frequency, using a grid-dip meter or an SWR indicator. Because the end of the coax is an open circuit while pieces are being snipped away, the input of a quarter-wave line will show a short circuit exactly at the fundamental frequency. Once the coax has been pruned to frequency, a short jumper is soldered across the end, and the response at the second harmonic frequency is measured.

We will examine further applications of quarter-wave transmission lines later in the next section.

Matching the Antenna to the Line

When transmission lines are used with a transmitter, the most common load is an antenna. When a transmission line is connected between an antenna and a receiver, the receiver input circuit is the load, not the antenna, because the power taken from a passing wave is delivered to the receiver.

Whatever the application, the conditions existing at the load, and *only* the load, determine the reflection coefficient, and hence the standing-wave ratio, on the line. If the load is purely resistive and equal to the characteristic impedance of the line, there will be no standing waves. If the load is not purely resistive, or is not equal to the line Z_0 , there will be standing waves. No adjustments can be made at the input end of the line to change the SWR at the load. Neither is the SWR affected by changing the line length, except as previously described when the SWR at the input of a lossy line is masked by the attenuation of the line.

Only in a few special cases is the antenna impedance the exact value needed to match a practical transmission line. In all other cases, it is necessary either to operate with a mismatch and accept the SWR that results, or else to bring about a match between the line and the antenna.

Technical literature sometimes uses the term *conjugate match* to describe the condition where the reactance seen looking toward the load from any point on the line is the complex conjugate of the impedance seen looking toward the source. A conjugate match is necessary to achieve the maximum power gain possible from a small-signal amplifier. For example, if a small-signal amplifier at 14.2 MHz has an output impedance of $25.8 + j 11.0 \Omega$, then the maximum power possible will be generated from that amplifier when the output load is $25.8 - j 11.0 \Omega$. The amplifier and load system is resonant because the $\pm 11.0\text{-}\Omega$ reactances cancel.

Now, assume that 100 ft of 50- Ω RG-213 coax at 14.2 MHz just happens to be terminated in an impedance of $115 - j 25 \Omega$. Eq 11 calculates that the impedance looking into the input of the line is $25.8 - j 11.0 \Omega$. If this transmission line is connected directly to the small-signal amplifier above, then a conjugate match is created, and the amplifier generates the maximum possible amount of power it can generate.

However, if the impedance at the output of the amplifier is not $25.8 - j 11.0 \Omega$, then a matching network is needed between the amplifier and its load for maximum power gain. For example, if 50 ft of RG-213 is terminated in a $72 - j 34 \Omega$ antenna impedance, the impedance at the line

input becomes $35.9 - j 21.6 \Omega$. A matching network is designed to transform $35.9 - j 21.6 \Omega$ to $25.8 - j 11.0 \Omega$, so that once again a conjugate match is created for the small-signal amplifier.

Now, let us consider what happens with amplifiers where the power level is higher than the milliwatt level of small-signal amplifiers. Most modern transmitters are designed to work into a 50- Ω load. Most will reduce power automatically if the load is not 50 Ω —this protects them against damage and ensures linear operation without distortion.

Many amateurs use an *antenna tuner* between their transmitter and the transmission line feeding the antenna. The antenna tuner's function is to transform the impedance, whatever it is, at the shack-end of the transmission line into the 50 Ω required by their transmitter. Note that the SWR on the transmission line between the antenna and the output of the antenna tuner is rarely exactly 1:1, even though the SWR on the short length of line between the tuner and the transmitter is 1:1.

Therefore, some loss is unavoidable: additional loss due to the SWR on the line, and loss in the antenna tuner itself. However, most amateur antenna installations use antennas that are reasonably close to resonance, making these types of losses small enough to be acceptable.

Despite the inconvenience, if the antenna tuner could be placed at the antenna rather than at the transmitter output, it can transform the $72 - j 34 \Omega$ antenna impedance to a nonreactive 50 Ω . Then the line SWR is 1:1.

Impedance matching networks can take a variety of physical forms, depending on the circumstances.

Matching the Antenna to the Line, at the Antenna

This section describes methods by which a network can be installed at the antenna itself to provide matching to a transmission line. Having the matching system up at the antenna rather than down in the shack at the end of a long transmission line does seem intuitively desirable, but it is not always very practical, especially in multiband antennas.

If a highly reactive antenna can be tuned to resonance, even without special efforts to make the resistive portion equal to the line's characteristic impedance, the resulting SWR is often low enough to minimize additional line loss due to SWR. For example, the multiband 100-ft long dipole in Table 21.3 has an antenna impedance of $4.5 - j 1673 \Omega$ at 1.8 MHz. Assume that the antenna reactance is tuned out with a network consisting of two symmetrical

inductors whose reactance is $+836.5 \Omega$ each, with a Q of 200. The inductors are made up of $73.95 \mu\text{H}$ coils in series with inherent loss resistances of $836.5/200 = 4.2 \Omega$. The total series resistance is thus $4.5 + 2 \times (4.2) = 12.9 \Omega$, and the antenna reactance and inductor reactance cancel out. See **Fig 21.6**.

If this tuned system is fed with 50- Ω coaxial cable, the SWR is $50/12.9 = 3.88:1$, and the loss in 100 ft of RG-8A cable would be 0.47 dB. The radiation efficiency is $4.5/12.9 = 34.9\%$. Expressed another way, there is 4.57 dB of loss. Adding the 0.47 dB of loss in the line yields an overall system loss of 5.04 dB. Compare this to the loss of 17.1 dB if the RG-8A coax is used to feed the antenna directly, without any matching at the antenna. The use of a moderately high-Q resonator has yielded almost 12 dB of “gain” (that is, less loss) compared to the nonresonator case. The drawback of course is that the antenna is now resonated on only one frequency, but it certainly is a lot more efficient on that one frequency.

The Quarter-Wave Transformer or “Q” Section

The range of impedances presented to the transmission line is usually relatively small on a typical amateur antenna, such as a dipole or a Yagi when it is operated close to resonance. In such antenna systems, the impedance-transforming properties of a quarter-wave section of transmission line are often utilized to match the transmission line at the antenna.

One example of this technique is an array of stacked Yagis on a single tower. Each antenna is resonant and is fed in parallel with the other Yagis, using equal lengths of coax to each antenna. A stacked array is used to produce not only gain, but also a wide vertical elevation pattern, suitable for coverage of a broad geographic area. (See *The ARRL Antenna Book* for details about Yagi stacking.) The feed-point impedance of two 50- Ω Yagis fed with equal lengths of feed line connected in parallel is 25Ω ($50/2 \Omega$); three in parallel yield 16.7Ω ; four in parallel yield 12.5Ω . The nominal SWR for a stack of four Yagis is 4:1 ($50/12.5$). This level of SWR does not cause excessive line loss, provided that low-loss coax feed line is used. However, many station designers want to be able to select, using relays, any individual antenna in the array, without having the load seen by the transmitter change. (Perhaps they might wish to turn one antenna in the stack in a different direction and use it by itself.) If the load changes, the amplifier must be retuned, an inconvenience at best.

See **Fig 21.7**. If the antenna impedance and the characteristic impedance of a feed line to be matched are known, the characteristic impedance needed for a quarter-wave matching section of low-loss cable is expressed by another simplification of Eq 11.

$$Z = \sqrt{Z_1 Z_0} \quad (14)$$

where

Z = characteristic impedance needed for matching section

Z_1 = antenna impedance

Z_0 = characteristic impedance of the line to which it is to be matched.

Example: To match a 50- Ω line to a Yagi stack consisting of two antennas fed in parallel to produce a 25- Ω load, the quarter-wave matching section would require a characteristic impedance of

$$Z = \sqrt{50 \times 25} = 35.4 \Omega$$

A transmission line with a characteristic impedance of 35Ω could be closely approximated by connecting two equal lengths of 75- Ω cable (such as RG-11A) in parallel to yield the equivalent of a 37.5- Ω cable. Three Yagis fed in parallel would require a quarter-wave transformer made using a cable having a characteristic impedance of

$$\sqrt{16.7 \times 50} = 28.9 \Omega$$

This is approximated by using a quarter-wave section of 50- Ω cable in parallel

with a quarter-wave section of 75- Ω cable, yielding a net impedance of 30Ω , quite close enough to the desired 28.9Ω . Four Yagis fed in parallel would require a quarter-wave transformer made up using cable with a characteristic impedance of 25Ω , easily created by using two 50- Ω cables in parallel.

T- and Gamma-Match Sections

Many types of antennas exhibit a feed-point impedance lower than the 50- Ω characteristic impedance of commonly available coax cable. Both the so-called *T-Match* and the *Gamma-Match* are used extensively on Yagi and quad beam antennas to increase the antenna feed impedance to 50 Ω .

The method of matching shown in **Fig 21.8** is based on the fact that the impedance between any two points equidistant from the center along a resonant antenna is resistive, and has a value that depends on the spacing between the two points. It is therefore possible to choose a pair of points between which the impedance will have the right value to match a transmission line. In practice, the line cannot be connected directly at these points because the distance between them is much greater than the conductor spacing of a practical transmission line. The T arrangement in Fig 21.8A overcomes this difficulty by using a second conductor paralleling the antenna to form a matching section to which the line may be connected.

The T is particularly well suited to use with parallel-conductor feed line. The

Fig 21.6—The efficiency of the dipole in Table 21.3 can be improved at 1.8 MHz with a pair of inductors inserted symmetrically at the feed point. Each inductor is assumed to have a Q of 200. By resonating the dipole in this fashion the system efficiency, when fed with RG8A coax, is almost 12 dB better than using this same antenna without the resonator. The disadvantage is that the formerly multiband antenna can only be used on a single band.

operation of this system is somewhat complex. Each T conductor (Y in the drawing) forms a short section of transmission line with the antenna conductor opposite it. Each of these transmission-line sections can be considered to be terminated in the impedance that exists at the point of connection to the antenna. Thus, the part of the antenna between the two points carries a transmission-line current in addition to the normal antenna current. The two transmission-line matching sections are in series, as seen by the main transmission line.

If the antenna by itself is resonant at the operating frequency, its impedance will be purely resistive. In this case the matching-section lines are terminated in a resistive load. As transmission-line sections, however, these matching sections are terminated in a short, and are shorter than a quarter wavelength. Thus their input impedance, the impedance seen by the main transmission line looking into the matching-section terminals, will be inductive as well as resistive. The reactive component of the input impedance must be tuned out before a proper match can be obtained.

One way to do this is to detune the antenna just enough, by shortening its length, to cause capacitive reactance to appear at the input terminals of the matching section, thus canceling the reactance introduced. Another method, which is considerably easier to adjust, is to insert a variable capacitor in series with each matching section where it connects to the transmission line, as shown in the chapter

on **Antennas**. The capacitors must be protected from the weather.

When the series-capacitor method of reactance compensation is used, the antenna should be the proper length for resonance at the operating frequency. Trial positions of the matching-section taps are then taken, each time adjusting the capacitor for minimum SWR, until the lowest possible SWR has been achieved. The unbalanced (gamma) arrangement in Fig 21.8B is similar in principle to the T, but is adapted for use with single coax line. The method of adjustment is the same.

The Hairpin Match

In beam antennas such as Yagis or quads, which utilize parasitic directors and reflectors to achieve directive gain, the mutual impedance between the parasitic and the driven elements lowers the resistive component of the driven-element impedance, typically to a value between 10 and 30 Ω . If the driven element is purposely cut slightly shorter than its half-wave resonant length, it will exhibit a capacitive reactance at its feed point. A shunt inductor as shown in Fig 21.9 placed across the feed-point center in-sulator can be used to transform the antenna resistance to match the characteristic impedance of the transmission line, while canceling out the capacitive reactance simultaneously. The antenna's capacitive reactance and the hairpin-shaped shunt inductor form an L network.

For mechanical convenience, the shunt inductor is often constructed using heavy-

gauge aluminum wire bent in the shape of a hairpin. The center of the hairpin, the end farthest from the driven element, is grounded to the boom, since this point in a balanced feed system is equidistant from the antenna feed terminals. This gives some protection against static buildup and a certain measure of lightning protection.

Fig 21.8—The T match (A) and gamma match (B).

Fig 21.7—Array of two stacked Yagis, illustrating use of quarter-wave matching sections. At the junction of the two equal lengths of 50- Ω feed line the impedance is 25 Ω . This is transformed back to 50 Ω by the two paralleled 75- Ω , quarter-wave lines, which together make a net characteristic impedance of 37.5 Ω . This is close to the 35.4 Ω value computed by the formula.

Fig 21.9—Hairpin match, sometimes called the Beta match. The "hairpin" is a shunt inductor, which together with the series capacitive reactance of an electrically short driven element forms an L network. This L network transforms the antenna resistive component to 50 Ω .

The disadvantage of the hairpin match is that it does require that the driven element be split and insulated at its center. The length of the driven element and the value of shunt inductance can be varied in the hairpin match to bring the SWR down to exactly 1:1 at a desired frequency in the band. This can also be achieved with the T or gamma matches previously described.

Matching the Line to the Transmitter

So far we have been concerned mainly with the measures needed to achieve acceptable amounts of loss and a low SWR when real coax lines are connected to real antennas. Not only is feed-line loss minimized when the SWR is kept within reasonable bounds, but also the transmitter is able to deliver its rated output power, at its rated level of distortion, when it sees the load resistance it was designed to feed.

Most modern amateur transmitters use broadband, untuned solid-state final amplifiers designed to work into a 50-Ω load. Such a transmitter very often utilizes built-in protection circuitry, which automatically reduces output power if the SWR rises to more than about 2:1. Protective circuits are needed because many solid-state devices will willingly and almost instantly destroy themselves attempting to deliver power into low-impedance loads. Solid-state devices are a lot less forgiving than vacuum tube amplifiers, which can survive momentary overloads without being destroyed instantly. Pi networks used in vacuum-tube amplifiers typically have the ability to match a surprisingly wide range of impedances on a transmission line. See the **RF Power Amplifiers** chapter in this *Handbook*.

Besides the rather limited option of using only inherently low-SWR antennas to ensure that the transmitter sees the load for which it was designed, we radio amateurs have another alternative. We can use an *antenna tuner*. The function of an

antenna tuner is to transform the impedance at the input end of the transmission line, whatever it may be, to the 50 Ω needed to keep the transmitter loaded properly. Do not forget: A tuner does not alter the SWR on the transmission line going to the antenna; it only keeps the transmitter looking into the load for which it was designed. Indeed, some solid-state transmitters incorporate (usually at extra cost) automatically tuned *antenna couplers* (another name for antenna tuner), so that they too can cope with practical antennas and transmission lines that are not perfectly flat. The range of impedances that can be matched is typically rather limited, however, especially at lower frequencies.

Over the years, radio amateurs have derived a number of circuits for use as tuners. At one time, when open-wire transmission line was more widely used, link-coupled tuned circuits were in vogue. See **Fig 21.10**. With the increasing popularity of coaxial cable used as feed lines, other circuits have become more prevalent. The most common form of antenna tuner in recent years is some variation of a T configuration, as shown in **Fig 21.11A**.

The T network can be visualized as being two L networks back to front, where the common element has been conceptually broken down into two inductors in parallel. See Fig 21.11B. The L network connected to the load transforms the output impedance $R_a \pm jX_a$ into its parallel equivalent

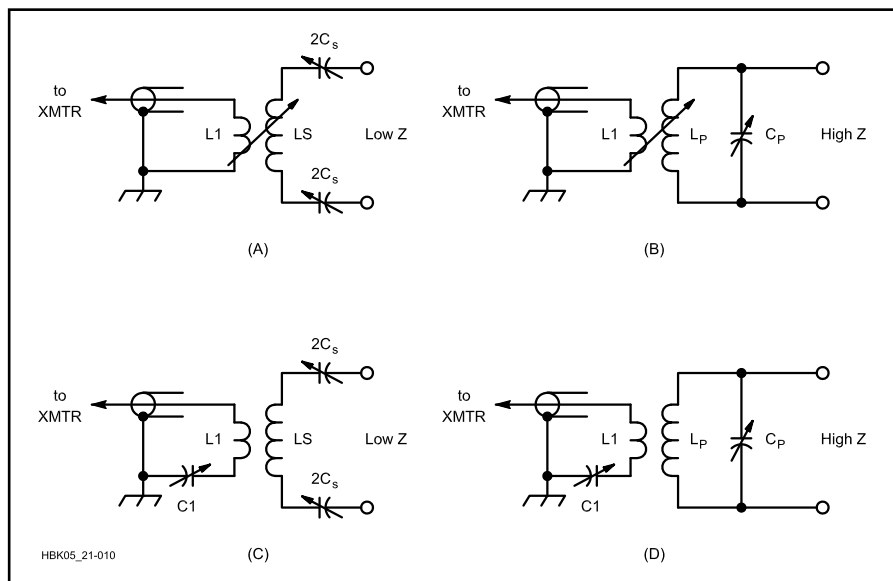

Fig 21.10—Simple antenna tuners for coupling a transmitter to a balanced line presenting a load different from the transmitter’s design load impedance, usually 50 Ω. A and B, respectively, are series and parallel tuned circuits using variable inductive coupling between coils. C and D are similar but use fixed inductive coupling and a variable series capacitor, C1. A series tuned circuit works well with a low-impedance load; the parallel circuit is better with high impedance loads (several hundred ohms or more).

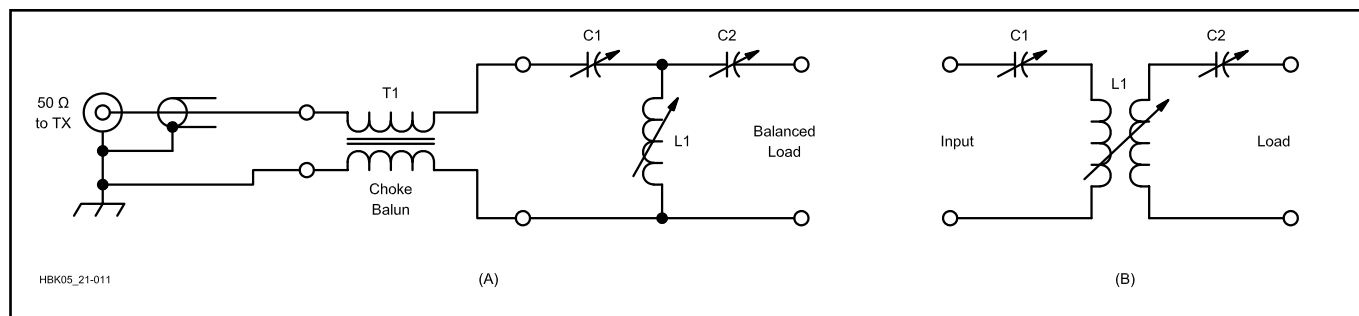

Fig 21.11—Antenna tuner network in T configuration. This network has become popular because it has the capability of matching a wide range of impedances. At A, the balun transformer at the input of the antenna tuner preserves balance when feeding a balanced transmission line. At B, the T configuration is shown as two L networks back to back.

lent by means of the series output capacitor C2. The first L network then transforms the parallel equivalent back into the series equivalent and resonates the reactance with the input series capacitor C1.

Note that the equivalent parallel resistance R_p across the shunt inductor can be a very large value for highly reactive loads, meaning that the voltage developed at this point can be very high. For example, assume that the load impedance at 3.8 MHz presented to the antenna tuner is $Z_a = 20 - j 1000$. If C2 is 300 pF, then the equivalent parallel resistance across L1 is 66,326 Ω . If 1500 W appears across this parallel resistance, a peak voltage of 14,106 V is produced, a very substantial level indeed. Highly reactive loads can produce very high voltages across components in a tuner.

The ARRL computer program TLA calculates and shows graphically the antenna-tuner values for operator selected antenna impedances transformed through lengths of various types of practical transmission lines. The **Station Layout and Accessories** chapter includes antenna tuner projects, and *The ARRL Antenna Book* contains detailed information on tuner design and construction.

Myths About SWR

This is a good point to stop and mention that there are some enduring and quite misleading myths in Amateur Radio concerning SWR.

- Despite some claims to the contrary, a high SWR *does not by itself* cause RFI, or TVI or telephone interference. While it is true that an antenna located close to such devices can cause overload and interference, the SWR on the feed line to that antenna has nothing to do with it, providing of course that the tuner, feed line or connectors are not arcing. The antenna is merely doing its job, which is to radiate. The transmission line is doing its job, which is to convey power from the transmitter to the radiator.
- A second myth, often stated in the same breath as the first one above, is that a high SWR will cause excessive radiation from a transmission line. SWR has nothing to do with excessive radiation from a line. *Imbalances* in open-wire lines cause radiation, but such imbalances are not related to SWR. This subject will be covered more in the section on baluns.
- A third and perhaps even more prevalent myth is that you can't "get out" if the SWR on your transmission line is higher than 1.5:1, or 2:1 or some other such arbitrary figure. On the HF bands,

if you use reasonable lengths of good coaxial cable (or even better yet, open-wire line), the truth is that you need not be overly concerned if the SWR at the load is kept below about 6:1. This sounds pretty radical to some amateurs who have heard horror story after horror story about SWR. The fact is that if you can load up your transmitter without any arcing inside, or if you use a tuner to make sure your transmitter is operating into its rated load resistance, you can enjoy a very effective station, using antennas with feed lines having high values of SWR on them. For example, a 450- Ω open-wire line connected to the multiband dipole shown in Table 21.3 would have a 19:1 SWR on it at 3.8 MHz. Yet time and again this antenna has proven to be a great performer at many installations.

Fortunately or unfortunately, SWR is one of the few antenna and transmission-line parameters easily measured by the average radio amateur. Ease of measurement does not mean that a low SWR should become an end in itself! The hours spent pruning an antenna so that the SWR is reduced from 1.5:1 down to 1.3:1 could

be used in far more rewarding ways—making contacts, for example, or studying transmission-line theory.

Loads and Balancing Devices

Center-fed dipoles and loops are *balanced*, meaning that they are electrically symmetrical with respect to the feed point. A balanced antenna should be fed by a balanced feeder system to preserve this electrical symmetry with respect to ground, thereby avoiding difficulties with unbalanced currents on the line and undesirable radiation from the transmission line itself. Line radiation can be prevented by a number of devices which detune or *decouple* the line for currents radiated by the antenna back onto the line that feeds it, greatly reducing the amplitude of such so-called *antenna currents*.

Many amateurs use center-fed dipoles or Yagis, fed with unbalanced coaxial line. Some method should be used for connecting the line to the antenna without upsetting the symmetry of the antenna itself. This requires a circuit that will isolate the balanced load from the unbalanced line, while still providing efficient power transfer. Devices for doing this are

Fig 21.12—Quarter-wave baluns. Radiator with coaxial feed (A) and methods of preventing unbalanced currents from flowing on the outside of the transmission line (B and C). The $\frac{1}{2}\lambda$ -phasing section shown at D is used for coupling to an unbalanced circuit when a 4:1 impedance ratio is desired or can be accepted.

Fig 21.13—At A, computer-generated azimuthal responses for two $\lambda/2$ dipoles placed 0.71λ high over typical ground. The solid line is for a dipole with no feed line. The dashed line is for an antenna with its feed line slanted 45° down to ground. Current induced on the outer braid of the $1\text{-}\lambda$ -long coax by its asymmetry with respect to the antenna causes the pattern distortion. At B, azimuthal response for two 5-element 20-meter Yagis placed 0.71λ over average ground. Again, the solid line is for a Yagi without a feed line and the dashed line is for an antenna with a 45° slanted, $1\text{-}\lambda$ long feed line. The distortion in the radiated pattern is now clearly more serious than for a simple dipole. A balun is needed at the feed point, and most likely $1/4\text{-}\lambda$ way down the feed line from the feed point, to suppress the common-mode currents and restore the pattern.

called *baluns* (a contraction for “balanced to unbalanced”). A balanced antenna fed with balanced line, such as two-wire ladder line, will maintain its inherent balance, so long as external causes of unbalance are avoided. However, even they will require some sort of balun at the transmitter, since modern transmitters have unbalanced (coax) outputs.

If a balanced antenna is fed at the center through a coaxial line without a balun, as indicated in **Fig 21.12A**, the inherent symmetry and balance is upset because one side of the radiator is connected to the shield while the other is connected to the inner conductor. On the side connected to the shield, current can be diverted from flowing into the antenna, and instead can flow down over the outside of the coaxial shield. The field thus set up cannot be canceled by the field from the inner conductor because the fields inside the cable cannot escape through the shielding of the outer conductor. Hence currents flowing on the outside of the line will be responsible for some radiation from the line.

This is a good point to say that striving for perfect balance in a line and antenna system is not always absolutely mandatory. For example, if a nonresonant center fed dipole is fed with open-wire line and a

tuner for multiband operation, the most desirable radiation pattern for general-purpose communication is actually an omnidirectional pattern. A certain amount of feed-line radiation might actually help fill in otherwise undesirable nulls in the azimuthal pattern of the antenna itself. Furthermore, the radiation pattern of a coaxial-fed dipole that is only a few tenths of a wavelength off the ground (50 ft high on the 80-m band, for example) is not very directional anyway, because of its severe interaction with the ground.

Purists may cry out in dismay, but there are many thousands of coaxial-fed dipoles in daily use worldwide that perform very effectively without the benefit of a balun. See **Fig 21.13A** for a worst-case comparison between a dipole with and without a balun at its feed point. This is with a $1\text{-}\lambda$ long feed line slanted downward 45° under one side of the antenna. *Common-mode currents* are radiated and conducted onto the braid of the feed line, which in turn radiates. The amount of pattern distortion is not particularly severe for a dipole. It is debatable whether the bother and expense of installing a balun for such an antenna is worthwhile.

However, some form of balun should be used to preserve the pattern of an antenna

that is purposely designed to be highly directional, such as a Yagi or a quad. **Fig 21.13B** shows the distortion that can result from common-mode currents conducted and radiated back onto the feed line for a 5-element Yagi. This antenna has purposely been designed for an excellent pattern but the common-mode currents seriously distort the rearward pattern and reduce the forward gain as well. A balun is highly desirable in this case.

Quarter-Wave Baluns

Fig 21.12B shows a balun arrangement known as a *bazooka*, which uses a sleeve over the transmission line. The sleeve, together with the outside portion of the outer coax conductor, forms a shorted quarter-wave line section. The impedance looking into the open end of such a section is very high, so the end of the outer conductor of the coaxial line is effectively isolated from the part of the line below the sleeve. The length is an electrical quarter wave, and because of the velocity factor may be physically shorter if the insulation between the sleeve and the line is not air. The bazooka has no effect on antenna impedance at the frequency where the quarter-wave sleeve is resonant. However, the sleeve adds inductive shunt reactance

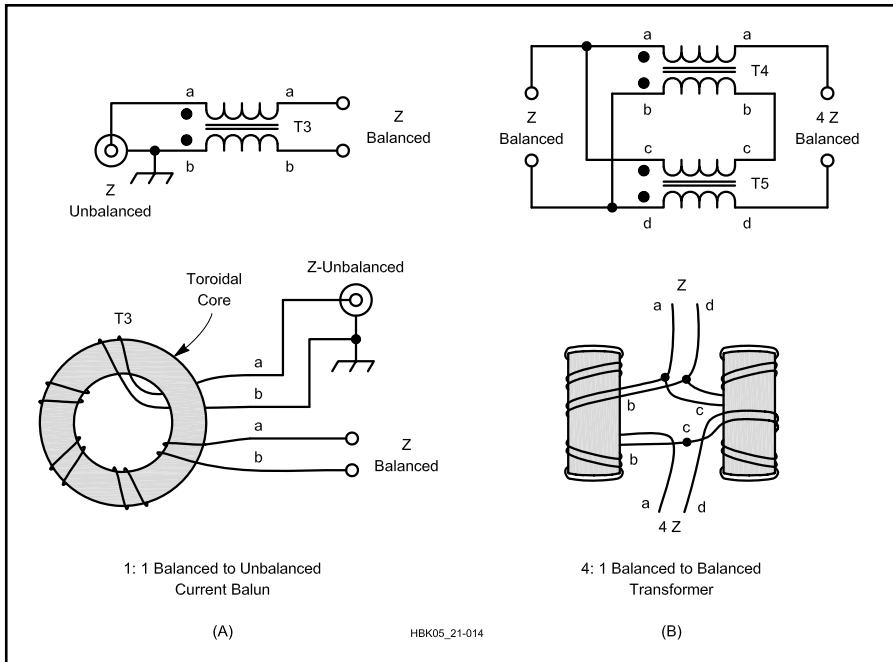

Fig 21.14—Broadband baluns. (A) 1:1 current balun and (B) 4:1 current transformer wound on two cores, which are separated. Use 12 bifilar turns of #14 enameled wire wound on FT240-43 cores for A and B. Distribute bifilar turns evenly around core.

Table 21.4

Effective Choke (Current Baluns)

Wind the indicated length of coaxial feed line into a coil (like a coil of rope) and secure with electrical tape. The balun is most effective when the coil is near the antenna. Lengths are not critical.

Single Band (Very Effective)

Freq, MHz	RG-213, RG-8	RG-58
3.5	22 ft, 8 turns	20 ft, 6-8 turns
7	22 ft, 10 turns	15 ft, 6 turns
10	12 ft, 10 turns	10 ft, 7 turns
14	10 ft, 4 turns	8 ft, 8 turns
21	8 ft, 6-8 turns	6 ft, 8 turns
28	6 ft, 6-8 turns	4 ft, 6-8 turns

Multiple Band

Freq, MHz	RG-8, 58, 59, 8X, 213
3.5-30	10 ft, 7 turns
3.5-10	18 ft, 9-10 turns
14-30	8 ft, 6-7 turns

at frequencies lower, and capacitive shunt reactance at frequencies higher than the quarter-wave-resonant frequency. The bazooka is mostly used at VHF, where its physical size does not present a major problem. On HF a quarter-wavelength rigid sleeve becomes considerably more challenging to construct, especially for a rotary antenna such as a Yagi.

Another method that gives an equivalent effect is shown at Fig 21.12C. Since the voltages at the antenna terminals are equal and opposite (with reference to

ground), equal and opposite currents flow on the surfaces of the line and second conductor. Beyond the shorting point, in the direction of the transmitter, these currents combine to cancel out. The balancing section acts like an open circuit to the antenna, since it is a quarter-wave parallel-conductor line shorted at the far end, and thus has no effect on normal antenna operation. This is not essential to the line balancing function of the device, however, and baluns of this type are sometimes made shorter than a quarter wavelength to

Fig 21.15—RF choke formed by coiling the feed line at the point of connection to the antenna. The inductance of the choke isolates the antenna from the remainder of the feed line.

Fig 21.16—W2DU bead balun consisting of 50 FB-73-2401 ferrite beads over a length of RG-303 coax. See text for details.

provide a shunt inductive reactance required in certain matching systems (such as the hairpin match).

Fig 21.12D shows a third balun, in which equal and opposite voltages, balanced to ground, are taken from the inner conductors of the main transmission line and half-wave phasing section. Since the voltages at the balanced end are in series while the voltages at the unbalanced end are in parallel, there is a 4:1 step-down in impedance from the balanced to the unbalanced side. This arrangement is useful for coupling between a 300-Ω balanced line and a 75-Ω unbalanced coaxial line.

Broadband Baluns

At HF and even at VHF, broadband baluns are generally used nowadays. Examples of broadband baluns are shown in Fig 21.14.

Choke or current baluns force equal and opposite currents to flow. The result is that currents radiated back onto the transmission line by the antenna are effectively reduced, or “choked off,” even if the antenna is not perfectly balanced. If winding inductive reactance becomes marginal at lower frequencies, the balun’s ability to

eliminate antenna currents is reduced, but (for the 1:1 balun) no winding impedance appears across the line.

If radiated current on the line is a problem, perhaps because the feed line must be run in parallel with the antenna for some portion of its length, additional choke baluns can be placed at approximately $\frac{1}{4}\lambda$ intervals along the line. Choke baluns are particularly useful for feeding asymmetrical antennas with unbalanced coax line.

Broadband Balun Construction

Either type of broadband balun can be constructed using a variety of techniques. Construction of choke (current) baluns is described here. The objective is to obtain a high impedance for currents that tend to flow on the line. Values from a few hundred to over a thousand ohms of inductive reactance are readily achieved. These baluns work best with antennas having resonant feed-point impedances less than $100\ \Omega$ or so ($400\ \Omega$ for 4:1 baluns). This is because the winding inductive reactance must be high relative to the antenna impedance for effective operation. A rule of thumb is that the inductive reactance should be four times higher than the antenna impedance. High impedances are difficult to achieve over a wide frequency range. Any sort of transformer operated at impedances for which it was not designed can fail, sometimes spectacularly.

The simplest construction method for a 1:1 balun for coaxial line is simply to wind a portion of the line into a coil. See **Fig 21.15**. This type of choke balun is simple, cheap and effective. Currents on the outside of the line encounter the coil's impedance, while currents on the inside are unaffected. A flat coil (like a coil of rope) shows a broad resonance that easily covers three octaves, making it reasonably effective over the entire HF range. If particular problems are encountered on a single band, a coil that is resonant at that band may be added. The coils shown in **Table 21.4** were constructed to have a high impedance at the indicated frequencies, as measured with an impedance meter. Many other geometries can also be effective. This construction technique is not effective with open-wire or twin-lead line because of coupling between adjacent turns. A 4:1 choke balun is shown in **Fig 21.14B**.

Ferrite-core baluns can provide a high impedance over the entire HF range. They may be wound either with two conductors in bifilar fashion, or with a single coaxial cable. Rod or toroidal cores may be used (**Fig 21.14A**). Current on the shield of a choke balun is the "antenna current" on

the line—If the balun is effective, this current is small. Baluns used for high-power operation should be tested by checking for temperature rise before use. If the core overheats, add turns or use a larger or lower-loss core. It also would be wise to investigate the imbalance causing such high line antenna currents.

Type 72, 73 or 77 ferrite gives the greatest impedance over the HF range. Type 43 ferrite has lower loss, but somewhat less impedance. Core saturation is not a problem with these ferrites at HF, since they overheat due to loss at flux levels well below saturation. The loss occurs because there is insufficient inductive reactance, especially at lower frequencies. Ten to twelve turns on a toroidal core or 10 to 15 turns on a rod are typical for the HF range. Winding impedance increases approximately as the square of the number of turns.

Another type of choke balun that is very effective was originated by M. Walter Maxwell, W2DU. A number of ferrite toroids are strung, like beads on a string, directly onto the coax where it is connected to the antenna. The "bead" choke balun in **Fig 21.16** consists of 50 FB-73-2401 ferrite beads slipped over a 1-ft length of Teflon-insulation RG-303 coax. The beads fit nicely over the insulating jacket of the coax and occupy a total length of $9\frac{1}{2}$ inches. Twelve FB-77-1024 or equivalent beads will come close to doing the same job using RG-8A or RG-213 coax. Type-73 material is recommended for 1.8 to 30 MHz use, but type-77 material may be substituted; use type-43 material for 30 to 250 MHz.

The cores present a high impedance to any RF current that would otherwise flow on the outside of the shield. The total

impedance is in approximate proportion to the stacked length of the cores. The impedance stays fairly constant over a wide range of frequencies. Again, 70-series ferrites are a good choice for the HF range; use type-43 if heating is a problem or increase the number of beads. Type-43 or -61 is the best choice for the VHF range. Cores of various materials can be used in combination, permitting construction of baluns effective over a very wide frequency range, such as from 2 to 250 MHz.

WAVEGUIDES

A waveguide is a hollow conducting tube, through which microwave energy is transmitted in the form of electromagnetic waves. The tube does not carry a current in the same sense that the wires of a two-conductor line do. Instead, it is a boundary that confines the waves to the enclosed space. Skin effect on the inside walls of the waveguide confines electromagnetic energy inside the guide, in much the same manner that the shield of a coaxial cable confines energy within the coax. Microwave energy is injected at one end (either through capacitive or inductive coupling or by radiation) and is received at the other end. The waveguide merely confines the energy of the fields, which are propagated through it to the receiving end by means of reflections off its inner walls.

Evolution of a Waveguide

Suppose an open-wire line is used to carry UHF energy from a generator to a load. If the line has any appreciable length, it must be well insulated from the supports to avoid high losses. Since high-quality insulators are difficult to make for microwave frequencies, it is logical to support the transmission line with quarter-wave

Fig 21.17—At its cutoff frequency a rectangular waveguide can be analyzed as a parallel two-conductor transmission line supported from top and bottom by an infinite number of quarter-wavelength stubs.

Fig 21.18—Field distribution in a rectangular waveguide. The $TE_{1,0}$ mode of propagation is depicted.

length stubs, shorted at the far end. The open end of such a stub presents an infinite impedance to the transmission line, provided that the shorted stub is non-reactive. However, the shorting link has finite length and, therefore, some inductance. This inductance can be nullified by making the RF current flow on the surface of a plate rather than through a thin wire. If the plate is large enough, it will prevent the magnetic lines of force from encircling the RF current.

An infinite number of these quarter-wave stubs may be connected in parallel without affecting the standing waves of voltage and current. The transmission line may be supported from the top as well as the bottom, and when infinitely many supports are added, they form the walls of

Fig 21.19—Coupling to waveguide and resonators. The probe at A is an extension of the inner conductor of coax line. At B an extension of the coax inner conductor is grounded to the waveguide to form a coupling loop.

a waveguide at its cutoff frequency. Fig 21.17 illustrates how a rectangular waveguide evolves from a two-wire parallel transmission line. This simplified analysis also shows why the cutoff dimension is a half wavelength.

While the operation of waveguides is usually described in terms of fields, current does flow on the inside walls, just as fields exist between the current-carrying conductors of a two-wire transmission line. At the waveguide cutoff frequency, the current is concentrated in the center of the walls, and disperses toward the floor and ceiling as the frequency increases.

Analysis of waveguide operation is based on the assumption that the guide material is a perfect conductor of electricity. Typical distributions of electric and magnetic fields in a rectangular guide are shown in Fig 21.18. The intensity of the electric field is greatest (as indicated by

closer spacing of the lines of force in Fig 21.18B) at the center along the X dimension and diminishes to zero at the end walls. Zero field intensity is a necessary condition at the end walls, since the existence of any electric field parallel to any wall at the surface would cause an infinite current to flow in a perfect conductor, an impossible situation.

Modes of Propagation

Fig 21.18 represents a relatively simple distribution of the electric and magnetic fields. An infinite number of ways exist in which the fields can arrange themselves in a guide, as long as there is no upper limit to the frequency to be transmitted. Each field configuration is called a *mode*. All modes may be separated into two general groups. One group, designated *TM* (transverse magnetic), has the magnetic field entirely crosswise to the direction of propagation, but has a component of electric field in the propagation direction. The other type, designated *TE* (transverse electric) has the electric field entirely crosswise to the direction of propagation, but has a component of magnetic field in the direction of propagation. TM waves are sometimes called E waves, and TE waves are sometimes called H waves. The TM and TE designations are preferred, however.

The particular mode of transmission is identified by the group letters followed by subscript numbers; for example $TE_{1,1}$, $TM_{1,1}$ and so on. The number of possible modes increases with frequency for a given size of guide. There is only one possible mode (called the *dominant mode*) for the lowest frequency that can be transmitted. The dominant mode is the one normally used in practical work.

Waveguide Dimensions

In rectangular guides the critical dimension (shown as X in Fig 21.18C) must be more than one-half wavelength at the lowest frequency to be transmitted. In practice, the Y dimension is usually made about equal to $1/2$ X to avoid the possibility of operation at other than the dominant mode. Cross-sectional shapes other than

**Table 21.5
Wavelength Formulas for Waveguide**

	Rectangular	Circular
Cut-off wavelength	2X	3.41R
Longest wavelength transmitted with little attenuation	1.6X	3.2R
Shortest wavelength before next mode becomes possible	1.1X	2.8R

rectangles can be used; the most important is the circular pipe.

Table 21.5 gives dominant-mode wavelength formulas for rectangular and circular guides. X is the width of a rectangular guide, and R is the radius of a circular guide.

Coupling to Waveguides

Energy may be introduced into or extracted from a waveguide or resonator by means of either the electric or magnetic field. The energy transfer frequently takes place through a coaxial line. Two methods for coupling are shown in **Fig 21.21**. The probe at A is simply a short extension of the inner conductor of the feed coaxial line, oriented so that it is parallel to the electric lines of force. The loop shown at B is arranged to enclose some of the magnetic lines of force. The point at which maximum coupling will be obtained depends on the particular mode of propagation in the guide or cavity; the coupling

will be maximum when the coupling device is in the most intense field.

Coupling can be varied by rotating the probe or loop through 90°. When the probe is perpendicular to the electric lines the coupling will be minimum; similarly, when the plane of the loop is parallel to the magnetic lines, the coupling will be minimum. See *The ARRL Antenna Book* for more information on waveguides.

Chapter 22

Antennas

Every ham needs at least one antenna, and most hams have built one. This chapter, by Chuck Hutchinson, K8CH, covers theory and construction of antennas for most radio amateurs. Here you'll find simple verticals and dipoles, as well as quad and Yagi projects and other antennas that you can build and use.

ANTENNA POLARIZATION

Most HF-band antennas are either vertically or horizontally polarized. Although circular polarization is possible, just as it is at VHF and UHF, it is seldom used at HF. *Polarization* is determined by the position of the radiating element or wire with respect to the earth. Thus a radiator that is parallel to the earth radiates horizontally, while a vertical antenna radiates a vertical wave. If a wire antenna is slanted above earth, it radiates waves that have both a vertical and a horizontal component.

For best results in line-of-sight communications, antennas at both ends of the circuit should have the same polarization; cross polarization results in many decibels of signal reduction. However, it is not essential for both stations to use the same antenna polarity for ionospheric propagation (sky wave). This is because the radiated wave is bent and it tumbles considerably during its travel through the ionosphere. At the far end of the communications path the wave may be horizontal, vertical or somewhere in between at any given instant. For that reason, the main consideration for a good DX antenna is a low angle of radiation rather than the polarization.

ANTENNA BANDWIDTH

The *bandwidth* of an antenna refers generally to the range of frequencies over which the antenna can be used to obtain a specified level of performance. The band-

width is often referenced to some SWR value, such as, "The 2:1 *SWR bandwidth* is 3.5 to 3.8 MHz." Popular amateur usage of the term bandwidth most often refers to the 2:1 SWR bandwidth. Other specific bandwidth terms are also used, such as the *gain bandwidth* and the *front-to-back ratio bandwidth*.

For the most part, the lower the operating frequency of a given antenna design, the narrower is the bandwidth. This follows the rule that the bandwidth of a resonant circuit doubles as the frequency of operation is doubled, assuming the Q is the same for each case. Therefore, it is often difficult to cover all of the 160 or 80-m band for a particular level of SWR with a dipole antenna. It is important to recognize that SWR bandwidth does not always relate directly to gain bandwidth. Depending on the amount of feed-line loss, an 80-m dipole with a relatively narrow 2:1 SWR bandwidth can still radiate a good signal at each end of the band, provided that an antenna tuner is used to allow the transmitter to load properly. Broadbanding techniques, such as fanning the far ends of a dipole to simulate a conical type of dipole, can help broaden the SWR response curve.

CURRENT AND VOLTAGE DISTRIBUTION

When power is fed to an antenna, the current and voltage vary along its length. The current is nearly zero (a current *node*) at the ends. The current does not actually reach zero at the current nodes, because of capacitance at the antenna ends. Insulators, loops at the antenna ends, and support wires all contribute to this capacitance, which is also called the *end effect*. In the case of a half-wave antenna there is a current maximum (a current *loop*) at the center.

The opposite is true of the RF voltage.

That is, there is a voltage loop at the ends, and in the case of a half-wave antenna there is a voltage minimum (node) at the center. The voltage is not zero at its node because of the resistance of the antenna, which consists of both the RF resistance of the wire (ohmic loss resistance) and the *radiation resistance*. The radiation resistance is the equivalent resistance that would dissipate the power the antenna radiates, with a current flowing in it equal to the antenna current at a current loop (maximum). The loss resistance of a half-wave antenna is ordinarily small, compared with the radiation resistance, and can usually be neglected for practical purposes.

IMPEDANCE

The *impedance* at a given point in the antenna is determined by the ratio of the voltage to the current at that point. For example, if there were 100 V and 1.4 A of RF current at a specified point in an antenna and if they were in phase, the impedance would be approximately 71 Ω .

Antenna impedance may be either resistive or complex (that is, containing resistance and reactance). This will depend on whether or not the antenna is *resonant* at the operating frequency. You need to know the impedance in order to match the feeder to the feedpoint. Some operators mistakenly believe that a mismatch, however small, is a serious matter. This is not true. The importance of a matched line is described in detail in the **Transmission Lines** chapter of this book. The significance of a perfect match becomes more pronounced only at VHF and higher, where feed-line losses are a major factor.

Some antennas possess a theoretical input impedance at the feedpoint close to that of certain transmission lines. For example, a 0.5- λ (or half-wave) center-fed dipole,

Fig 22.1 — Curves showing the radiation resistance of vertical and horizontal half-wavelength dipoles at various heights above ground. The broken-line portion of the curve for a horizontal dipole shows the resistance over average real earth, the solid line for perfectly conducting ground.

Fig 22.2 — Effect of antenna diameter on length for half-wavelength resonance, shown as a multiplying factor, K, to be applied to the free-space, half-wavelength equation.

placed at a correct height above ground, will have a feedpoint impedance of approximately 75 Ω. In such a case it is practical to use a 75-Ω coaxial or balanced line to feed the antenna. But few amateur half-wave dipoles actually exhibit a 75-Ω impedance. This is because at the lower end of the high-frequency spectrum the typical height above ground is rarely more than 1/4 λ. The 75-Ω feed-point impedance is most likely to be realized in a practical installation when the horizontal dipole is approximately 1/2, 3/4 or 1 wavelength above ground. Coax cable having a 50-Ω characteristic impedance is the most common transmission line used in amateur work.

Fig 22.1 shows the difference between the effects of perfect ground and typical earth at low antenna heights. The effect of height on the radiation resistance of a horizontal half-wave antenna is not drastic so long as the height of the antenna is greater

than 0.2 λ. Below this height, while decreasing rapidly to zero over perfectly conducting ground, the resistance decreases less rapidly with height over actual ground. At lower heights the resistance stops decreasing at around 0.15 λ, and thereafter increases as height decreases further. The reason for the increasing resistance is that more and more of the induction field of the antenna is absorbed by the earth as the height drops below 1/4 λ.

CONDUCTOR SIZE

The impedance of the antenna also depends on the diameter of the conductor in relation to the wavelength, as indicated in Fig 22.2. If the diameter of the conductor

is increased, the capacitance per unit length increases and the inductance per unit length decreases. Since the radiation resistance is affected relatively little, the decreased L/C ratio causes the Q of the antenna to decrease so that the resonance curve becomes less sharp with change in frequency. This effect is greater as the diameter is increased, and is a property of some importance at the very high frequencies where the wavelength is small.

DIRECTIVITY AND GAIN

All antennas, even the simplest types, exhibit directive effects in that the intensity of radiation is not the same in all directions from the antenna. This property

of radiating more strongly in some directions than in others is called the *directivity* of the antenna.

The *gain* of an antenna is closely related to its directivity. Because directivity is based solely on the shape of the directive pattern, it does not take into account any power losses that may occur in an actual antenna system. Gain takes those losses into account.

Gain is usually expressed in decibels, and is based on a comparison with a *standard* antenna—usually a dipole or an *isotropic radiator*. An isotropic radiator is a theoretical antenna that would, if placed in the center of an imaginary sphere, evenly illuminate that sphere with radiation. The isotropic radiator is an unambiguous standard, and for that reason frequently used as the comparison for gain measurements. When the standard is the isotropic radiator in free space, gain is expressed in dBi. When the standard is a dipole, *also located in free space*, gain is expressed in dBd.

The more the directive pattern is compressed—or focused—the greater the power gain of the antenna. This is a result of power being concentrated in some directions at the expense of others. The directive pattern, and therefore the gain, of an antenna at a given frequency is determined by the size and shape of the antenna, and on its position and orientation relative to the Earth.

ELEVATION ANGLE

For long-distance HF communication, the (vertical) *elevation angle* of maximum radiation is of considerable importance. You will want to erect your antenna so that it radiates at desirable angles. **Tables 22.1, 22.2 and 22.3** show optimum elevation angles from locations in the continental US. These figures are based on statistical averages over all portions of the solar sunspot cycle.

Since low angles usually are most

Fig 22.3 — Elevation patterns for two 40-m dipoles over average ground (conductivity of 5 mS/m and dielectric constant of 13) at $\frac{1}{4} \lambda$ (33 ft) and $\frac{1}{2} \lambda$ (66 ft) heights. The higher dipole has a peak gain of 7.1 dBd at an elevation angle of about 26° , while the lower dipole has more response at high elevation angles.

Fig 22.4 — Elevation patterns for a vertical dipole over sea water compared to average ground. In each case the center of the dipole is just over $\frac{1}{4} \lambda$ high. The low-angle response is greatly degraded over average ground compared to sea water, which is virtually a perfect ground.

effective for long distance communications, this generally means that horizontal antennas should be high—higher is usually better. Experience shows that satisfactory results can be attained on the bands above 14 MHz with antenna heights between 40 and 70 ft. **Fig 22.3** shows this effect at work in horizontal dipole antennas.

The higher angles can be useful for medium to short-range communications. Dean Straw, N6BV, illustrates this in *The ARRL Antenna Book*. Straw shows that elevation angles between 20° and 65° are useful on the 40 and 80-m bands over the roughly 550-mile path between Cleveland and Boston. Even higher angles may be useful on shorter paths when using these lower HF frequencies. A 75-m dipole between 30 and 70 ft high works well for ranges out to several hundred miles. See the **Propagation of RF Signals** chapter.

IMPERFECT GROUND

Earth conducts, but is far from being a perfect conductor. This influences the radiation pattern of the antennas that we use. The effect is most pronounced at high vertical angles (the ones that we're least interested in for long-distance communications) for horizontal antennas. The consequences for vertical antennas are greatest at low angles, and are quite dramatic as can be clearly seen in **Fig 22.4**, where the elevation pattern for a 40-m vertical half-wave dipole located over average ground is compared to one located over saltwater. At 10° elevation, the saltwater antenna has about 7 dB more gain than its landlocked counterpart.

An HF vertical antenna may work very well for a ham living in the area between Dallas, Texas and Lincoln, Nebraska. This area is pastoral, has low hills, and rich soil. Ground of this type has very good conductivity. By contrast, a ham living in New Hampshire, where the soil is rocky and a poor conductor, may not be satisfied with the performance of a vertical HF antenna.

Dipoles and the Half-Wave Antenna

A fundamental form of antenna is a wire whose length is half the transmitting wavelength. It is the unit from which many more complex forms of antennas are constructed and is known as a *dipole antenna*. The length of a half-wave in free space is

$$\text{Length (ft)} = \frac{492}{f \text{ (MHz)}} \quad (1)$$

The actual length of a resonant $\frac{1}{2}\lambda$ antenna will not be exactly equal to the half wavelength in space, but depends on the thickness of the conductor in relation to the wavelength. The relationship is shown in Fig 22.2, where K is a factor that must be multiplied by the half wavelength in free space to obtain the resonant antenna length. An additional shortening effect occurs with wire antennas supported by insulators at the ends because of the capacitance added to the system by the insulators. This shortening is called end effect. The following formula is sufficiently accurate for wire antennas for frequencies up to 30 MHz.

Length of half-wave antenna (ft)

$$= \frac{492 \times 0.95}{f \text{ (MHz)}} = \frac{468}{f \text{ (MHz)}} \quad (2)$$

Example: A half-wave antenna for 7150 kHz (7.15 MHz) is $468/7.15 = 65.45$ ft, or 65 ft 5 inches.

Above 30 MHz use the following formulas, particularly for antennas constructed from rod or tubing. K is taken from Fig 22.2.

$$\text{Length (ft)} = \frac{492 \times K}{f \text{ (MHz)}} \quad (3)$$

$$\text{Length (in)} = \frac{5904 \times K}{f \text{ (MHz)}} \quad (4)$$

Example: Find the length of a half-wave antenna at 50.1 MHz, if the antenna is made of $\frac{1}{2}$ -inch-diameter tubing. At 50.1 MHz, a half wavelength in space is

$$\frac{492}{50.1} = 9.82 \text{ ft}$$

The ratio of half wavelength to conductor diameter (changing wavelength to inches) is

$$\frac{(9.82 \text{ ft} \times 12 \text{ in/ft})}{0.5 \text{ in}} = 235.7$$

From Fig 22.2, $K = 0.945$ for this ratio. The length of the antenna, from equation 3 is

$$\frac{492 \times 0.945}{50.1} = 9.28 \text{ ft}$$

or 9 ft $3\frac{3}{8}$ inches. The answer is obtained directly in inches by substitution in equation 4

$$\frac{5904 \times 0.945}{50.1} = 111.4 \text{ in}$$

The length of a half-wave antenna is also affected by the proximity of the dipole ends to nearby conductive and semiconductive objects. In practice, it is often necessary to do some experimental *pruning* of the wire after cutting the antenna to the computed length, lengthening or shortening it in increments to obtain a low SWR. When the lowest SWR is obtained for the desired part of an amateur band, the antenna is resonant at that frequency. The value of the SWR indicates the quality of the match between the antenna and the feed line. If the lowest SWR obtainable is too high for use with solid-state rigs, a Transmatch or line-input matching network may be used, as described in the **Transmission Lines** chapter.

RADIATION CHARACTERISTICS

The radiation pattern of a dipole antenna in free space is strongest at right angles to the wire (Fig 22.5). This figure-8 pattern appears in the real world if the

Fig 22.5 — Response of a dipole antenna in free space, where the conductor is along 90° to 270° axis, solid line. If the currents in the halves of the dipole are not in phase, slight distortion of the pattern will occur, broken line. This illustrates the case where a balun is not used on a balanced antenna fed with unbalanced line.

dipole is $\frac{1}{2}\lambda$ or greater above earth and is not degraded by nearby conductive objects. This assumption is based also on a symmetrical feed system. In practice, a coaxial feed line may distort this pattern slightly, as shown in Fig 22.5. Minimum horizontal radiation occurs off the ends of the dipole if the antenna is parallel to the earth.

As a horizontal antenna is brought closer to ground, the elevation pattern peaks at a higher elevation angle as shown in Fig 22.3. Fig 22.6 illustrates what hap-

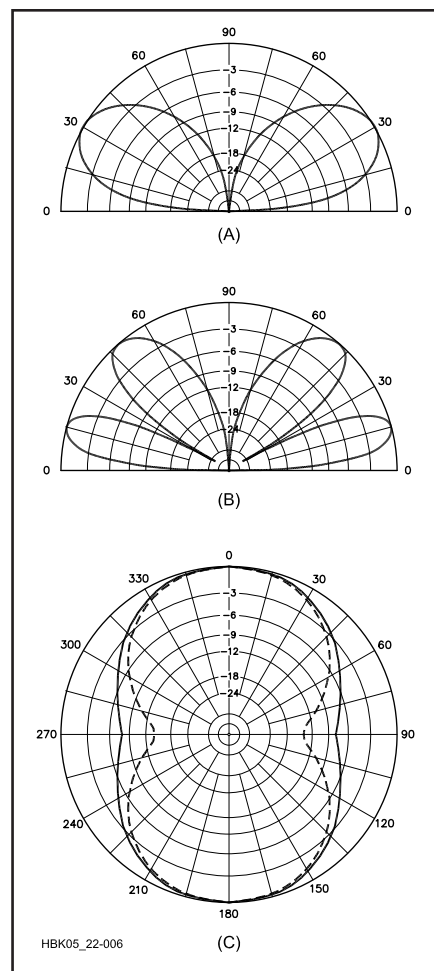

Fig 22.6 — At A, elevation response pattern of a dipole antenna placed $\frac{1}{2}\lambda$ above a perfectly conducting ground. At B, the pattern for the same antenna when raised to one wavelength. For both A and B, the conductor is coming out of the paper at right angle. C shows the azimuth patterns of the dipole for the two heights at the most-favored elevation angle, the solid-line plot for the $\frac{1}{2}\lambda$ height at an elevation angle of 30° , and the broken-line plot for the 1λ height at an elevation angle of 15° . The conductor in C lies along 90° to 270° axis.

pens to the directional pattern as antenna height changes. Fig 22.6C shows that there is significant radiation off the ends of a low horizontal dipole. For the $\frac{1}{2}\lambda$ height (solid line), the radiation off the ends is only 7.6 dB lower than that in the broadside direction.

FEED METHODS

Most amateurs use either *coax* or *open-wire* transmission line. Coax is the common choice because it is readily available, its characteristic impedance is close to that of the antenna and it may be easily routed through or along walls and among other cables. The disadvantages of coax are increased RF loss and low working voltage (compared to that of open-wire line). Both disadvantages make coax a poor choice for high-SWR systems.

Take care when choosing coax. Use $\frac{1}{4}$ -inch foam-dielectric cables only for low power (25 W or less) HF transmissions. Solid-dielectric $\frac{1}{4}$ -inch cables are okay for 300 W if the SWR is low. For high-power installations, use $\frac{1}{4}$ -inch or larger cables.

The most common two-wire transmission lines are *ladder line* and *twin lead*. Since the conductors are not shielded, two-wire lines are affected by their environment. Use standoffs and insulators to keep the line several inches from structures or other conductors. Ladder line has very low loss (twin lead has a little more), and it can stand very high voltages (high SWR) as long as the insulators are clean.

Two-wire lines are usually used in balanced systems, so they should have a balun at the transition to an unbalanced transmitter or coax. A Transmatch will be needed to match the line input impedance to the transmitter.

BALUNS

A balun is a device for feeding a balanced load with an unbalanced line, or vice versa (see the Transmission Lines chapter of this book). Because dipoles are balanced (electrically symmetrical about their feed-points), a balun is often used at the feed-point when a dipole is fed with coax. When coax feeds a dipole directly (as in Fig 22.7), current flows on the outside of the cable shield. The shield can conduct RF onto the transmitter chassis and induce RF onto metal objects near the system. Shield currents can impair the function of instruments connected to the line (such as SWR meters and SWR-protection circuits in the transmitter). The shield current also produces some feed-line radiation, which changes the antenna radiation pattern, and allows objects near the cable to affect the antenna-system performance.

Fig 22.7 — Method of affixing feed line to the center of a dipole antenna. A plastic block is used as a center insulator. The coax is held in place by a clamp. A balun is often used to feed dipoles or other balanced antennas to ensure that the radiation pattern is not distorted. See text for explanation.

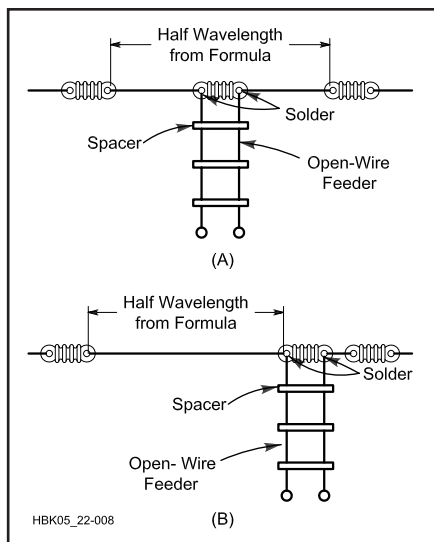

Fig 22.8 — Center-fed multiband Zepp antenna at A and an end-fed Zepp at B. See also Fig 22.11 for connection details.

The consequences may be negligible: A slight skewing of the antenna pattern usually goes unnoticed. Or, they may be significant: False SWR readings may cause the transmitter to shut down or destroy the output transistors; radiating coax near a TV feed line may cause strong local interference. Therefore, it is better to eliminate feed-line radiation whenever possible, and a balun should be used at any transition between balanced and unbalanced systems. (The **Transmission Lines** chapter thoroughly describes baluns and their construction.) Even so, balanced or unbalanced systems without a balun often operate with no apparent problems. For temporary or emergency stations, do not let the lack of a balun deter you from operating.

PRACTICAL DIPOLE ANTENNAS

A classic dipole antenna is $\frac{1}{2}\lambda$ long and

fed at the center. The feed-point impedance is low at the resonant frequency, f_0 , and odd harmonics thereof. (The impedance is high near even harmonics.) When fed with coax, a classic dipole provides a reasonably low SWR at f_0 and its odd harmonics.

When fed with ladder line (see Fig 22.8A) and a Transmatch, the classic dipole should be usable near f_0 and all harmonic frequencies. (With a wide-range Transmatch, it may work on all frequencies.) If there are problems (such as extremely high SWR or evidence of RF on objects at the operating position), change the feed-line length by adding or subtracting $\frac{1}{8}\lambda$ at the problem frequency. A few such adjustments should yield a workable solution. Such a system is sometimes called a *center-fed Zepp*. A true *Zepp* antenna is an end-fed dipole that is matched by $\frac{1}{4}\lambda$ of open-wire feed line (see Fig 22.8B). The antenna was originally used on zeppelins, with the dipole trailing from the feeder, which hung from the airship cabin. It is intended for use on a single band, but should be usable near odd harmonics of f_0 .

Most dipoles require a little pruning to reach the desired resonant frequency. So, cut the wire 2 to 3% longer than the calculated length and record the length. Next, raise the dipole to the working height and check the SWR at several frequencies. Multiply the frequency of the SWR minimum by the antenna length and divide the result by the desired f_0 . The result is the finished length; trim both ends equally to reach that length and you're done.

BUILDING DIPOLE AND OTHER WIRE ANTENNAS

The purpose of this section is to offer information on the actual physical construction of wire antennas. Because the dipole, in one of its configurations, is probably the most common amateur wire antenna, it is used in the following examples. The techniques described here, however, enhance the reliability and safety of all wire antennas.

Wire

Choosing the right type of wire for the project at hand is the key to a successful antenna—the kind that works well and stays up through a winter ice storm or a gusty spring wind storm. What gauge of wire to use is the first question to settle, and the answer depends on strength, ease of handling, cost, availability and visibility. Generally, antennas that are expected to support their own weight, plus the weight of the feed line should be made from #12 wire. Horizontal dipoles, Zepps,

some long wires and the like fall into this category. Antennas supported in the center, such as inverted-V dipoles and delta loops, may be made from lighter material, such as #14 wire—the minimum size called for in the National Electrical Code.

The type of wire to be used is the next important decision. The wire specifications table in the **Component Data and References** chapter shows popular wire styles and sizes. The strongest wire suitable for antenna service is *copperclad steel*, also known as *copperweld*. The copper coating is necessary for RF service because steel is a relatively poor conductor. Practically all of the RF current is confined to the copper coating because of *skin effect*. Copper-clad steel is outstanding for permanent installations, but it can be difficult to work with. Kinking, which severely weakens the wire, is a potential problem when handling any solid conductor. Solid-copper wire, either hard drawn or soft drawn, is another popular material. Easier to handle than copper-clad steel, solid copper is available in a wide range of sizes. It is generally more expensive however, because it is all copper. Soft drawn tends to stretch under tension, so periodic pruning of the antenna may be necessary in some cases. Enamel-coated *magnet-wire* is a suitable choice for experimental antennas because it is easy to manage, and the coating protects the wire from the weather. Although it stretches under tension, the wire may be prestretched before final installation and adjustment. A local electric motor rebuilder might be a good source for magnet wire.

Hook-up wire, speaker wire or even ac lamp cord are suitable for temporary installations. Almost any copper wire may be used, as long as it is strong enough for the demands of the installation. Steel wire is a poor conductor at RF; avoid it.

It matters not (in the HF region at least) whether the wire chosen is insulated or bare. If insulated wire is used, a 3 to 5% shortening beyond the standard $468/f$ length will be required to obtain resonance at the desired frequency. This is caused by the increased distributed capacitance resulting from the dielectric constant of the plastic insulating material. The actual length for resonance must be determined experimentally by pruning and measuring because the dielectric constant of the insulating material varies from wire to wire. Wires that might come into contact with humans or animals should be insulated to reduce the chance of shock or burns.

Insulators

Wire antennas must be insulated at the ends. Commercially available insulators

are made from ceramic, glass or plastic. Insulators are available from many Amateur Radio dealers. RadioShack and local hardware stores are other possible sources.

Acceptable homemade insulators may be fashioned from a variety of material including (but not limited to) acrylic sheet or rod, PVC tubing, wood, fiberglass rod or even stiff plastic from a discarded container. **Fig 22.9** shows some homemade insulators. Ceramic or glass insulators will usually outlast the wire, so they are highly recommended for a safe, reliable, permanent installation. Other materials may tear under stress or break down in the presence of sunlight. Many types of plastic do not weather well.

Many wire antennas require an insulator at the feedpoint. Although there are many ways to connect the feed line, there are a few things to keep in mind. If you feed your antenna with coaxial cable, you have two choices. You can install an SO-239 connector on the center insulator and use a PL-259 on the end of your coax,

or you can separate the center conductor from the braid and connect the feed line directly to the antenna wire. Although it costs less to connect direct, the use of connectors offers several advantages.

Coaxial cable braid soaks up water. If you do not adequately seal the antenna end of the feed line, water will find its way into the braid. Water in the feed line will lead to contamination, rendering the coax useless long before its normal lifetime is up. It is not uncommon for water to drip from the end of the coax inside the shack after a year or so of service if the antenna connection is not properly waterproofed. Use of a PL-259/SO-239 combination (or other connector of your choice) makes the task of waterproofing connections much easier. Another advantage to using the PL-259/SO-239 combination is that feed line replacement is much easier, should that become necessary or desirable.

Whether you use coaxial cable, ladder line, or twin lead to feed your antenna, an often-overlooked consideration is the mechanical strength of the connection.

Fig 22.9 — Some ideas for homemade antenna insulators.

Fig 22.10 — Some homemade dipole center insulators. The one in the center includes a built-in SO-239 connector. Others are designed for direct connection to the feed line. (See the Transmission Lines chapter for details on baluns.)

Fig 22.11 — A piece of cut Plexiglas can be used as a center insulator and to support a ladder-line feeder. The Plexiglas acts to reduce the flexing of the wires where they connect to the antenna.

Wire antennas and feed lines tend to move a lot in the breeze, and unless the feed line is attached securely, the connection will weaken with time. The resulting failure can range from a frustrating intermittent electrical connection to a complete separation of feed line and antenna. **Fig 22.10**

illustrates several different ways of attaching the feed line to the antenna. An idea for supporting ladder line is shown in **Fig 22.11**.

Putting It Together

Fig 22.12 shows details of antenna con-

Table 22.4
Dipole Dimensions for Amateur Bands

Freq MHz	Overall Length	Leg Length
28.4	16' 6"	8' 3"
24.9	18' 9 1/2"	9' 4 3/4"
21.1	22' 2"	11' 1"
18.1	25' 10"	12' 11"
14.1	33' 2"	16' 7"
10.1	46' 4"	23' 2"

5.37	87' 2"	43' 7"
3.6	130' 0"	65' 0"

struction. Although a dipole is used for the examples, the techniques illustrated here apply to any type of wire antenna. **Table 22.4** shows dipole lengths for the amateur HF bands.

How well you put the pieces together is second only to the ultimate strength of the materials used in determining how well your antenna will work over the long term. Even the smallest details, such as how you connect the wire to the insulators (**Fig 22.12A**), contribute significantly to antenna longevity. By using plenty of wire at the insulator and wrapping it tightly, you will decrease the possibility of the wire pulling loose in the wind. There is no need to solder the wire once it is wrapped. There is no electrical connection here, only mechanical. The high

Fig 22.12 — Details of dipole antenna construction. The end insulator connection is shown at A, while B illustrates the completed antenna. This is a balanced antenna and is often fed with a balun.

heat needed for soldering can anneal the wire, significantly weakening it at the solder point.

Similarly, the feed-line connection at the center insulator should be made to the antenna wires after they have been secured to the insulator (Fig 22.12B). This way, you will be assured of a good electrical connection between the antenna and feed line without compromising the mechanical strength. Do a good job of soldering the antenna and feed-line connections. Use a heavy iron or a torch, and be sure to clean the materials thoroughly before starting the job. Proper planning should allow you to solder indoors at a workbench, where the best possible joints may be made. Poorly soldered or unsoldered connections will become headaches as the wire oxidizes and the electrical integrity degrades with time. Besides degrading your antenna performance, poorly made joints can even be a cause of TVI because of rectification. Spray paint the connections with acrylic for waterproofing.

If made from the right materials, the dipole should give a builder years of maintenance-free service—unless of course a tree falls on it. As you build your antenna, keep in mind that if you get it right the first time, you won't have to do it again for a long time.

SHORTENED DIPOLES

Inductive loading increases the electrical length of a conductor without increasing its physical length. Therefore, we can build physically short dipole antennas by placing inductors in the antenna. These are called *loaded antennas*, and *The ARRL Antenna Book* shows how to design them. There are some trade-offs involved: Inductively loaded antennas are less efficient and have narrower bandwidths than full-size antennas. Generally they should not be shortened more than 50%.

DIPOLE ORIENTATION

Dipole antennas need not be installed horizontally and in a straight line. They are generally tolerant of bending, sloping or drooping. Bent dipoles may be used where antenna space is at a premium. Fig 22.13 shows a couple of possibilities; there are many more. Bending distorts the radiation pattern somewhat and may affect the impedance as well, but compromises may be acceptable when the situation demands them. Remember that dipole antennas are RF conductors. For safety's sake, mount all antennas away from conductors (especially power lines), combustibles and well beyond the reach of passersby. When an antenna bends back on itself (as in Fig 22.13B) some of the

Fig 22.13 — When limited space is available for a dipole antenna, the ends can be bent downward as shown at A, or back on the radiator as shown at B. The inverted V at C can be erected with the ends bent parallel with the ground when the available supporting structure is not high enough.

signal is canceled; avoid this if possible.

DROOPING DIPOLE

A drooping dipole, also known as an *Inverted V dipole*, appears in Fig 22.14. While V describes the shape of this antenna, this antenna should not be confused with long-wire V antennas, which are highly directive. The radiation pattern and dipole impedance depend on the apex angle, and it is very important that the ends do not come too close to lossy ground. Remember that current produces the radiated signal, and current is maximum at the dipole center. Therefore, performance is best when the central area of the antenna is straight, high and clear of nearby objects.

SLOPING DIPOLE

A sloping dipole is shown in Fig 22.15. This antenna is often used to favor one direction (the *forward direction* in the figure). With a nonconducting support and poor earth, signals off the back are weaker than those off the front. With a nonconducting mast and good earth, the response is omnidirectional. There is no gain in any direction with a nonconducting mast.

A conductive support such as a tower

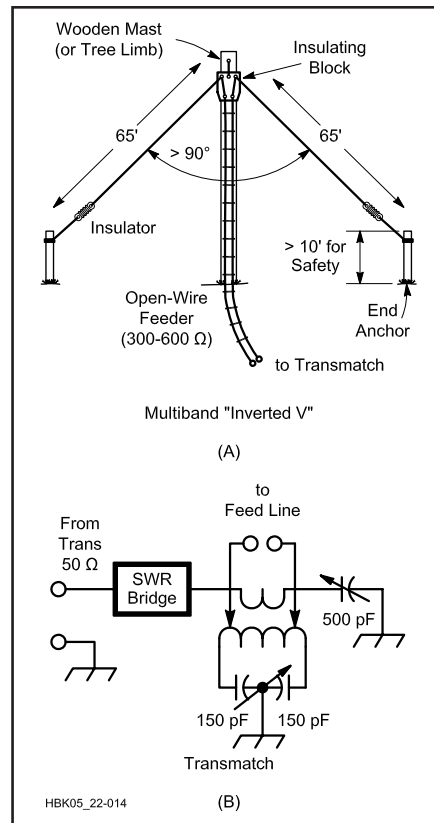

Fig 22.14 — At A, details for an inverted V fed with open-wire line for multiband HF operation. A Transmatch is shown at B, suitable for matching the antenna to the transmitter over a wide frequency range. The included angle between the two legs should be greater than 90° for best performance.

Fig 22.15 — Example of a sloping $\frac{1}{2}\lambda$ dipole, or *full sloper*. On the lower HF bands, maximum radiation over poor to average earth is off the sides and in the *forward direction* as indicated, if a non-conductive support is used. A metal support will alter this pattern by acting as a parasitic element. How it alters the pattern is a complex issue depending on the electrical height of the mast, what other antennas are located on the mast, and on the configuration of any guy wires.

acts as a parasitic element. (So does the coax shield, unless it is routed at 90° from the antenna.) The parasitic effects vary with earth quality, support height and other conductors on the support (such as a beam at the top). With such variables, performance is very difficult to predict.

Losses increase as the antenna ends approach the support or the ground. To prevent feed-line radiation, route the coax away from the feed-point at 90° from the antenna, and continue on that line as far as possible.

HALF-WAVE VERTICAL DIPOLE (HVD)

Unlike its horizontal counterpart, which has a figure-8 pattern, the azimuthal pattern of a vertical dipole is omnidirectional. In other words, it looks like a circle. Look again at Figs 22.3 and 22.4 and note the comparison between horizontal and

vertical dipole elevation patterns. These two figures illustrate the fact that performance of a horizontal dipole depends to a great extent on its height above ground. By contrast, *half-wave vertical dipole* (HVD) performance is highly dependent on ground conductivity and dielectric constant.

After looking at these figures, you might easily conclude that there is no advantage to an HVD. Is that really the case? Experiments at K8CH run between 2001 and 2003 showed that the HVD mounted above average ground works well for long-distance (DX) contacts. Two antennas were used in the trials. The first was a 15-m HVD with its base 14 ft above ground (feedpoint at 25 ft). The second (reference) antenna was a 40-m dipole modified to operate with low SWR on 15 m. The reference dipole feedpoint was at 29 feet and the ends drooped slightly to provide a

160° included angle. Signals from outside North America were usually stronger on the HVD. Computer analysis revealed the reasons for this.

Fig 22.16 shows the elevation patterns for the vertical dipole and for the reference dipole at a pattern peak and at a null. The vertical dipole does not look impressive, does it? The large lobe in the HVD pattern at 48° is caused by the antenna being elevated 14 ft above ground. This lobe will shrink at lower heights.

Data compiled by Dean Straw, N6BV, shows that 90% of DX contacts from K8CH should use elevation angles of 10° or less. Further, nearly half of the contacts would use 3° or less. The azimuthal patterns for 10° are shown in **Fig 22.17** and for 3° in **Fig 22.18**. You can clearly see in the patterns the DX potential of an HVD.

Another advantage of the HVD is its radiation resistance at low heights. Look back in Fig 22.1 at the curve for the vertical half-wave antenna. With its base just above ground, the HVD will have a radiation resistance of over 90 Ω. That can easily be turned to an advantage. Capacitive loading will lower the radiation resistance and shorten the antenna. It is possible to make a loaded vertical dipole that is half the height of an HVD and that has a good SWR when fed with 50-Ω coax.

MULTIBAND DIPOLES

There are several ways to construct coax-fed multiband dipole systems. These techniques apply to dipoles of all orientations. Each method requires a little more

Fig 22.16 — Elevation patterns for the HVD (solid line) and the inverted V comparison antenna in its best case (dashed line) and worst case (dotted line).

Fig 22.17 — Azimuth patterns at 10° elevation for the HVD (dashed line) and inverted V (solid line).

Fig 22.18 — Azimuth patterns at 3° elevation for the HVD (dashed line) and the inverted V (solid line).

Fig 22.19 — Multiband antenna using paralleled dipoles, all connected to a common 50 or 75-Ω coax line. The half-wave dimensions may be either for the centers of the various bands or selected for favorite frequencies in each band. The length of a half wave in feet is $468/\text{frequency in MHz}$, but because of interaction among the various elements, some pruning for resonance may be needed on each band. See text.

Fig 22.20 — Example of a trap dipole antenna. L1 and C1 can be tuned to the desired frequency by means of a dip meter *before* they are installed in the antenna.

work than a single dipole, but the materials don't cost much.

Paralleled dipoles are a simple and convenient answer. See **Fig 22.19**. Center-fed dipoles present low-impedances near f_0 , or its odd harmonics, and high impedances elsewhere. This lets us construct simple multiband systems that automatically select the appropriate antenna. Consider a 50-Ω resistor connected in parallel with a 5-kΩ resistor. A generator connected across the two resistors will see 49.5 Ω, and 99% of the current will flow through the 50-Ω resistor. When resonant and nonresonant antennas are parallel connected, the nonresonant antenna takes

little power and has little effect on the total feed-point impedance. Thus, we can connect several antennas together at the feed-point, and power naturally flows to the resonant antenna.

There are some limits, however. Wires in close proximity tend to couple and produce mutual inductance. In parallel dipoles, this means that the resonant length of the shorter dipoles lengthens a few percent. Shorter antennas don't affect longer ones much, so adjust for resonance in order from longest to shortest. Mutual inductance also reduces the bandwidth of shorter dipoles, so a Transmatch may be needed to achieve an acceptable SWR across all bands cov-

ered. These effects can be reduced by spreading the ends of the dipoles.

Also, the power-distribution mechanism requires that only one of the parallel dipoles is near resonance on any amateur band. Separate dipoles for 80 and 30 m should not be parallel connected because the higher band is near an odd harmonic of the lower band ($80/3 \approx 30$) and center-fed dipoles have low impedance near odd harmonics. (The 40 and 15-m bands have a similar relationship.) This means that you must either accept the lower performance of the low-band antenna operating on a harmonic or erect a separate antenna for those odd-harmonic bands. For example, four parallel-connected dipoles cut for 80, 40, 20 and 10 m (fed by a single Transmatch and coaxial cable) work reasonably on all HF bands from 80 through 10 m.

Trap dipoles provide multiband operation from a coax-fed single-wire dipole. **Fig 22.20** shows a two-band trap antenna. A trap comprises inductance and capacitance in parallel. At resonance that effectively disconnects wire beyond the trap at the resonant frequency. Above resonance, traps provide capacitive loading. Below resonance, they provide inductive loading. Traps may be constructed from coiled sections of coax or from discrete LC components.

Choose capacitors (C1 in the figure) that are rated for high current and voltage. Mica transmitting capacitors are good. Ceramic transmitting capacitors may work, but their values may change with temperature. Use large wire for the inductors to reduce loss. Any reactance (X_L and X_C) above 100 Ω (at f_0) will work, but bandwidth increases with reactance (up to several thousand ohms).

Check trap resonance before installation. This can be done with a dip meter and a receiver. To construct a trap antenna, cut a dipole for the highest frequency and connect the pretuned traps to its ends. It is fairly complicated to calculate the additional wire needed for each band, so just add enough wire to make the antenna $1/2 \lambda$ and prune it as necessary. Because the inductance in each trap reduces the physical length needed for resonance, the finished antenna will be shorter than a simple $1/2\text{-}\lambda$ dipole.

A 135-FT MULTIBAND CENTER-FED DIPOLE

An 80-m dipole fed with ladder line is a versatile antenna. If you add a wide-range matching network, you have a low-cost antenna system that works well across the entire HF spectrum. Countless hams have used one of these in single-antenna stations and for Field Day operations.

For best results place the antenna as high as you can, and keep the antenna and ladder line clear of metal and other conductive objects. Despite significant SWR on some bands, system losses are low. (See the **Transmission Lines** chapter.) You can

make the dipole horizontal, or you can install it as an inverted V. ARRL staff analyzed a 135-ft dipole at 50 ft above typical ground and compared that to an inverted V with the center at 50 ft, and the ends at 10 ft. The results show that on the 80-m band, it won't make much difference which configuration you choose. (See **Fig 22.21**.) The inverted V exhibits additional losses because of its proximity to ground.

Fig 22.22 shows a comparison between a 20-m flat-top dipole and the 135-ft flat-top dipole when both are placed at 50 ft

above ground. At a 10° elevation angle, the 135-ft dipole has a gain advantage. This advantage comes at the cost of two deep, but narrow, nulls that are broadside to the wire.

Fig 22.23 compares the 135-ft dipole to the inverted-V configuration of the same antenna on 14.1 MHz. Notice that the inverted-V pattern is essentially omnidirectional. That comes at the cost of gain, which is less than that for a horizontal flat-top dipole.

As expected, patterns become more

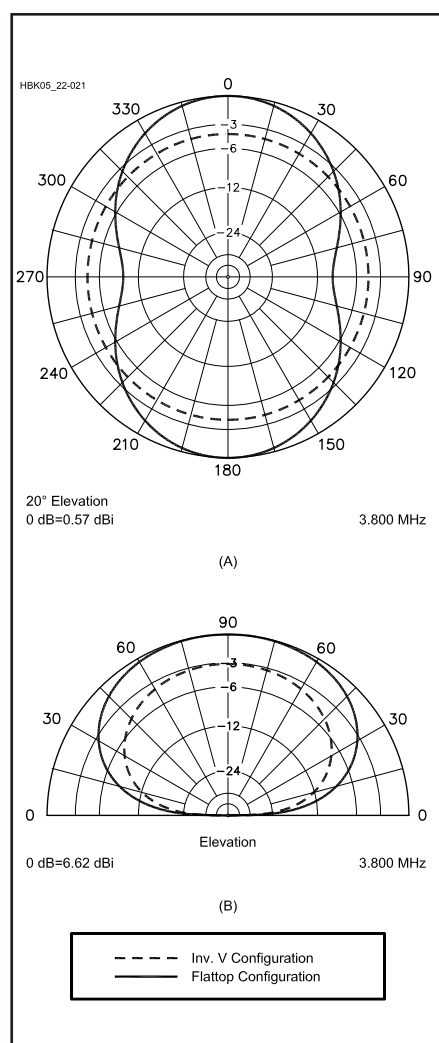

Fig 22.21 — Patterns on 80 m for 135-ft, center-fed dipole erected as a horizontal dipole at 50 ft, and as an inverted V with the center at 50 ft and the ends at 10 ft. The azimuth pattern is shown at A, where the conductor lies in the 90° to 270° plane. The elevation pattern is shown at B, where the conductor comes out of paper at a right angle. At the fundamental frequency the patterns are not markedly different.

Fig 22.22 — Patterns on 20 m comparing a standard $\frac{1}{2}\lambda$ dipole and a multiband 135-ft dipole. Both are mounted horizontally at 50 ft. The azimuth pattern is shown at A, where conductors lie in the 90° to 270° plane. The elevation pattern is shown at B. The longer antenna has four azimuthal lobes, centered at 35°, 145°, 215°, and 325°. Each is about 2 dB stronger than the main lobes of the $\frac{1}{2}\lambda$ dipole. The elevation pattern of the 135-ft dipole is for one of the four maximum-gain azimuth lobes, while the elevation pattern for the $\frac{1}{2}\lambda$ dipole is for the 0° azimuthal point.

Fig 22.23 — Patterns on 20 m for two 135-ft dipoles. One is mounted horizontally as a flat-top and the other as an inverted V with 120° included angle between the two legs. The azimuth pattern is shown at A, and the elevation pattern is shown at B. The inverted V has about 6 dB less gain at the peak azimuths, but has a more uniform, almost omnidirectional, azimuthal pattern. In the elevation plane, the inverted V has a fat lobe overhead, making it a somewhat better antenna for local communication, but not quite so good for DX contacts at low elevation angles.

Fig 22.24 — Patterns on 10 m for 135-ft dipole mounted horizontally and as an inverted V, as in Fig 22.23. The azimuth pattern is shown at A, and the elevation pattern is shown at B. Once again, the inverted-V configuration yields a more omnidirectional pattern, but at the expense of almost 8 dB less gain than the flat-top configuration at its strongest lobes.

complicated at 28.4 MHz. As you can see in Fig 22.24, the inverted V has the advantage of a pattern with slight nulls, but with reduced gain compared to the flat-top configuration.

Installed horizontally, or as an inverted V, the 135-ft center-fed dipole is a simple antenna that works well from 3.5 to 30 MHz. Bandswitching is handled by a Transmatch that is located near your operating position.

Antenna Modeling by Computer

Modern computer programs have made it a *lot* easier for a ham to evaluate antenna performance. The elevation plots for the 135-ft long center-fed dipole were generated using a sophisticated computer program known as *NEC*, short for “Numerical Electromagnetics Code.” *NEC* is a general-purpose antenna modeling program, capable of modeling almost any antenna type, from the simplest dipole to extremely complex antenna designs. Various mainframe versions of *NEC* have been under continuous development by US government researchers for several decades.

But because it is a general-purpose program, *NEC* can be very slow when modeling some antennas—such as long-boom, multi-element Yagis. There are other, specialized programs that work on Yagis much faster than *NEC*. Indeed, *NEC* has developed a reputation for being accurate (if properly applied!), but decidedly difficult to learn and use. A number of commercial software developers have risen to the challenge and created more *user-friendly* versions. Check the ads in *QST*.

NEC uses a *Method of Moments* algorithm. The mathematics behind this algorithm are pretty formidable to most hams, but the basic principle is simple. An antenna is broken down into a set of straight-line wire *segments*. The fields resulting from the current in each segment and from the mutual interaction between segments are vector-summed in the far field to create azimuth and elevation-plane patterns.

The most difficult part of using a *NEC*-type of modeling program is setting up the antenna's geometry—you must condition yourself to think in three-dimensional coordinates. Each end point of a wire is represented by three numbers: an x, y and z coordinate. An example should help sort things out. See Fig A, showing a *model* for a 135-foot center-fed dipole, made of #14 wire placed 50 ft above flat ground. This antenna is modeled as a single, straight wire.

For convenience, ground is located at the *origin* of the coordinate system, at (0, 0, 0) feet, directly under the center of the dipole. The dipole runs parallel to, and above, the y-axis. Above the origin, at a height of 50 feet, is the dipole's feedpoint. The *wingspread* of the dipole goes toward the left (that is, in the *negative y* direction) one-half the overall length, or -67.5 ft. Toward the right, it goes +67.5 ft. The x dimension of our dipole is zero. The dipole's ends are thus represented by two points, whose coordinates are: (0, -67.5, 50) and (0, 67.5, 50) ft. The thickness of the antenna is the diameter of the wire, #14 gauge.

To run the program you must specify the

number of segments into which the dipole is divided for the method-of-moments analysis. The guideline for setting the number of segments is to use at least 10 segments per half-wavelength. In Fig A, our dipole has been divided into 11 segments for 80-m operation. The use of 11 segments, an odd rather than an even number such as 10, places the dipole's feedpoint (the *source* in NEC-parlance) right at the antenna's center and at the center of segment number six.

Since we intend to use our 135-foot long dipole on all HF amateur bands, the number of segments used actually should vary with frequency. The penalty for using more segments in a program like *NEC* is that the program slows down roughly as the square of the segments—double the number and the speed drops to a fourth. However, using too few segments will introduce inaccuracies, particularly in computing the feed-point impedance. The commercial versions of *NEC* handle such nitty-gritty details automatically.

Let's get a little more complicated and specify the 135-ft dipole, configured as an inverted-V. Here, as shown in Fig B, you must specify *two* wires. The two wires join at the top, (0, 0, 50) ft. Now the specification of the source becomes more complicated. The easiest way is to specify two sources, one on each end segment at the junction of the two wires. If you are using the *native* version of *NEC*, you may have to go back to your high-school trigonometry book to figure out how to specify the end points of our droopy dipole, with its 120° included angle. Fig B shows the details, along with the trig equations needed.

So, you see that antenna modeling isn't entirely a cut-and-dried procedure. The commercial programs do their best to hide some of the more unwieldy parts of *NEC*, but there's still some art mixed in with the science. And as always, there are trade-offs to be made—segments versus speed, for example.

However, once you do figure out exactly how to use them, computer models are wonderful tools. They can help you while away a dreary winter's day, designing antennas on-screen—without having to risk life and limb climbing an ice-covered tower. And in a relatively short time a computer model can run hundreds, or even thousands, of simulations as you seek to

optimize an antenna for a particular parameter. Doesn't that sound better than trying to optimally tweak an antenna by means of a thousand cut-and-try measurements, all the while hanging precariously from your tower by a climbing belt?!—*R. Dean Straw, N6BV, Senior Assistant Technical Editor*

A 40-M AND 15-M DUAL-BAND DIPOLE

As mentioned earlier, dipoles have harmonic resonances at odd multiples of their fundamental resonances. Because 21 MHz is the third harmonic of 7 MHz, 7-MHz dipoles are harmonically resonant in the popular ham band at 21 MHz. This is attractive because it allows you to install a 40-m dipole, feed it with coax, and use it without an antenna tuner on both 40 and 15 m.

But there's a catch: The third harmonic resonance is actually higher than three times the fundamental resonant frequency. This is because there is no end effect in the center portion of the antenna.

An easy fix for this, as shown in Fig 22.25, is to capacitively load the antenna about a quarter wavelength (at 21.2 MHz) away from the feedpoint in both wires. Known as *capacitance hats*, the simple loading wires shown lower the antenna's resonant frequency on 15 m without substantially affecting resonance on 40 m.

Fig 22.25 — Figure-8-shaped capacitance hats made and placed as described in the text, can make your 40-m dipole resonate anywhere you like in the 15-m band.

To put this scheme to use, first measure, cut and adjust the dipole to resonance at the desired 40-m frequency. Then, cut two 2-ft-long pieces of stiff wire (such as #12 or #14 house wire) and solder the ends of each one together to form two loops. Twist the loops in the middle to form figure-8s, and strip and solder the wires where they cross. Install these capacitance hats on the dipole by stripping the antenna wire (if necessary) and soldering the hats to the dipole about a third of the way out from the feedpoint (placement isn't critical) on each wire. To resonate the antenna on 15 m, adjust the loop shapes (*not while you're transmitting!*) until the SWR is acceptable in the desired segment of the 15-m band.

THE K8SYL 75 AND 10-M DIPOLE

The same idea was adapted by Sylvia Hutchinson, K8SYL, to make a two-band dipole for 75 and 10 m. Her account was published in July 2002 *QST*.

She discovered that a dipole resonant in the General Class portion of the 75-m band is also resonant on 10 m. As in the case of the 40 and 15-m dipole, some additional loading may be required to move the 10-m resonance to the desired portion of the band.

There is another catch. The radiation resistance on 10 m is about 120 Ω . In other words, if you feed this antenna with 50- Ω coax your best SWR will be around 2.4:1. A quarter wavelength (at 10 m) of 75- Ω coax (such as RG-11) will transform that 120- Ω feedpoint impedance to just under 50 Ω . In this case, the SWR will be better than 1.1:1 at resonance.

The length of the matching section is a small fraction of a wavelength at 3.9 MHz. This will tend to narrow the SWR bandwidth, but only slightly. The antenna is shown in **Fig 22.26**.

Make each capacitance hat from an 18 to 20-in length of #12 or #14 house wire. Solder the ends together to form a loop, leaving a couple of inches free for attaching to the dipole. Next, twist the loop to form a figure-8. The portion of the loop

Fig 22.26 — The K8SYL dipole operates on the 75 and 10-m bands. A quarter-wave section of 75- Ω coax transforms the 10-m impedance. See text.

where the ends meet should be at the center of the figure-8. Strip the crossing wire at this point and the capacitance hat is ready to attach to the dipole.

Tune the antenna on 75 m first. Trim the dipole ends for resonance in your favorite

portion of the band. For K8SYL, each leg was 59 ft, 4 inches long. Then check the SWR on 10 m. Adjust the loop shapes (*not while you're transmitting!*) until the SWR is acceptable in the desired segment of the 10-m band.

THE W4RNL INVERTED-U ANTENNA

This simple rotatable dipole was designed and built by L. B. Cebik, W4RNL, for use during the ARRL Field Day. For this and other portable operations we look for three antenna characteristics: simplicity, small size, and light weight. Complex assemblies increase the number of things that can go wrong. Large antennas are difficult to transport and sometimes do not fit the space available. Heavy antennas require heavy support structures, so the overall weight seems to increase exponentially with every added pound of antenna.

Today, a number of light-weight collapsible masts are available. Some will support—when properly guyed—antennas in the 5-10 pound range. Most are suitable for 10-m tubular dipoles and allow the user to hand-rotate the antenna. Extend the range of the antenna to cover 20-10 m, and you put these 20-30-foot

masts to even better use. The inverted U meets this need.

THE BASIC IDEA OF THE INVERTED U

A dipole's highest current occurs within the first half of the distance from the feedpoint to the outer tips. Therefore, very little performance is lost if the outer end sections are bent. The W4RNL inverted U starts with a 10-m tubular dipole. You add extensions for 12, 15, 17, or 20 m to cover those bands.

You only need enough space to erect a 10-m rotatable dipole. The extensions hang down. **Fig 22.27** shows the relative proportions of the antenna on all bands from 10 to 20 m. The 20-m extensions are the length of half the 10-m dipole. Therefore, safety dictates an antenna height of at least 20 ft to keep the tips above 10 ft high.

At any power level, the ends of a dipole have high RF voltages, and we must keep them out of contact with human body parts.

Not much signal strength is lost by drooping up to half the overall element length straight down. What is lost in bi-directional gain shows up in decreased side-nulls. **Fig 22.28** shows the free-space E-plane (azimuth) patterns of the inverted U with a 10-m horizontal section. There is an undetectable decrease in gain between the 10-m and 15-m versions. The 20-m version shows a little over a half-dB gain decrease and a signal increase off the antenna ends.

The real limitation of an inverted-U is a function of the height of the antenna above ground. With the feedpoint at 20 ft above ground, we obtain the elevation patterns shown in **Fig 22.29**. The 10-m pattern is

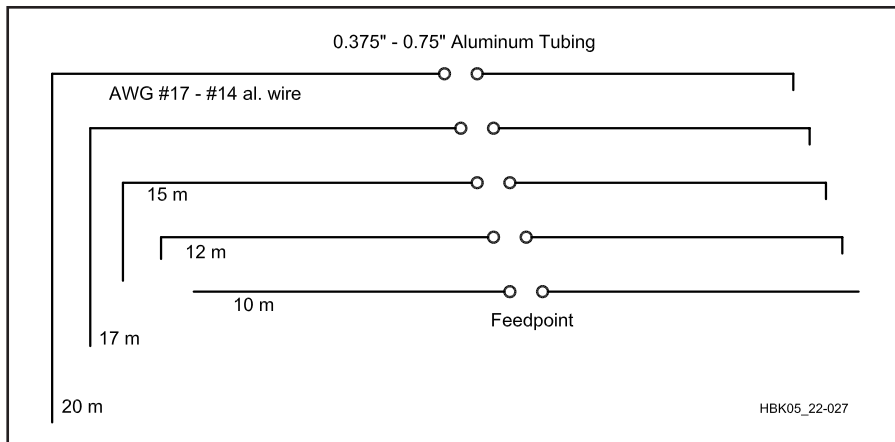

Fig 22.27 — The general outline of the inverted-U field dipole for 20 through 10 m. Note that the vertical end extension wires apply to both ends of the main 10-m dipole, which is constant for all bands.

Fig 22.28 — Free-space E-plane (azimuth) patterns of the inverted-U for 10, 15, and 20 m, showing the pattern changes with increasingly longer vertical end sections.

Fig 22.29 — Elevation patterns of the inverted-U for 10, 15, and 20 m, with the antenna feedpoint 20 ft above average ground. Much of the decreased gain and higher elevation angle of the pattern at the lowest frequencies is due to its ever-lower height as a fraction of a wavelength.

typical for a dipole that is about $\frac{5}{8} \lambda$ above ground. On 15, the antenna is only 0.45λ high, with a resulting increase in the overall elevation angle of the signal and a reduction in gain. At 20 m, the angle grows still higher, and the signal strength diminishes as the antenna height drops to under 0.3λ . Nevertheless, the signal is certainly usable. A full-size dipole at 20 m would show only a little more gain, and the elevation angle would be similar to that of the invert U, despite the difference in antenna shape. If we raise the inverted-U to 40 feet, the 20-m performance would be very similar to that shown by the 10-m elevation plot in Fig 22.29.

The feedpoint impedance of the inverted-U remains well within acceptable limits for virtually all equipment, even at 20 feet above ground. Also, the SWR curves are very broad, reducing the criticalness of finding exact dimensions, even for special field conditions.

BUILDING AN INVERTED-U

Approach the construction of an inverted-U in 3 steps: 1. the tubing arrangement, 2. the center hub and feedpoint assembly, and 3. the drooping extensions. A parts list appears in Table 22.5.

The Aluminum Tubing Dipole for 10 meters.

The aluminum tubing dipole consists of three longer sections of tubing and a short section mounted permanently to the feed point plate, as shown in Fig 22.30. Let's consider each half of the element separately. Counting from the center of the plate—the feedpoint—the element extends 5 inches using $\frac{3}{4}$ -inch aluminum tubing. Then we have two 33 inch exposed tubing sections, with an additional 3 inches of tubing overlap per section. These sections are $\frac{5}{8}$ - and $\frac{1}{2}$ -inch diameter, respectively. The outer section is 30 inches long exposed (with at least a 3 inches overlap) and consists of $\frac{3}{8}$ -inch diameter tubing.

Since the $\frac{5}{8}$ - and $\frac{1}{2}$ -inch sections are 36 inches long, you can make the outer $\frac{3}{8}$ -inch section the same overall length and use more overlap, or you can cut the tubing to 33 inches and use the 3 inch overlap. Three inches of overlap is sufficient to ensure a strong junction, and it minimizes excess weight. However, when not in use, the 3 outer tubing sections will nest inside each other for storage, and a 36-inch length for the outer section is a bit more convenient to un-nest for assembly. Keep the end hitch pin on the $\frac{3}{8}$ inch tubing as an easy way of pulling it into final position. You may use the readily available 6063-T832 aluminum tubing that nests well and has a long history of antenna service.

Table 22.5

Parts List for the Inverted-U

Amount	Item	Comments
6'	0.375" OD aluminum tubing	2 - 3' pieces
6'	0.5" OD aluminum tubing	2 - 3' pieces
6'	0.625" OD aluminum tubing	2 - 3' pieces
10'	0.75" OD aluminum tubing	2 - 5" pieces
4"	0.5" nominal ($\frac{5}{8}$ " OD) CPVC	
50'	Aluminum wire AWG #17	
8	Hitch pin clips	Sized to fit tubing junctions.
1	4" by 4" by $\frac{1}{4}$ " Lexan plate	Other materials suitable.
2	SS U-bolts	Sized to fit support mast
2	Sets SS #8/10 1.5" bolt, nut, washers	SS = stainless steel
2	Sets SS #8 1" bolt, nut, washers	
2	Sets SS #8 .5" bolt, nut, washers	
1	Coax connector bracket, $\frac{1}{16}$ " aluminum	See text for dimensions and shape
1	Female coax connector	
2	Solder lugs, #8 holes	
2	Short pieces copper wire	From coax connector to solder lugs

Note: 6063-T832 aluminum tubing is preferred and can be obtained from such outlets as Texas Towers (www.texastowers.com). Lexan (polycarbonate) is available from such sources as McMaster-Carr (www.mcmasters.com), as are the hitch pin clips (if not locally available). Other items should be available from local home centers and radio parts stores.

Fig 22.30 — The general tubing layout for the inverted-U for each half element. The opposite side of the dipole is a mirror image of the one shown.

Fig 22.31 — A close-up of the element mounting plate assembly, including the hitch pin clips used to secure the next section of tubing.

The only construction operation that you need to perform on the tubing is to drill a hole at about the center of each junction to pass a hitch pin clip. Obtain hitch pin clips (also called hairpin cotter pin clips in some literature) that fit snugly over the tubing. One size will generally handle about 2 or 3 tubing sizes. In this antenna, I used $\frac{3}{32}$ (pin diameter) by $2\frac{5}{8}$ inch long clips for the $\frac{3}{4}$ - to $\frac{5}{8}$ -inch and the $\frac{5}{8}$ - to $\frac{1}{2}$ -inch junctions, with $\frac{3}{32}$ to the loop end of each clip. Spotting the ribbon on the ground is simpler than probing for the clip alone.

Each half element is 101 inches long, for a total 10-m dipole element length of 202 inches (16 ft 10 inches). Length is not critical within about 1 inch, so you may pre-assemble the dipole using the listed dimensions. However, if you wish a more precisely tuned element, tape the outer section in position and test the dipole on your mast at the height that you will use. Adjust the length of the outer tubing segments equally at both ends for the best SWR curve on the lower 1 MHz of the 10-m band. Even though the impedance will be above 50Ω throughout the band, you should easily

use. Good electrical contact requires clean, dry aluminum surfaces, so do not use any type of lubricant to assist the nesting and un-nesting of the tubes. Instead, clean both the inner and outer surfaces of the tubes before and after each use.

The hitch pin clips are fairly large and harder to lose in the grass of a field site than most nuts and bolts. However, you may wish to attach a short colorful ribbon from the ground is simpler than probing for the clip alone.

Each half element is 101 inches long, for a total 10-m dipole element length of 202 inches (16 ft 10 inches). Length is not critical within about 1 inch, so you may pre-assemble the dipole using the listed dimensions. However, if you wish a more precisely tuned element, tape the outer section in position and test the dipole on your mast at the height that you will use. Adjust the length of the outer tubing segments equally at both ends for the best SWR curve on the lower 1 MHz of the 10-m band. Even though the impedance will be above 50Ω throughout the band, you should easily

obtain an SWR curve under 2:1 that covers the entire band segment.

The Center Hub: Mounting and Feedpoint Assembly.

Construct the plate for mounting the element and the mast from a $4 \times 4 \times \frac{1}{4}$ -inch-thick scrap of polycarbonate (trade name Lexan), as shown in **Fig 22.32**. You may use other materials so long as they will handle the element weight and stand up to field conditions.

At the top and bottom of the plate are holes for the U-bolts that fit around my mast. Since masts may vary in diameter at the top, size your U-bolts and their holes to suit the mast.

The element center, consisting of 2 5-inch lengths of $\frac{3}{4}$ -inch aluminum tubing, is just above the centerline of the plate (to allow room for the coax fitting below). $\frac{1}{2}$ -inch nominal CPVC has an outside diameter of about $\frac{5}{8}$ inch and makes a snug fit inside the $\frac{3}{4}$ -inch tubing. The CPVC aligns the two aluminum tubes in a straight line and allows for a small (about $\frac{1}{2}$ inch) gap between them. When centered between the two tubes, the CPVC is the same width as the plate. A pair of 1.5-inch #8 or #10 stainless steel bolts—with washers and a nut—secures the element to the plate.

Note in the sketch that you may insert the $\frac{5}{8}$ -inch tube as far into the $\frac{3}{4}$ -inch tube as it will go and be assured of a 3-inch overlap. Drill all hitch pin clip holes perpendicular to the plate. Although this alignment is not critical to the junctions of the tubes, it is important to the outer ends of the tubes when you use the antenna below 10 m.

Mount a single-hole female UHF connector on a bracket made from a scrap of $\frac{1}{16}$ -inch-thick L-stock that is 1 inch on a side. Drill the UHF mounting hole first, before cutting the L-stock to length and trimming part of the mounting side. Then drill two holes for $\frac{1}{2}$ -inch long #8 stainless steel bolts about 1 inch apart, for a

Fig 22.32 — The element and feedpoint mounting plate, with details of the construction used in the prototype.

total length of L-stock of about 1.5 inches. The reason for the wide strip is to place the bolt heads for the bracket outside the area where the mast will meet the plate on the back side. Note in Fig 22.32 that the bracket nuts are on the bracket-side of the main plate, while the heads face the mast. The bracket-to-plate mounting edge of the bracket needs to be only about $\frac{3}{4}$ inch wide, so you may trim that side of the L-stock accordingly.

With the element center sections and the bracket in place, drill two holes for 1 inch long #8 stainless steel bolts at right angles to the mounting bolts and as close as feasible to the edges of the tubing at the gap. These bolts have solder lugs attached for short leads to the coax fitting. Solder lugs do not come in stainless steel, so you should check these junctions before and after each use for any corrosion that may require replacement.

With all hardware in place, the hub unit is about $4 \times 10 \times 1$ inch (plus U-bolts). It will remain a single unit from this point onward, so that your only field assembly requirements will be to extend tubing sections and install hitch pin clips. You are now ready to perform the initial 10-m resonance tests on your field mast.

The Drooping Extensions for 12 Through 20 Meters

The drooping end sections consist of aluminum wire. Copper is usable, but aluminum is lighter and quite satisfactory for this application. Table 22.6 lists the approximate lengths of each extension below the element. Add 3 to 5 inches of wire—

Table 22.6
 Inverted-U Drooping Wire Lengths

Band <i>m</i>	Wire Length <i>inches</i>
10	n/a
12	15.9
15	37.4
17	62.0
20	108.0

Note: The wire length for the drooping ends is measured from the end of the tubular dipole to the tip for AWG #17 wire. Little change in length occurs as a function of the change in wire size. However, a few inches of additional wire length is required for attachment to the element.

less for 12 m, more for 20 m—to each length listed.

Common #17 aluminum electric fencing wire works well. Fence wire is stiffer than most wires of similar diameter, and it is cheap. Stiffness is the more important property, since you do not want the lower ends of the wire to wave excessively in the breeze, potentially changing the feedpoint properties of the antenna while it is in use.

When stored, the lengths of wire extensions for 12 and 15 m can be laid out without any bends. However, the longer extensions for 17 and 20 m will require some coiling or folding to fit the same space as the tubing when nested. Fold or coil the wire around any kind of small spindle that has at least a

Fig 22.33 — A simple method of clamping the end wires to the $\frac{3}{8}$ -inch tube end using a hitch pin clip.

Fig 22.34 — Typical 50-Ω SWR curves for the inverted-U antenna at a feedpoint height of 20 ft.

Fig 22.35 — The entire inverted-U antenna parts collection in semi-nested form, with its carrying bag. The tools stored with the antenna include a wrench to tighten the U-bolts for the mast-to-plate mount and a pair of pliers to help remove end wires from the tubing. The pliers have a wire-cutting feature to help replace a broken end wire. A pair of locking pliers makes a good removable handle for turning the mast. The combination of the locking and regular pliers helps to uncoil the wire extensions for any band; give them a couple of sharp tugs to straighten the wire.

2-inch diameter (larger is better). This measure prevents the wire from crimping and eventually breaking. Murphy dictates that a wire will break in the middle of an operating session. So carry some spare wire for replacement ends. All together, the ends require about 50 ft of wire.

Fig 22.33 shows the simple mounting scheme for the end wires. Push the straight wires through a pair of holes aligned vertically to the earth and bend the top portion slightly. To clamp the wire, insert a hitch pin clip through holes parallel to the ground, pushing the wire slightly to one side to reach the far hole in the tube. The double bend holds the wire securely (for a short-term field operation), but allows the wire to be pulled out when the session is over or to change bands.

Add a few inches to the lengths given in Table 22.6 as an initial guide for each band. Test the lengths and prune the wires until you obtain a smooth SWR curve below 2:1 at the ends of each band. Since an inverted-U antenna is full length, the SWR curves will be rather broad and suffer none of the narrow bandwidths associated with inductively loaded elements. Fig 22.34 shows typical SWR curves for each band to guide your expectations.

You should not require much, if any, adjustment once you have found satisfactory lengths for each band. So you can mark the wire when you finish your initial test adjustments. However, leave enough excess so that you can adjust the lengths in the field.

Do not be too finicky about your SWR curves. An initial test and possibly one adjustment should be all that you need to arrive at an SWR value that is satisfactory for your equipment. Spending half of your operating time adjusting the elements for as near to a 1:1 SWR curve as possible will rob you of valuable contacts without changing your signal strength in any manner that is detectable.

Changing bands is a simple matter. Remove the ends for the band you are using and install the ends for the new band. An SWR check and possibly one more adjustment of the end lengths will put you back on the air.

FINAL NOTES

The inverted-U dipole with interchangeable end pieces provides a compact field antenna. All of the parts fit in a 3-ft long bag. A draw-string bag works very well. Fig 22.35 shows the parts in their travel form. When assembled and mounted at least 20' up (higher is even better), the antenna will compete with just about any other dipole mounted at the same height. But the inverted-U is lighter than most dipoles at frequencies lower than 10 m. It

also rotates easily by hand—assuming that you can rotate the mast by hand. Being able to broadside the dipole to your target station gives the inverted-U a strong advantage over a fixed wire dipole.

With a dipole having drooping ends, safety is very important. Do not use the antenna unless the wire ends for 20 m are

higher than any person can touch when the antenna is in use. Even with QRP power levels, the RF voltage on the wire ends can be dangerous. With the antenna at 20 ft at its center, the ends should be at least 10 ft above ground.

Equally important is the maintenance that you give the antenna before and after

each use. Be sure that the aluminum tubing is clean—both inside and out—when you nest and un-nest the sections. Grit can freeze the sections together, and dirty tubing can prevent good electrical continuity. Carry a few extra hitch pin clips in the package to be sure you have spares in case you lose one.

TWO W8NX MULTIBAND, COAX-TRAP DIPOLES

Over the last 60 or 70 years, amateurs have used many kinds of multiband antennas to cover the traditional HF bands. The availability of the 30, 17 and 12-m bands has expanded our need for multiband antenna coverage.

Two different antennas are described here. The first covers the traditional 80, 40, 20, 15 and 10-m bands, and the second covers 80, 40, 17 and 12 m. Each uses the same type of W8NX trap—connected for different modes of operation—and a pair of short capacitive stubs to enhance coverage. The W8NX coaxial-cable traps have two different modes: a high- and a low-impedance mode. The inner-conductor windings and shield windings of the traps are connected in series for both modes. However, either the low- or high-impedance point can be used as the trap's output terminal. For low-impedance trap operation, only the center conductor turns of the trap windings are used. For high-impedance operation, all turns are used, in the conventional manner for a trap. The short stubs on each antenna are strategically sized and located to permit more flexibility in adjusting the resonant frequencies of the antenna.

80, 40, 20, 15 AND 10-METER DIPOLE

Fig 22.36 shows the configuration of the 80, 40, 20, 15 and 10-m antenna. The radiating elements are made of #14 stranded copper wire. The element lengths are the wire span lengths in feet. These lengths do not include the lengths of the pigtails at the balun, traps and insulators. The 32.3-ft-long inner 40-m segments are measured from the eyelet of the input balun to the tension-relief hole in the trap coil form. The 4.9-ft segment length is measured from the tension-relief hole in the trap to the 6-ft stub. The 16.1-ft outer-segment span is measured from the stub to the eyelet of the end insulator.

The coaxial-cable traps are wound on PVC pipe coil forms and use the low-impedance output connection. The stubs are 6-ft lengths of 1/8-inch stiffened aluminum or copper rod hanging perpendicular

Fig 22.36 — A W8NX multiband dipole for 80, 40, 20, 15 and 10 m. The values shown (123 pF and 4 μ H) for the coaxial-cable traps are for parallel resonance at 7.15 MHz. The low-impedance output of each trap is used for this antenna.

Fig 22.37 — A W8NX multiband dipole for 80, 40, 17 and 12 m. For this antenna, the high-impedance output is used on each trap. The resonant frequency of the traps is 7.15 MHz.

to the radiating elements. The first inch of their length is bent 90° to permit attachment to the radiating elements by large-diameter copper crimp connectors. Ordinary #14 wire may be used for the stubs, but it has a tendency to curl up and may tangle unless weighed down at the end. You should feed the antenna with 75- Ω coax cable using a good 1:1 balun.

This antenna may be thought of as a modified W3DZZ antenna due to the addition of the capacitive stubs. The length and location of the stub give the antenna designer two extra degrees of freedom to place the resonant frequencies within the amateur bands. This additional flexibility is particularly helpful to bring the 15 and 10-m resonant frequencies to more desirable locations in these bands. The actual 10-m resonant frequency of the original W3DZZ antenna is somewhat above 30 MHz, pretty remote from the more desirable low frequency end of 10 m.

80, 40, 17 AND 12-METER DIPOLE

Fig 22.37 shows the configuration of the 80, 40, 17 and 12-m antenna. Notice

that the capacitive stubs are attached immediately outboard after the traps and are 6.5 ft long, 1/2 ft longer than those used in the other antenna. The traps are the same as those of the other antenna, but are connected for the high-impedance parallel-resonant output mode. Since only four bands are covered by this antenna, it is easier to fine tune it to precisely the desired frequency on all bands. The 12.4-ft tips can be pruned to a particular 17-m frequency with little effect on the 12-m frequency. The stub lengths can be pruned to a particular 12-m frequency with little effect on the 17-m frequency. Both such pruning adjustments slightly alter the 80-m resonant frequency. However, the bandwidths of the antennas are so broad on 17 and 12 m that little need for such pruning exists. The 40-m frequency is nearly independent of adjustments to the capacitive stubs and outer radiating tip elements. Like the first antennas, this dipole is fed with a 75- Ω balun and feed line.

Fig 22.38 shows the schematic diagram of the traps. It illustrates the difference between the low and high-impedance

modes of the traps. Notice that the high-impedance terminal is the output configuration used in most conventional trap applications. The low-impedance connection is made across only the inner conductor turns, corresponding to one-half of the total turns of the trap. This mode steps the trap's impedance down to approximately one-fourth of that of the high-impedance level. This is what allows a single trap design to be used for two different multi-band antennas.

Fig 22.39 is a drawing of a cross-section of the coax trap shown through the long axis of the trap. Notice that the traps are conventional coaxial-cable traps, except for the added low-impedance output terminal. The traps are $8\frac{3}{4}$ close-spaced turns of RG-59 (Belden 8241) on a $2\frac{3}{8}$ -inch-OD PVC pipe (schedule 40 pipe with a 2-inch ID) coil form. The forms are $4\frac{1}{8}$ inches long. Trap resonant frequency is very sensitive to the outer diameter of the coil form, so check it carefully. Unfortunately, not all PVC pipe is made with the same wall thickness. The trap frequencies should be checked with a dip meter and general-coverage receiver and adjusted to

within 50 kHz of the 7150 kHz resonant frequency before installation. One inch is left over at each end of the coil forms to allow for the coax feed-through holes and holes for tension-relief attachment of the antenna radiating elements to the traps. Be sure to seal the ends of the trap coax cable with RTV sealant to prevent moisture from entering the coaxial cable.

Also, be sure that you connect the 32.3-ft wire element at the start of the inner conductor winding of the trap. This avoids detuning the antenna by the stray capacitance of the coaxial-cable shield. The trap output terminal (which has the shield stray capacitance) should be at the outboard side of the trap. Reversing the input and output terminals of the trap will lower the 40-meter frequency by approximately 50 kHz, but there will be negligible effect on the other bands.

Fig 22.40 shows a coaxial-cable trap. Further details of the trap installation are shown in **Fig 22.41**. This drawing applies specifically to the 80, 40, 20, 15 and 10-m antenna, which uses the low-impedance trap connections. Notice the lengths of the trap pigtails: 3 to 4 inches at each terminal of the trap. If you use a different arrangement, you must modify the span lengths accordingly. All connections can be made using crimp connectors rather than by soldering. Access to the trap's interior is attained more easily with a crimping tool than with a soldering iron.

At his location in Akron, Ohio, the antenna runs essentially east and west. It is installed as an inverted V, 40 ft high at the center, with a 120° included angle between the legs. Since the stubs are very short, they radiate little power and make only minor contributions to the radiation patterns. In theory, the pattern has four major lobes on 17 m, with maxima to the northeast, southeast, southwest and northwest. These provide low-angle radiation into Europe, Africa, South Pacific, Japan and Alaska. A narrow pair of minor broadside

Fig 22.38 — Schematic for the W8NX coaxial-cable trap. RG-59 is wound on a $2\frac{3}{8}$ -inch OD PVC pipe.

PERFORMANCE

The performance of both antennas has been very satisfactory. W8NX uses the 80, 40, 17 and 12-m version because it covers 17 and 12 m. (He has a triband Yagi for 20, 15 and 10 m.) The radiation pattern on 17 m is that of $\frac{3}{2}$ -wave dipole. On 12 m, the pattern is that of a $\frac{5}{2}$ -wave dipole.

Fig 22.39 — Construction details of the W8NX coaxial-cable trap.

Fig 22.40 — Other views of a W8NX coax-cable trap.

Fig 22.41 — Additional construction details for the W8NX coaxial-cable trap.

lobes provides north and south coverage into Central America, South America and the polar regions.

There are four major lobes on 12 m, giving nearly end-fire radiation and good low-angle east and west coverage. There are also three pairs of very narrow, nearly broadside, minor lobes on 12 m, down about 6 dB from the major end-fire lobes. On 80 and 40 m, the antenna has the usual figure-8 patterns of a half-wave-length dipole.

Both antennas function as electrical half-wave dipoles on 80 and 40 m with a low SWR. They both function as odd-harmonic current-fed dipoles on their other operating frequencies, with higher, but still acceptable, SWR. The presence of the stubs can either raise or lower the input impedance of the antenna from those of the usual third and fifth harmonic dipoles. Again W8NX

recommends that 75- Ω , rather than 50- Ω , feed line be used because of the generally higher input impedances at the harmonic operating frequencies of the antennas.

The SWR curves of both antennas were carefully measured using a 75 to 50- Ω transformer from Palomar Engineers inserted at the junction of the 75- Ω coax feed line and a 50- Ω SWR bridge. The transformer is required for accurate SWR measurement if a 50- Ω SWR bridge is used with a 75- Ω line. Most 50- Ω rigs operate satisfactorily with a 75- Ω line, although this requires different tuning and load settings in the final output stage of the rig or antenna tuner. The author uses the 75 to 50- Ω transformer only when making SWR measurements and at low power levels. The transformer is rated for 100 W, and when he runs his 1-kW PEP linear amplifier the trans-

former is taken out of the line.

Fig 22.42 gives the SWR curves of the 80, 40, 20, 15 and 10-m antenna. Minimum SWR is nearly 1:1 on 80 m, 1.5:1 on 40 m, 1.6:1 on 20 m, and 1.5:1 on 10 m. The minimum SWR is slightly below 3:1 on 15 m. On 15 m, the stub capacitive reactance combines with the inductive reactance of the outer segment of the antenna to produce a resonant rise that raises the antenna input resistance to about 220 Ω , higher than that of the usual $3/2$ -wavelength dipole. An antenna tuner may be required on this band to keep a solid-state final output stage happy under these load conditions.

Fig 22.43 shows the SWR curves of the 80, 40, 17 and 12-m antenna. Notice the excellent 80-m performance with a nearly unity minimum SWR in the middle of the band. The performance approaches that of a full-size 80-m wire dipole. The short stubs and the low-inductance traps shorten the antenna somewhat on 80 m. Also observe the good 17-m performance, with the SWR being only a little above 2:1 across the band.

But notice the 12-m SWR curve of this antenna, which shows 4:1 SWR across the band. The antenna input resistance approaches 300 Ω on this band because the capacitive reactance of the stubs combines with the inductive reactance of the outer antenna segments to give resonant rises in impedance. These are reflected back to the input terminals. These stub-induced resonant impedance rises are similar to those on the other antenna on 15 meters, but are even more pronounced.

Fig 22.42 — Measured SWR curves for an 80, 40, 20, 15 and 10-meter antenna, installed as an inverted-V with 40-ft apex and 120° included angle between legs.

Fig 22.43 — Measured SWR curves for an 80, 40, 17 and 12-meter antenna, installed as an inverted-V with 40-ft apex and 120° included angle between legs.

Too much concern must not be given to SWR on the feed line. Even if the SWR is as high as 9:1 *no destructively high voltages will exist on the transmission line*. Recall that transmission-line voltages increase as the square root of the SWR in the line. Thus, 1 kW of RF power in 75-Ω line corresponds to 274 V line voltage for a 1:1 SWR. Raising the SWR to 9:1 merely triples the maximum voltage that the line must withstand to 822 V. This voltage is well below the 3700-V rating of RG-11, or the 1700-V rating of RG-59, the two most popular 75-Ω coax lines. Voltage breakdown in the traps is also very unlikely. As will be pointed out later, the operating power levels of these antennas are limited by RF power dissipation in the traps, not trap voltage breakdown or feed-line SWR.

TRAP LOSSES AND POWER RATING

Table 22.7 presents the results of trap Q measurements and extrapolation by a two-frequency method to higher frequencies above resonance. W8NX employed an old, but recently calibrated, Boonton Q meter for the measurements. Extrapolation to higher-frequency bands assumes

that trap resistance losses rise with skin effect according to the square root of frequency, and that trap dielectric losses rise directly with frequency. Systematic measurement errors are not increased by frequency extrapolation. However, random measurement errors increase in magnitude with upward frequency extrapolation. Results are believed to be accurate within 4% on 80 and 40 m, but only within 10 to 15% at 10 m. Trap Q is shown at both the high- and low-impedance trap terminals. The Q at the low-impedance output terminals is 15 to 20% lower than the Q at the high-impedance output terminals.

W8NX computer-analyzed trap losses for both antennas in free space. Antenna-input resistances at resonance were first calculated, assuming lossless, infinite-Q traps. They were again calculated using the Q values in Table 22.7. The radiation efficiencies were also converted into equivalent trap losses in decibels. **Table 22.8** summarizes the trap-loss analysis for the 80, 40, 20, 15 and 10-m antenna and **Table 22.9** for the 80, 40, 17 and 12-m antenna.

The loss analysis shows radiation efficiencies of 90% or more for both antennas

on all bands except for the 80, 40, 20, 15 and 10-m antenna when used on 40 m. Here, the radiation efficiency falls to 70.8%. A 1-kW power level at 90% radiation efficiency corresponds to 50-W dissipation per trap. In W8NX's experience, this is the trap's survival limit for extended key-down operation. SSB power levels of 1 kW PEP would dissipate 25 W or less in each trap. This is well within the dissipation capability of the traps.

When the 80, 40, 20, 15 and 10-m antenna is operated on 40 m, the radiation efficiency of 70.8% corresponds to a dissipation of 146 W in each trap when 1 kW is delivered to the antenna. This is sure to burn out the traps—even if sustained for only a short time. Thus, the power should be limited to less than 300 W when this antenna is operated on 40 m under prolonged key-down conditions. A 50% CW duty cycle would correspond to a 600-W power limit for normal 40-m CW operation. Likewise, a 50% duty cycle for 40-m SSB corresponds to a 600-W PEP power limit for the antenna.

The author knows of no analysis where the burnout wattage rating of traps has been rigorously determined. Operating experience seems to be the best way to determine trap burn-out ratings. In his own experience with these antennas, he's had no traps burn out, even though he operated the 80, 40, 20, 15 and 10-m antenna on the critical 40-m band using his AL-80A linear amplifier at 600-W PEP output. He did not make a continuous, key-down, CW operating tests at full power purposely trying to destroy the traps!

Some hams may suggest using a different type of coaxial cable for the traps. The dc resistance of 40.7 Ω per 1000 feet of RG-59 coax seems rather high. However, W8NX has found no coax other than RG-59 that has the necessary inductance-to-capacitance ratio to create the trap characteristic reactance required for the 80, 40, 20, 15 and 10-m antenna. Conventional traps with wide-spaced, open-air inductors and appropriate fixed-value capacitors could be substituted for the coax traps, but the convenience, weather-proof configuration and ease of fabrication of coaxial-cable traps is hard to beat.

Table 22.7

Vertical Antennas

One of the more popular amateur antennas is the *vertical*. It usually refers to a single radiating element placed vertically over the ground. A typical vertical is an electrical $\frac{1}{4}\lambda$ long and is constructed of wire or tubing.

Single vertical antennas are omnidirectional radiators. This can be beneficial or detrimental, depending on the exact situation. On transmission there are no nulls in any direction, unlike most horizontal antennas. However, QRM on receive can't be nulled out from the directions that are not of interest, unless multiple verticals are used in an array.

When compared to horizontal antennas, verticals also suffer more acutely from two main types of losses—*ground return losses* for currents in the near field, and *far-field ground losses*. Ground losses in

the near field can be minimized by using many ground radials. This is covered in the sidebar, **Optimum Ground Systems for Vertical Antennas**.

Far-field losses are highly dependent on the conductivity and dielectric constant of the earth around the antenna, extending out as far as 100λ from the base of the antenna. There is very little that someone can do to change the character of the ground that far away—other than moving to a small island surrounded by saltwater! Far-field losses greatly affect low-angle radiation, causing the radiation patterns of practical vertical antennas to fall far short of theoretical patterns over *perfect ground*, often seen in classical texts.

Fig 22.44 shows the elevation pattern response for two different 40-m quarter-wave verticals. One is placed over a

theoretical infinitely large, infinitely conducting ground. The second is placed over an extensive radial system over average soil, having a conductivity of 5 mS/m and a dielectric constant of 13. This sort of soil is typical of heavy clay found in pastoral regions of the US mid-Atlantic states. At a 10° elevation angle, the real antenna losses are almost 6 dB compared to the theoretical one; at 20° the difference is about 3 dB. See *The ARRL Antenna Book* chapter on the effects of the earth for further details.

While real verticals over real ground are not a magic method to achieve low-angle radiation, cost versus performance and ease of installation are incentives that inspire many antenna builders. For use on the lower frequency amateur bands—notably 160 and 80 m—it is not always

Optimum Ground Systems for Vertical Antennas

A frequent question brought up by old-timers and newcomers alike is: “So, how many ground radials do I *really* need for my vertical antenna?” Most hams have heard the old standby tales about radials, such as “if a few are good, more must be better” or “lots of short radials are better than a few long ones.”

John Stanley, K4ERO, eloquently summarized a study he did of the professional literature on this subject in his article “Optimum Ground Systems for Vertical Antennas” in December 1976 *QST*. His approach was to present the data in a sort of “cost-benefit” style in Table A, reproduced here. John somewhat wryly created a new figure of merit—the total amount of wire needed for various radial configurations. This is expressed in terms of wavelengths of total radial wire.

Table A

Optimum Ground-System Configurations

Configuration Designation	A	B	C	D	E	F
Number of radials	16	24	36	60	90	120
Length of each radial in wavelengths	0.1	0.125	0.15	0.2	0.25	0.4
Spacing of radials in degrees	22.5	15	10	6	4	3
Total length of radial wire installed, in wavelengths	1.6	3	5.4	12	22.5	48
Power loss in dB at low angles with a quarter-wave radiating element	3	2	1.5	1	0.5	0*
Feed-point impedance in ohms with a quarter-wave radiating element	52	46	43	40	37	35

Note: Configuration designations are indicated only for text reference.

*Reference. The loss of this configuration is negligible compared to a perfectly conducting ground.

The results almost jumping out of this table are:

- If you can only install 16 radials (Case A), they needn't be very long— 0.1λ is sufficient. You'll use 1.6λ of radial wire in total, which is about 450 feet at 3.5 MHz.
- If you have the luxury of laying down 120 radials (Case F), they should be 0.4λ long, and you'll gain about 3 dB over the 16-radial case. You'll also use 48λ of total wire—For 80 meters, that would be about 13,500 feet!
- If you can't put out 120 radials, but can install 36 radials that are 0.15λ long (Case C), you'll lose only 1.5 dB compared to the optimal Case F. You'll also use 5.4λ of total wire, or 1,500 feet at 3.5 MHz.
- A 50- Ω SWR of 1:1 isn't necessary a good thing—the worst-case ground system in Case A has the lowest SWR.

Table A represents the case for “Average” quality soil, and it is valid for radial wires either laid on the ground or buried several inches in the ground. Note that such ground-mounted radials are detuned because of their proximity to that ground and hence don't have to be a classical quarter-wave length that they need to be were they in “free space.”

In his article John also made the point that ground-radial losses would only be significant on transmit, since the atmospheric noise on the amateur bands below 30 MHz is attenuated by ground losses, just like actual signals would be. This limits the ultimate signal-to-noise ratio in receiving.

So, there you have the tradeoffs—the loss in transmitted signal compared to the cost (and effort) needed to install more radial wires. You take your pick.

Fig 22.44 — Elevation patterns for two quarter-wave vertical antennas over different ground. One vertical is placed over *perfect* ground, and the other is placed over *average* ground. The far-field response at low elevation angles is greatly affected by the quality of the ground — as far as 100λ away from the vertical antenna.

Fig 22.45 — Radiation resistance (solid curve) and reactance (dotted curve) of vertical antennas as a function of their physical height.

practical to erect a full-size vertical. At 1.8 MHz, a full-sized quarter-wave vertical is 130 ft high. In such instances it is often necessary to accept a shorter radiating element and use some form of *loading*.

Fig 22.45 provides curves for the physical height of verticals in wavelength versus radiation resistance and reactance. Although the plots are based on perfectly conducting ground, they show general trends for installations where many radials have been laid out to make a ground screen. As the radiator is made shorter, the radiation resistance decreases—with 6Ω being typical for a $0.1\text{-}\lambda$ high antenna. The lower the radiation resistance, the more the antenna efficiency depends on ground conductivity and the effectiveness of the ground screen. Also, the bandwidth decreases markedly as the length is reduced toward the left of the scale in Fig 22.45. It

can be difficult to develop suitable matching networks when radiation resistance is very low.

GROUND SYSTEMS

Generally a large number of shorter radials offers a better ground system than a few longer ones. For example, 8 radials of $\frac{1}{4} \lambda$ are preferred over 4 radials of $\frac{1}{4} \lambda$. Optimum radial lengths are described in the sidebar.

The conductor size of the radials is not especially significant. Wire gauges from #4 to #20 have been used successfully by amateurs. Copper wire is preferred, but where soil is low in acid (or alkali), aluminum wire can be used. The wires may be bare or insulated, and they can be laid on the earth's surface or buried a few inches below ground. Insulated wires will have greater longevity by virtue of reduced corrosion and dissolution from soil chemicals.

When property dimensions do not allow a classic installation of equally spaced radial wires, they can be placed on the ground as space permits. They may run away from the antenna in only one or two compass directions. They may be bent to fit on your property.

A single ground rod, or group of them

bonded together, is seldom as effective as a collection of random-length radial wires.

All radial wires should be connected together at the base of the vertical antenna. The electrical bond needs to be of low resistance. Best results will be obtained when the wires are soldered together at the junction point. When a grounded vertical is used, the ground wires should be affixed securely to the base of the driven element.

Ground return losses are lower when vertical antennas and their radials are elevated above ground, a point that is well-known by those using *ground plane* antennas on their roofs. Even on 160 or 80 m, effective vertical antenna systems can be made with as few as four quarter-wave long radials elevated 10 to 20 ft off the ground.

FULL-SIZE VERTICAL ANTENNAS

When it is practical to erect a full-size $\frac{1}{4}\text{-}\lambda$ vertical antenna, the forms shown in **Fig 22.46** are worthy of consideration. The example at A is the well-known *vertical ground plane*. The ground system consists of four above-ground radial wires. The length of the driven element and $\frac{1}{4}\text{-}\lambda$ radials is derived from the standard equation

Fig 22.46 — Various types of vertical antennas.

$$L(f) = \frac{234}{f(\text{MHz})} \quad (6)$$

With four equidistant radial wires drooped at approximately 30° (Fig 22.46A), the feed-point impedance is roughly 50Ω . When the radials are at right angles to the radiator (Fig 22.46B) the impedance approaches 36Ω . Besides minimizing ground return losses, another major advantage in this type of vertical antenna over a ground-mounted type is that the system can be elevated well above nearby conductive objects (power lines, trees, buildings and so on). When drooping radials are used, they can also serve as guy wires for the mast that supports the antenna. The coax shield braid is connected to the radials, and the center conductor to the driven element.

The *Marconi* vertical antenna shown in Fig 22.46C is the classic form taken by a ground-mounted vertical. It can be grounded at the base and shunt fed, or it can be isolated from ground, as shown, and series fed. As always, this vertical antenna depends on an effective ground system for efficient performance. If a perfect ground were located below the antenna, the feed impedance would be near 36Ω . In a practical case, owing to imperfect ground, the impedance is more apt to be in the vicinity of 50Ω .

A gamma feed system for a grounded $1/4\text{-}\lambda$ vertical is presented in Fig 22.46D. Some rules of thumb for arriving at workable gamma-arm and capacitor dimensions are to make the rod length 0.04 to 0.05λ , its diameter $1/3$ to $1/2$ that of the driven element and the center-to-center spacing between the gamma arm and the driven element roughly 0.007λ . The capacitance of C_1 at a $50\text{-}\Omega$ matched condition will be about 7 pF per meter of wavelength. The absolute value of C_1 will depend on whether the vertical is resonant and on the precise value of the radiation resistance. For best results, make the radiator approximately 3% shorter than the resonant length.

Amateur antenna towers lend themselves to use as shunt-fed verticals, even though an HF-band beam antenna is usually mounted on the tower. The overall system should be close to resonance at the desired operating frequency if a gamma feed is used. The HF-band beam will contribute somewhat to *top loading* of the tower. The natural resonance of such a system can be checked by dropping a #12 or #14 wire from the top of the tower (connecting it to the tower top) to form a folded unipole (Fig 22.46E). A four- or five-turn link can be inserted between the lower end of the drop wire and the ground system. A

dip meter is then inserted in the link to determine the resonant frequency. If the tower is equipped with guy wires, they should be broken up with strain insulators to prevent unwanted loading of the vertical. In such cases where the tower and beam antennas are not able to provide $1/4\text{-}\lambda$ resonance, portions of the top guy wires can be used as top-loading capacitance. Experiment with the guy-wire lengths (using the dip-meter technique) while determining the proper dimensions.

A folded-unipole is depicted at E of Fig 22.46. This system has the advantage of increased feed-point impedance. Furthermore, a Transmatch can be connected between the bottom of the drop wire and the ground system to permit operation on more than one band. For example, if the tower is resonant on 80 m , it can be used as shown on 160 and 40 m with reasonable results, even though it is not electrically long enough on 160 . The drop wire need not be a specific distance from the tower, but you might try spacings between 12 and 30 inches.

The method of feed shown at Fig 22.46F is commonly referred to as *slant-wire feed*. The guy wires and the tower combine to provide quarter-wave resonance.

A matching network is placed between the lower end of one guy wire and ground and adjusted for an SWR of $1:1$. It does not matter at which level on the tower the guy wires are connected, assuming that the Transmatch is capable of effecting a match to 50Ω .

PHYSICALLY SHORT VERTICALS

A group of short vertical radiators is presented in Fig 22.47. Illustrations A and B are for top and center loading. A capacitance hat is shown in each example. The hat should be as large as practical to increase the radiation resistance of the antenna and improve the bandwidth. The wire in the loading coil is chosen for the largest gauge consistent with ease of winding and coil-form size. The larger wire diameters will reduce the resistive (I^2R) losses in the system. The coil-form material should have a medium or high dielectric constant. Phenolic or fiberglass tubing is entirely adequate.

A base-loaded vertical is shown at C of Fig 22.47. The primary limitation is that the high current portion of the vertical exists in the coil rather than the driven element. With center loading, the portion of the antenna below the coil carries high

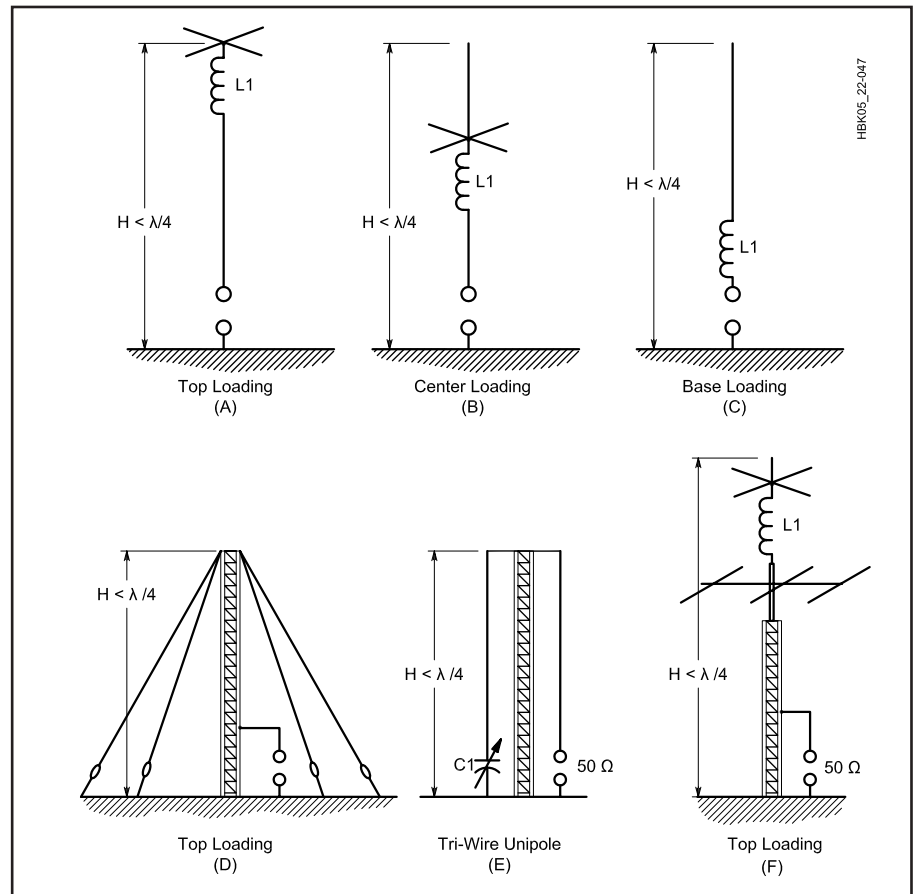

Fig 22.47 — Vertical antennas that are less than one-quarter wavelength in height.

current, and in the top-loaded version the entire vertical element carries high current. Since the high-current part of the antenna is responsible for most of the radiating, base loading is the least effective of the three methods. The radiation resistance of the coil-loaded antennas shown is usually less than 16 Ω .

A method for using guy wires to top load a short vertical is illustrated in Fig 22.47D. This system works well with gamma feed. The loading wires are trimmed to provide an electrical quarter wavelength for the overall system. This method of loading will result in a higher radiation resistance and greater bandwidth than the systems shown at A through C. If an HF or VHF array is at the top the tower, it will simply contribute to the top loading.

A three-wire unipole is shown at E. Two #8 drop wires are connected to the top of the tower and brought to ground level. The wires can be spaced any convenient distance from the tower—normally 12 to 30 inches from one side. C1 is adjusted for best SWR. This type of vertical has a fairly narrow bandwidth, but because C1 can be motor driven and controlled from the operating position, frequency changes can be accomplished easily. This technique will not be suitable for matching to 50- Ω line unless the tower is less than an electrical

quarter wavelength high.

A different method for top loading is shown at F. Barry Boothe, W9UCW, described this method in December 1974 *QST*. An extension is used at the top of the tower to effect an electrical quarter-wavelength vertical. L1 is a loading coil with sufficient inductance to provide antenna resonance. This type of antenna lends itself to operation on 160 m.

A method for constructing the top-loading shown in Fig 22.47F is illustrated in Fig 22.48. Pipe section D is mated with the mast above the HF-band beam antenna. A loading coil is wound on solid Plexiglas rod or phenolic rod (item C), then clamped inside the collet (B). An aluminum slug (part A) is clamped inside item B. The top part of A is bored and tapped for a $3/8 \times 24$ stud. This permits a standard 8-ft stainless-steel mobile whip to be threaded into item A above the loading coil. The capacitance hat (Fig 22.48B) can be made from a $1/4$ -inch-thick brass or aluminum plate. It may be round or square. Lengths of $1/8$ -inch brazing rod can be threaded and screwed into the edge of the aluminum plate. The plate contains a row of holes along its perimeter, each having been tapped for a 6-32 thread. The capacitance hat is affixed to item A by means of the 8-ft whip antenna. The whip will increase

the effective height of the vertical antenna.

CABLES AND CONTROL WIRES ON TOWERS

Most vertical antennas of the type shown in Fig 22.46 consist of towers, usually with HF or VHF beam antennas at the top. The rotator control wires and the coaxial feeders to the top of the tower will not affect antenna performance adversely. In fact, they become a part of the composite antenna. To prevent unwanted RF currents from following the wires into the shack, simply dress them close to the tower legs and bring them to ground level. This decouples the wires at RF. The wires should then be routed along the earth surface (or buried underground) to the operating position. It is not necessary to use bypass capacitors or RF chokes in the rotator control leads if this is done, even when maximum legal power is employed.

TRAP VERTICALS

The 2-band trap vertical antenna of Fig 22.49 operates in much the same manner as a trap dipole or trap Yagi. The notable

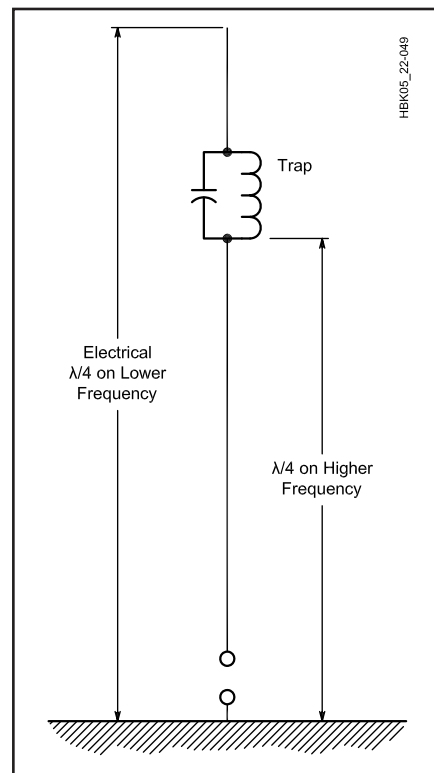

Fig 22.49 — A two-band trap vertical antenna. The trap should be resonated by itself as a parallel resonant circuit at the center of the operating range for the higher frequency band. The reactance of either the inductor or the capacitor range from 100 to 300 Ω . At the lower frequency the trap will act as a loading inductor, adding electrical length to the total antenna.

difference is that the vertical is one half of a dipole. The radial system (in-ground or above-ground) functions as a ground plane for the antenna, and represents the missing half of the dipole. Once again, the more effective the ground system, the better will be the antenna performance.

Trap verticals usually are adjusted as $1/4\text{-}\lambda$ radiators. The portion of the antenna below the trap is adjusted as a $1/4\text{-}\lambda$ radiator at the higher proposed operating frequency. That is, a 20/15-m trap vertical would be a resonant quarter wavelength at 15 m from the feedpoint to the bottom of the trap. The trap and that portion of the antenna above the trap (plus the 15-m section below the trap) constitute the complete antenna during 20-m operation. But because the trap is in the circuit, the overall physical length of the vertical antenna will be slightly less than that of a single-band, full-size 20-m vertical.

TRAPS

The trap functions as the name implies: It traps the 15-m energy and confines it to the part of the antenna below the trap.

During 20-m operation it allows the RF energy to reach all of the antenna. The trap in this example is tuned as a parallel resonant circuit to 21 MHz. At this frequency it divorces the top section of the vertical from the lower section because it presents a high impedance (barrier) at 21 MHz. Generally, the trap inductor and capacitor have a reactance of 100 to 300 Ω . Within that range it is not critical.

The trap is built and adjusted separately from the antenna. It should be resonated at the center of the portion of the band to be operated. Thus, if one's favorite part of the 15-m band is between 21.0 and 21.1 MHz, the trap should be tuned to 21.05 MHz.

Resonance is checked by using a dip meter and detecting the dipper signal in a calibrated receiver. Once the trap is adjusted it can be installed in the antenna, and no further adjustment will be required. It is easy, however, to be misled after the system is assembled: Attempts to check the trap with a dip meter will suggest that the trap has moved much lower in frequency (approximately 5 MHz lower in a

20/15-m vertical). This is because the trap is part of the overall antenna, and the resultant resonance is that of the total antenna. Measure the trap separate from the rest of the antenna.

Multiband operation is quite practical by using the appropriate number of traps and tubing sections. The construction and adjustment procedure is the same, regardless of the number of bands covered. The highest frequency trap is always closest to the feed end of the antenna, and the lowest frequency trap is always the farthest from the feedpoint. As the operating frequency is progressively lowered, more traps and more tubing sections become a functional part of the antenna.

Traps should be weatherproofed to prevent moisture from detuning them. Several coatings of high dielectric compound, such as Polystyrene Q Dope, are effective. Alternatively, a protective sleeve of heat-shrink tubing can be applied to the coil after completion. The coil form for the trap should be of high dielectric quality and be rugged enough to sustain stress during periods of wind.

DUAL-BAND VERTICALS FOR 17/40 OR 12/30 M

Thanks to the harmonic relationships between the HF ham bands, many antennas can be made to do double duty. The simple verticals described here cover two bands at once. Here's how to turn a 30-m $1/4\text{-}\lambda$ vertical into a $0.625\text{-}\lambda$ vertical for the 12-m band, and a 40-m $1/4\text{-}\lambda$ vertical into a $0.625\text{-}\lambda$ vertical for the 17-m band. These verticals were designed and constructed by John J. Reh, K7KGP. The write-up first appeared in April 1989 *QST*.

CONSTRUCTION DETAILS

For the 30 and 12-m vertical, an old aluminum multiband vertical was cut to a length of 25 ft, 3 inches. This corresponds to a design frequency of 24.95 MHz. The length-to-diameter ratio is approximately 460. The input impedance of a vertical that is substantially longer than a $1/4\text{-}\lambda$ (in this case 0.625λ) is particularly sensitive to the λ/D ratio of the radiating element. If this antenna is duplicated with materials having a significantly different λ/D ratio, the results may be different.

After installing a good ground system, the input impedance was measured and found to have a resistance of about 50 Ω , and a capacitance of about $-155\ \Omega$ (at 24.95 MHz). At 10.125 MHz, the input impedance was just under 50 Ω , and

purely resistive. To tune out the reactance at 24.95 MHz, a series inductor is installed (see Fig 22.50) and tapped to resonance at the design frequency. The easiest way to find resonance is by measuring the antenna SWR. Use a good-quality coil for the series inductor. The recommended coil has a diameter of $2\frac{1}{2}$ inches, and has 6 turns per inch (B&W stock no. 3029). Resonance on 12 m was established with $3\frac{1}{4}$ turns. The SWR on 12 m is 1.1:1, and on 30 m, 1:1. To change bands from 12 to 30 m, move the coil tap to the end of the coil closest to the vertical element. Alternatively, a single-pole switch or remotely operated relay can be installed at the base of the vertical for bandswitching. Later, you'll see how to build the antenna with automatic bandswitching.

THE GROUND SYSTEM

Maximum RF current density—and therefore maximum ground losses—for $1/4\text{-}\lambda$ verticals occurs in the immediate area of the base of the antenna. Maximum return current ground loss for a $0.625\text{-}\lambda$ vertical occurs about $1/2\lambda$ away from the base of the antenna. It's important to have the lowest possible losses in the immediate area for both types of verticals. In addition to a ground radial system, 6x6-ft

Fig 22.50 — Dual-band vertical. Use a switch or relay to remove the loading coil from the circuit for lower frequency operation. Adjust the coil tap for best SWR on the higher-frequency band. The radial system should be as extensive as possible. See *The ARRL Antenna Book* for more information on ground systems for vertical antennas.

aluminum ground screen is used at the base of the antenna. The screen makes a good tie point for the radials and conducts ground currents efficiently. Seventeen wire radials, each about 33 ft long, are spaced evenly around the antenna. More radials would probably work better. Each radial is bolted to the screen using corrosion-resistant #10-24 hardware. (Do not attempt to connect copper directly to aluminum. The electrical connection between the two metals will quickly deteriorate.) The radials can be made of bare or insulated wire. Make sure the ground screen is bolted to the ground side of the antenna with heavy-gauge wire. Current flow is fairly heavy at this point.

Table 22.10 gives specifications for the dual-band vertical. If your existing 40-m

Table 22.10
Specifications for Dual-Band Verticals

Bands	Height	Required Matching Inductance (μH)
12 m & 30 m	23' 5"	0.99
17 m & 40 m	32' 3"	1.36

vertical is a few inches longer than 32 ft, 3 inches, try using it anyway—a few inches isn't too critical to performance on 17 m.

AUTOMATIC BANDSWITCHING

In October 1989 *QST*, James Johnson,

W8EUI, presented this scheme for automatic bandswitching of the 40/17-m vertical. Johnson shortened his 40-m vertical approximately 12 inches and found an inductance that gave him 40 and 17-m band operation with an SWR of less than 1.4:1 across each band. He used an inductor made from B&W air-wound coil stock (no. 3033). This coil is 3 inches in diameter, and has $3\frac{1}{8}$ turns of #12 wire wound at 6 turns per inch, providing an inductance of about 2.8 μH . Johnson experimentally determined the correct tap position.

For the 30/12-m version, start with the vertical radiator 9 inches shorter than the value given in the table. In both cases, radiator height and inductance should be adjusted for optimum match on the two bands covered.

Inverted L and Sloper Antennas

This section covers variations on the vertical antenna. **Fig 22.51A** shows a flat-top T vertical. Dimension H should be as tall as possible for best results. The horizontal section, L, is adjusted to a length that provides resonance. Maximum radiation is polarized vertically despite the horizontal top-loading wire. A variation of the T antenna is depicted at B of Fig 22.51. This antenna is commonly referred to as an *inverted L*. Vertical member H should be as long as possible. L is added to provide an electrical quarter wavelength overall.

THE HALF-SLOPER ANTENNA

Many hams have had excellent results with *half-sloper* antennas, while others

have not had such luck. Investigations by ARRL Technical Advisor John S. Belrose, VE2CV, have brought some insight to the situation through computer modeling with *ELNEC* and antenna-range tests. The following is taken from VE2CV's Technical Correspondence in Feb 1991 *QST*, pp 39 and 40. Essentially, the half sloper is a top-fed vertical antenna worked against a ground plane (such as a grounded Yagi antenna) at the top of the tower. The tower acts as a reflector.

For half slopers, the input impedance, the resonant length of the sloping wire and the antenna pattern all depend on the tower height, the angle (between the sloper and tower) the type of Yagi and the Yagi orientation. Here are several configurations

extracted from VE2CV's work:

At 160 m—use a 40-m beam on top of a 95-ft tower with a 55° sloper apex angle. The radiation pattern varies little with Yagi type. The pattern is slightly cardioid with about 8 dB front-to-back ratio at a 25° takeoff angle (see Fig 22.51D and E). Input impedance is about 50 Ω .

At 80 m—use a 20-m beam on top of a 50-ft tower with a 55° sloper apex angle. The radiation pattern and input impedance are similar to those of the 160-m half sloper.

At 40 m—use a 20-m beam on top of a 50-ft tower with a 55° sloper apex angle. The radiation pattern and impedance depend strongly on the azimuth orientation of the Yagi. Impedance varies from 76 to 127 Ω depending on Yagi direction.

Fig 22.51 — Some variations in vertical antennas. D is the vertical radiation pattern in the plane of a half sloper, with the sloper to the right. E is the azimuthal pattern of the half sloper (90° azimuth is the direction of the sloping wire). Both patterns apply to 160- and 80-m antennas described in the text.

1.8-MHz INVERTED L

The antenna shown in Fig 22.52 is simple and easy to construct. It is a good antenna for the beginner or the experienced 1.8 MHz DXer. Because the overall electrical length is greater than $\frac{1}{4} \lambda$, the feed-point resistance is on the order of 50Ω , with an inductive reactance. That reactance is canceled by a series capacitor, which for power levels up to the legal limit can be an air-variable capacitor with a voltage rating of 1500 V. Adjust antenna length and vari-

Fig 22.52 — The 1.8-MHz inverted L. Overall wire length is 165 to 175 ft. The variable capacitor has a maximum capacitance of 500 to 800 pF.

able capacitor for lowest SWR.

A yardarm or a length of line attached to a tower can be used to support the vertical section of the antenna. (Keep the inverted

L as far from the tower as is practical. Certain combinations of tower height and Yagi top loading can interact severely with the Inverted-L antenna—a 70-ft tower and

a 5-element Yagi, for example.) For best results the vertical section should be as long as possible. A good ground system is necessary for good results.

THE HALF-WAVE VERTICAL DIPOLE (HVD)

Chuck Hutchinson, K8CH, describes a 15-m vertical dipole (HVD) that he built in the ARRL book, *Simple and Fun Antennas for Hams*. The performance of this antenna, with its base at 14 ft, compares favorably with a horizontal dipole at 30 ft when making intercontinental QSOs.

CONSTRUCTION OF A 15-M HVD

The 15-meter HVD consists of four 6-ft lengths of 0.875-inch aluminum tube with 0.058 wall thickness. In addition there are two 1-ft lengths of 0.75-inch tubing for splices, and two one-foot lengths of 0.75-inch fiberglass rod for insulators. See **Table 22.11** for dimensions.

Start by cutting off 1 foot from a 6-ft length of 0.875-inch tubing. Next, insert six inches of one of the 1-foot-long 0.75-inch tubes into the machine-cut end of your tubing and fasten the tubes together. Now, slide an end of a 6-ft length of 0.875 tube over the protruding end of the 0.75 tube and fasten them together. Repeat this procedure

with the remaining 0.875-inch tubing.

You should now have two 11-ft-long elements. As you can see in **Fig 22.53**, K8CH was temporarily out of aluminum pop rivets, so he used sheet metal screws. Either will work fine, but pop rivets can easily be drilled out and the antenna disas-

sembled if you ever want to make changes.

Because hand-made cuts are not perfectly square, put those element ends at the center of the antenna. Slip these cut ends over the ends of a 1-ft length of 0.75-inch fiberglass rod. This rod serves as the center insulator. Leave about a 1-inch gap at the center. Drill aluminum and fiberglass for #8 hardware as shown in **Fig 22.54**.

Now, slip half of the remaining 1-ft length of 0.75-inch fiberglass rod into one end the dipole. (This end will be the bottom end or base.) Drill and secure with #8 hardware. See **Fig 22.55**.

The final step is to secure the guy wires to your vertical. You can see how K8CH did that in **Fig 22.56**. Start by drilling a pilot hole and then drive a sheet metal screw into the antenna about a foot above the center. The purpose of that screw is to prevent the clamp and guys from sliding down the antenna.

The guys are clean lengths of $\frac{3}{16}$ -inch Dacron line. (The Dacron serves a dual purpose: it supports the antenna vertically, and it acts as an insulator.) Tie secure knots into the guy ends and secure these knotted ends to the antenna with a stainless-steel worm-screw-type hose clamp. Take care to not over tighten the clamps. You don't want the clamp to slip (the knots and the sheet-metal screw will help), but you especially don't want to cut your guy lines. Your

Fig 22.54 — The center insulator of the 15-m HVD is a 1-ft length of 0.75-inch fiberglass rod. Insulator and elements have been drilled to accept #8 hardware.

Fig 22.55 — The HVD base insulator is a 1-ft length of 0.75-inch fiberglass rod.

Table 22.11
HVD Dimensions

Length using 0.875-inch aluminum tubing		
MHz	Feet	Inches
18.11	33	11
21.2	22	0
24.94	18	9
28.4	16	5

These lengths should be divided by two to determine the length of the dipole legs.

Fig 22.53 — Element splice uses a 1-ft length of 0.75-inch tubing inserted into the 0.875-inch sections to join them together. Self-tapping sheet-metal screws are used in this photo, but aluminum pop rivets or machine screws with washers and nuts can be used.

Fig 22.56 — Guys are made of Dacron line that is attached to the HVD by a stainless-steel worm-screw-type hose clamp. A self-tapping sheet-metal screw (not visible in the photo) prevents the clamp from sliding down the antenna.

Fig 22.57 — At K8CH, the HVD base insulator sits in this saddle-shaped wooden fixture. This photo was taken before the fixture was painted—a necessary step to protect against the weather.

Fig 22.58 — The HVD installed at K8CH. An eye screw that is used for securing one of the guy lines is visible in the foreground. You can also see the two choke baluns that are used in the feed system (see text).

antenna is ready for installation.

INSTALLATION

Installation requires two things. First, a place to sit or mount the base insulator. Second, you need anchors for the support guys.

K8CH used a piece of 2×6 lumber to make a socket to hold the HVD base securely in place. He drilled a $\frac{3}{4}$ -inch-deep hole with a $\frac{3}{4}$ -inch spade bit. A couple of pieces of 2×2 lumber at the ends of the base form a saddle which nicely straddles the ridge at the peak of his garage roof. You can see how I did this in **Fig 22.57**. The dimensions are not critical, but you should paint your base to protect it from the weather.

BALUN

This antenna needs a common-mode choke to ensure that stray RF doesn't flow on the shield of the coax. This device is also known as a choke balun. Unlike a horizontal dipole, don't consider it an option to omit the common-mode choke when building and installing an HVD.

You can use 8 ft of the RG-213 feed line wound into 7 turns for a balun. Secure the turns together with electrical tape so that each turn lies parallel with the next turn, forming a solenoid coil. Secure the feed line and balun to one of the guy lines with UV-resistant cable ties.

Because the feed line slants away from the antenna, you'll want to do *all* that you can to eliminate common-mode currents from the feed line. For that reason, make another balun about 11.5 ft from the first one. This balun also consists of 8 ft of the RG-213 feed line wound into 7 turns. See **Fig 22.58**.

THE COMPACT VERTICAL DIPOLE (CVD)

An HVD for 20 m will be about 33 ft tall, and for 30 m, it will be around 46 ft tall. Even the 20-m version can prove to be a mechanical challenge. The compact vertical dipole (CVD), designed by Chuck Hutchinson, K8CH, uses capacitance loading to shorten the antenna. Starting with the 15-m HVD described in the previous project, Chuck added capacitance loading wires to lower the resonance to 30 m. Later, he shortened the wires to move resonance to the 20-m band. This project describes those two CVDs.

PERFORMANCE ISSUES

Shortened antennas frequently suffer reduced performance caused by the shortening. A dipole that is less than a half wave in length is a compromise antenna. The question becomes how much is lost in the compromise. In this case there are two areas of primary interest, radiation efficiency and SWR bandwidth.

Radiation Efficiency

Capacitance loading at the dipole ends is the most efficient method of shortening the antenna. Current distribution in the high-current center of the antenna remains virtually unchanged. Since radiation is related directly to current, this is the most desirable form of loading. Computer modeling shows that radiation from a 30-m CVD is only 0.66 dB less than that from a full-size 30-m HVD when both have their bases 8 ft above ground. The

angle of maximum radiation shifts up a bit for the CVD. Not a bad compromise when you consider that the CVD is 22-ft long compared to the approximately 46-ft length of the HVD.

SWR and SWR Bandwidth

Shortened antennas usually have lower radiation resistance and less SWR bandwidth than the full-size versions. The amount of change in the radiation resistance is related to the amount and type of loading (shortening), being lower with shorter the antennas. This can be a benefit in the case of a shortened vertical dipole. In **Fig 22.1** you can see that vertical dipoles have a fairly high radiation resistance. With the dipole's lower end $\frac{1}{8} \lambda$ above ground, the radiation resistance is roughly 80Ω . In this case, a shorter antenna can have a better SWR when fed with $50\text{-}\Omega$ coax.

SWR bandwidth tends to be wide for vertical dipoles in general. A properly designed CVD for 7-MHz or higher should give you good SWR (1.5:1 or better) across the entire band!

As you can see, in theory the CVD provides excellent performance in a compact package. Experience confirms the theory.

CONSTRUCTION

To convert the K8CH 15-m HVD to 20 or 30 m, you'll need to add four loading wires at the top and four more at the bottom of the HVD. The lengths are shown in

Table 22.12. The upper wires droop at a 45° angle and the lower wires run horizontally. The antenna is supported by 4 guy lines. See **Fig 22.59**. You can connect the wires to the vertical portion with #8 hardware. Crimp and solder terminals on the wire ends to make connections easier. The technique is illustrated in **Fig 22.60**.

The upper loading wires can be extended with insulated line and used for additional guying. The lower wires are extended with insulated line and fasten to the guy lines so that the lower wires run horizontally.

Prune the lower wires for best SWR across the band of interest. The K8CH CVD has its base at 14 ft. This antenna has an SWR of less than 1.2:1 on 30 m and less than 1.3:1 across the entire 20-m band.

EXPERIENCE

The 30-m CVD was compared to a ground-mounted quarter-wave vertical and a horizontal dipole at 30 ft. In tests, the CVD was always the superior antenna.

Table 22.12
CVD Loading Wires

Band	Feet	Inches	
30 m	6	0	Top & Bottom
20 m	4	$2\frac{1}{4}$	Top
20 m	3	$\frac{1}{2}$	Bottom

Fig 22.59 — The CVD consists of a vertical dipole and loading wires. Only one set of the four loading wires and only one guy line is shown in this drawing. See text for details.

Every DX station that was called by K8CH responded with one or two calls. What more could you ask for?

Later, the CVD loading wires were shortened for operation on 20 m. Once again the results were very encouraging. Many contest QSOs were entered in the log using this antenna.

Finally, a late winter ice storm depos-

ited about $\frac{3}{4}$ inch of radial ice on the antenna, loading wires and guys. The antenna would probably have survived had it not been for the sustained 45 mph winds that followed. The upper loading wires and their guy lines were not heavy enough to support the load and the antenna bent and broke. This combination of ice and wind is very unusual.

ALL WIRE 30-M CVD

If you have a tree or other support that will support the upper end of a CVD at 32 ft above the ground, you might want to consider an all-wire version of the 30-m CVD. The vertical is 24 ft long and it will have an SWR of less than 1.1:1 across the band. The four loading wires at top and bottom are each 5 ft, 2 inches long.

The configuration is shown in **Fig 22.61**. As with any vertical dipole, you'll need to use a balun between the feedline and the antenna.

Alternatively you can use two loading wires at the top and two at the bottom. In this case each of the loading wires is 8 ft $7\frac{1}{2}$ inches long.

Fig 22.60 — CVD loading wires can be attached using #8 hardware. Crimp and solder terminals on the wire ends to make connections easier.

Fig 22.61 — The all-wire 30-m CVD consists of a vertical dipole and loading wires. It can be made entirely with #14 wire. Support lines have been omitted for simplicity. See text for details.

Yagi and Quad Directive Antennas

Most antennas described earlier in this chapter have unity gain compared to a dipole, or just slightly more. For the purpose of obtaining gain and directivity it is convenient to use a Yagi-Uda or cubical quad beam antenna. The former is commonly called a *Yagi*, and the latter is usually referred to as a *quad*.

Most operators prefer to erect these antennas for horizontal polarization, but they can be used as vertically polarized arrays merely by rotating the elements by 90°. In effect, the beam antenna is turned on its side for vertical polarity. The number of elements used will depend on the gain desired and the limits of the supporting structure. Many amateurs obtain satisfactory results with only two elements in a beam antenna, while others have four or five elements operating on a single amateur band.

Regardless of the number of elements used, the height-above-ground considerations discussed earlier for dipole antennas remain valid with respect to the angle of radiation. This is demonstrated in Fig 22.62 at A and B where a comparison of radiation characteristics is given for a 3-element Yagi at one-half and one wavelength above average ground. It can be seen that the higher antenna (Fig 22.62B) has a main lobe that is more favorable for DX work (roughly 15°) than the lobe of the lower antenna in Fig 22.62A (approximately 30°). The pattern at B shows that some useful high-angle radiation exists also, and the higher lobe is suitable for short-skip contacts when propagation conditions dictate the need.

The azimuth pattern for the same antenna is provided in Fig 22.63. Most of the power is concentrated in the *main lobe* at 0° azimuth. The lobe directly behind the main lobe at 180° is often called the *backlobe*. Note that there are small *sidelobes* at approximately 110° and 260° in azimuth. The peak power difference, in decibels, between the *nose* of the main lobe at 0° and the strongest rearward lobe is called the *front-to-rear ratio (F/R)*. In this case the worst-case rearward lobe is at 180°, and the F/R is 12 dB. It is infrequent that two 3-element Yagis with different element spacings and tuning will yield the same lobe patterns. The pattern of Fig 22.63 is shown only for illustrative purposes.

PARASITIC EXCITATION

In most of these arrangements the additional elements receive power by induction or radiation from the driven element and reradiate it in the proper phase relationship to give the desired effect. These elements are called *parasitic elements*, as

contrasted to *driven elements*, which receive power directly from the transmitter through the transmission line.

The parasitic element is called a *director* when it reinforces radiation on a line pointing to it from the driven element, and a *reflector* when the reverse is the case. Whether the parasitic element is a director or reflector depends on the parasitic element tuning, which is usually adjusted by changing its length.

GAIN, FRONT-TO-REAR RATIO AND SWR

The gain of an antenna with parasitic elements varies with the spacing and tun-

ing of the elements. Element tuning is a function of length, diameter and taper schedule if the element is constructed with telescoping tubing. For any given spacing, there is a tuning condition that will give maximum gain at this spacing. However, the maximum front-to-rear ratio seldom, if ever, occurs at the same condition that gives maximum forward gain. The impedance of the driven element in a parasitic array, and thus the SWR, also varies with the tuning and spacing.

It is important to remember that all these parameters change as the operating frequency is varied. For example, if you operate both the CW and phone portions

Fig 22.62 — Elevation-plane response of a 3-element Yagi placed $\frac{1}{2} \lambda$ above perfect ground at A and the same antenna spaced 1λ above ground at B.

Fig 22.63 — Azimuth-plane pattern of a typical three-element Yagi in free space. The Yagi's boom is along the 0° to 180° axis.

Fig 22.64 — Gain vs element spacing for a 2-element Yagi, having one driven and one parasitic element. The reference point, 0 dB, is the field strength from a half-wave antenna alone. The greatest gain is in the direction A at spacings of less than 0.14λ , and in direction B at greater spacings. The front-to-rear ratio is the difference in decibels between curves A and B. Variation in radiation resistance of the driven element is also shown. These curves are for the special case of a self-resonant parasitic element, but are representative of how a 2-element Yagi works. At most spacings the gain as a reflector can be increased by slight lengthening of the parasitic element; the gain as a director can be increased by shortening. This also improves the front-to-rear ratio.

Fig 22.65 — General relationship of gain of 3-element Yagi vs director spacing, the reflector being fixed at 0.2λ . This antenna is tuned for maximum forward gain.

Table 22.13

10-m Optimized Yagi Designs

of the 20-m band with a Yagi or quad antenna, you probably will want an antenna that *spreads out* the performance over most of the band. Such designs typically must sacrifice a little gain in order to achieve good F/R and SWR performance across the band. The longer the boom of a Yagi or a quad, and the more elements that are placed on that boom, the better will be the overall performance over a given amateur band. For the lower HF bands, the size of the antenna quickly becomes impractical for truly *optimal* designs, and compromise is necessary.

TWO-ELEMENT BEAMS

A 2-element beam is useful—especially where space or other considerations prevent the use of a three element, or larger, beam. The general practice is to tune the parasitic element as a reflector and space it about 0.15λ from the driven element, although some successful antennas have been built with 0.1λ spacing and director tuning. Gain vs element spacing for a 2-element antenna is given in Fig 22.64 for the special case where the parasitic element is resonant. It is indicative of the performance to be expected under maximum-gain tuning conditions. Changing the tuning of the driven element in a Yagi or quad will not materially affect the gain or F/R. Thus, only the spacing and the tuning of the single parasitic element have any effect on the performance of a 2-element Yagi or quad. Most 2-element Yagi designs achieve a compromise F/R of about 10 dB, together with acceptable SWR and gain across a frequency band with a percentage bandwidth less than about 4%. A 2-ele-

ment quad can achieve better F/R, gain and SWR across a band, at the expense of greater mechanical complexity compared to a Yagi.

THREE-ELEMENT BEAMS

A theoretical investigation of the 3-element case (director, driven element and reflector) has indicated a maximum gain of about 9.7 dBi. A number of experimental investigations have shown that the spacing between the driven element and reflector for maximum gain is in the region of 0.15 to $.25 \lambda$. With 0.2λ reflector spacing, Fig 22.65 shows that the gain variation with director spacing is not especially critical. Also, the overall length of the array (boom length in the case of a rotatable antenna) can be anywhere between 0.35 and 0.45λ with no appreciable difference in the maximum gain obtainable.

If maximum gain is desired, wide spacing

Fig 22.67 — The boom-to-element plate at A uses muffer-clamp-type U-bolts and saddles to secure the round tubing to the flat plate. The boom-to-mast plate at B is similar to the boom-to-element plate. The main difference is the size of materials used.

Fig 22.66 — Some methods of connecting telescoping tubing sections to build beam elements. See text for a discussion of each method.

of both elements is beneficial because adjustment of tuning or element length is less critical and the input resistance of the driven element is generally higher than with close spacing. A higher input resistance improves the efficiency of the antenna and makes a greater bandwidth possible. However, a total antenna length, director to reflector, of more than 0.3λ at frequencies of the order of 14 MHz introduces difficulty from a construction standpoint. Lengths of 0.25 to 0.3λ are therefore used frequently for this band, even though they are less than opti-

Fig 22.68 — Illustrations of gamma and T matching systems. At A, the gamma rod is adjusted along with C until the lowest SWR is obtained. A T match is shown at B. It is the same as two gamma-match rods. The rods and C1 and C2 are adjusted alternately for a best SWR. A coaxial 4:1 balun transformer is shown at C. A toroidal balun can be used in place of the coax model shown. The toroidal version has a broader frequency range than the coaxial one. The T match is adjusted for 200Ω and the balun steps this balanced value down to 50Ω , unbalanced. Or the T match can be set for 300Ω , and the balun used to step this down to 75Ω unbalanced. Dimensions for the gamma and T match rods will depend on the tubing size used, and the spacing of the parasitic elements of the beam. Capacitors C, C1 and C2 can be 140 pF for 14-MHz beams. Somewhat less capacitance will be needed at 21 and 28 MHz.

imum from the viewpoint of maximum gain.

In general, Yagi antenna gain drops off less rapidly when the reflector length is increased beyond the optimum value than it does for a corresponding decrease below the optimum value. The opposite is true of a director. It is therefore advisable to err, if necessary, on the long side for a reflector and on the short side for a director. This also tends to make the antenna performance less dependent on the exact frequency at which it is operated: An increase above the design frequency has the same effect as increasing the length of both parasitic elements, while a decrease in frequency has the same effect as shortening both elements. By making the director slightly short and the reflector slightly long, there will be a greater spread between the upper and lower frequencies at which the gain starts to show a rapid decrease.

We recommend *plumbers delight* construction, where all elements are mounted directly on, and grounded to, the boom. This puts the entire array at dc ground potential, affording better lightning protection. A gamma- or T-match section can be used for matching the feed line to the array.

COMPUTER-OPTIMIZED YAGIS

Yagi designers are now able to take advantage of powerful personal computers and software to optimize their designs for the parameters of gain, F/R and SWR across frequency bands. ARRL Senior Assistant Technical Editor Dean Straw, N6BV, has designed a family of Yagis for HF bands. These can be found in **Tables 22.13, 22.14, 22.15, 22.16** and **22.17**, for the 10, 12, 15, 17 and 20-m amateur bands.

For 12 through 20 m, each design has been optimized for better than 20 dB F/R, and an SWR of less than 2:1 across the entire amateur frequency band. For the 10-m band, the designs were optimized for the lower 800 kHz of the band, from 28.0 to 28.8 MHz. Each Yagi element is made of telescoping 6061-T6 aluminum tubing, with 0.058 inch thick walls. This type of element can be telescoped easily, using techniques shown in **Fig 22.66**. Measuring each element to an accuracy of $1/8$ inch results in performance remarkably consistent with the computations, without any need for *tweaking* or fine-tuning when the Yagi is on the tower.

Each element is mounted above the boom with a heavy rectangular aluminum plate, by means of galvanized U-bolts with saddles, as shown in **Fig 22.67**. This method of element mounting is rugged and stable, and because the element is mounted away from the boom, the amount of element detuning due to the presence of

the boom is minimal. The element dimensions given in each table already take into account any element detuning due to the boom-to-element mounting plate. The element-to-boom mounting plate for all the 10-m Yagis is a 0.250-inch thick flat aluminum plate, 4 inches wide by 4 inches long. For the 12 and 15-m Yagis, a 0.375-inch thick flat aluminum plate, 5 inches wide by 6 inches long is used, and for the 17 and 20-m Yagis, a 0.375-inch thick flat aluminum plate, 6 inches wide by 8 inches long is used. Where the plate is rectangular, the long dimension is in line with the element.

Each design table shows the dimensions for *one-half* of each element, mounted on one side of the boom. The other half of each element is the same, mounted on the other side of the boom. Use a tubing sleeve inside the center portion of the element so that the element is not crushed by the mounting U-bolts. Each telescoping section is inserted 3 inches into the next size of tubing. For example, in the 310-08.YAG design (3 elements on an 8-ft boom), the reflector tip, made out of $1/2$ -inch OD tubing, sticks out 66.75 inches from the $5/8$ -inch OD tubing. For each 10-m element, the overall length of each $5/8$ -inch OD piece of tubing is 21 inches, before insertion into the $3/4$ -inch piece. Since the $3/4$ -inch OD tubing is 24 inches long on each side of the boom, the center portion of each element is actually 48 inches of uncut $3/4$ -inch OD tubing.

The boom for all these antennas should be constructed with at least 2-inch-OD tubing, with 0.065-inch wall thickness. Because each boom has 3 inches extra space at each end, the reflector is actually placed 3 inches from one end of the boom. For the 310-08.YAG, the driven element is placed 36 inches ahead of the reflector, and the director is placed 54 inches ahead of the driven element.

Each antenna is designed with a driven element length appropriate for a gamma or T matching network, as shown in **Fig 22.68**. The variable gamma or T capacitors can be housed in small plastic enclosures for weatherproofing; receiving-type variable capacitors with close plate spacing can be used at powers up to a few hundred watts. Maximum capacitance required is usually 140 pF at 14 MHz and proportionally less at the higher frequencies.

The driven-element's length may require slight readjustment for best match, particularly if a different matching network is used. *Do not change either the lengths or the telescoping tubing schedule of the parasitic elements*—they have been optimized for best performance and will not be affected by tuning of the driven element.

TUNING ADJUSTMENTS

Preliminary matching adjustments can be done on the ground. The beam should be set up so the reflector element rests on the earth, with the beam pointing upward. The matching system is then adjusted for best SWR. When the antenna is raised to its operating height, only slight touch-up of the matching network may be required.

CONSTRUCTION OF YAGIS

Most beams and verticals are made from sections of aluminum tubing. Compromise beams have been fashioned from less-expensive materials such as electrical conduit (steel) or bamboo poles wrapped with conductive tape or aluminum foil. The steel conduit is heavy, is a poor conductor and is subject to rust. Similarly, bamboo with conducting material attached to it may deteriorate rapidly in the weather. The dimensions shown for the Yagis in the preceding section are designed for specific telescoping aluminum elements, but the elements may be scaled to different sizes by using the information about tapering and scaling in Chapter 2 of *The ARRL Antenna Book*, although with a likelihood of deterioration in performance over the whole frequency band.

For reference, **Table 22.18** details the standard sizes of aluminum tubing, available in many metropolitan areas. Dealers may be found in the Yellow Pages under *Aluminum*. Tubing usually comes in 12-ft lengths, although 20-ft lengths are available in some sizes. Your aluminum dealer will probably also sell aluminum plate in various thicknesses needed for boom-to-mast and boom-to-element connections.

Aluminum is rated according to its hardness. The most common material used in antenna construction is grade 6061-T6. This material is relatively strong and has good workability. In addition, it will bend without taking a *set*, an advantage in antenna applications where the pieces are constantly flexing in the wind. The softer grades (5051, 3003 and so on) will bend much more easily, while harder grades (7075 and so on) are more brittle.

Wall thickness is of primary concern when selecting tubing. It is of utmost importance that the tubing fits snugly where the element sections join. Sloppy joints will make a mechanically unstable antenna. The magic wall thickness is 0.058 inch. For example (from Table 22.18), 1-inch outside diameter (OD) tubing with a 0.058-inch wall has an inside diameter (ID) of 0.884 inch. The next smaller size of tubing, $7/8$ inch, has an OD of 0.875 inch. The 0.009-inch difference provides just the right amount of clearance for a snug fit.

*These sizes are extruded; all other sizes are drawn tubes. Shown here are standard sizes of aluminum tubing that are stocked by most aluminum suppliers or distributors in the United States and Canada.

Fig 22.66 shows several methods of fastening antenna element sections together. The slot and hose clamp method shown in Fig 22.66A is probably the best for joints where adjustments are needed. Generally, one adjustable joint per element half is sufficient to tune the antenna—usually the tips at each end of an element are made adjustable. Stainless steel hose clamps (beware—some “stainless steel” models do not have a stainless screw and will rust) are recommended for longest antenna life.

Fig 22.66B, C and D show possible fastening methods for joints that are not adjustable. At B, machine screws and nuts hold the elements in place. At C, sheet metal screws are used. At D, rivets secure the tubing. If the antenna is to be assembled permanently, rivets are the best choice. Once in place, they are permanent. They will never work free, regardless of vibration or wind. If aluminum rivets with aluminum mandrels are employed, they will

never rust. Also, being aluminum, there is no danger of corrosion from interaction between dissimilar metals. If the antenna is to be disassembled and moved periodically, either B or C will work. If machine screws are used, however, take precautions to keep the nuts from vibrating free. Use of lock washers, lock nuts and flexible adhesive such as silicone bathtub sealant will keep the hardware in place.

Use of a conductive grease at the element joints is essential for long life. Left untreated, the aluminum surfaces will oxidize in the weather, resulting in a poor connection. Some trade names for this conductive grease are Penetrox, Noalox and Dow Corning Molykote 41. Many electrical supply houses carry these products.

BOOM MATERIAL

The boom size for a rotatable Yagi or quad should be selected to provide stability to the entire system. The best diameter for the boom depends on several factors,

but mostly the element weight, number of elements and overall length. Two-inch-diameter booms should not be made any longer than 24 ft unless additional support is given to reduce both vertical and horizontal bending forces. Suitable reinforcement for a long 2-inch boom can consist of a truss or a truss and lateral support, as shown in Fig 22.69.

Fig 22.69 — A long boom needs both vertical and horizontal support. The crossbar mounted above the boom can support a double truss, which will help keep the antenna in position.

A boom length of 24 ft is about the point where a 3-inch diameter begins to be very worthwhile. This dimension provides a considerable amount of improvement in overall mechanical stability as well as increased clamping surface area for element hardware. The latter is extremely important to prevent rotation of elements around the boom if heavy icing is commonplace. Pinning an element to the boom with a large bolt helps in this regard. On smaller diameter booms, however, the elements sometimes work loose and tend to elongate the pinning holes in both the element and the boom. After some time the elements shift their positions slightly (sometimes from day to day) and give a ragged appearance to the system, even though this may not harm the electrical performance.

A 3-inch-diameter boom with a wall thickness of 0.065 inch is very satisfactory for antennas up to about a 5-element, 20-m array that is spaced on a 40-ft boom. A truss is recommended for any boom longer than 24 ft. One possible source for large boom material is irrigation tubing

sold at farm supply houses.

PUTTING IT TOGETHER

Once you assemble the boom and elements, the next step is to fasten the elements to the boom securely and then fasten the boom to the mast or supporting structure. Be sure to leave plenty of material on either side of the U-bolt holes on the element-to-boom mounting plates. The U-bolts selected should be a snug fit for the tubing. If possible, buy muffler-clamp U-bolts that come with saddles.

The boom-to-mast plate shown in Fig 22.67B is similar to the boom-to-element plate. The size of the plate and number of U-bolts used will depend on the size of the antenna. Generally, antennas for the bands up through 20 m require only two U-bolts each for the mast and boom. Longer antennas for 15 and 20 m (35-ft booms and up) and most 40-m beams should have four U-bolts each for the boom and mast because of the torque that the long booms and elements exert as the antennas move in the wind. When tighten-

ing the U-bolts, be careful not to crush the tubing. Once the wall begins to collapse, the connection begins to weaken. Many aluminum suppliers sell 1/4-inch or 3/8-inch plates just right for this application. Often they will shear pieces to the correct size on request. As with tubing, the relatively hard 6061-T6 grade is a good choice for mounting plates.

The antenna should be put together with good-quality hardware. Stainless steel is best for long life. Rust will attack plated steel hardware after a short while, making nuts difficult, if not impossible, to remove. If stainless muffler clamps are not available, the next best thing is to have them plated. If you can't get them plated, then at least paint them with a good zinc-chromate primer and a finish coat or two. Good-quality hardware is more expensive initially, but if you do it right the first time, you won't have to take the antenna down after a few years and replace the hardware. Also, when repairing or modifying an installation, nothing is more frustrating than fighting rusty hardware at the top of a tower.

Quad Antennas

One of the more effective DX arrays is called a *quad* antenna. It consists of two or more loops of wire, each supported by a bamboo or fiberglass cross-arm assembly. The loops are a quarter wavelength per side (full wavelength overall). One loop is driven and the other serves as a parasitic element—usually a reflector. A variation of the quad is called the *delta loop*. The electrical properties of both antennas are the same. Both antennas are shown in Fig 22.70. They differ mainly in their physical properties, one being of plumber's delight construction, while the other uses insulating support members. One or more directors can be added to either antenna if additional gain and directivity are desired, though most operators use the 2-element arrangement.

It is possible to interlace quads or deltas for two or more bands, but if this is done the formulas given in Fig 22.70 may have to be changed slightly to compensate for the proximity effect of the second antenna. For quads the length of the full-wave loop can be computed from

$$\text{Full-wave loop} = \frac{1005}{f \text{ (MHz)}} \text{ ft} \quad (7)$$

If multiple arrays are used, each antenna should be tuned separately for maximum forward gain, or best front-to-rear ratio, as observed on a field-strength meter. The

reflector stub on the quad should be adjusted for this condition. The gamma match should be adjusted for best SWR. The resonance of the antenna can be found by checking the frequency at which the

lowest SWR occurs. By lengthening or shortening it, the driven element length can be adjusted for resonance in the most-used portion of the band.

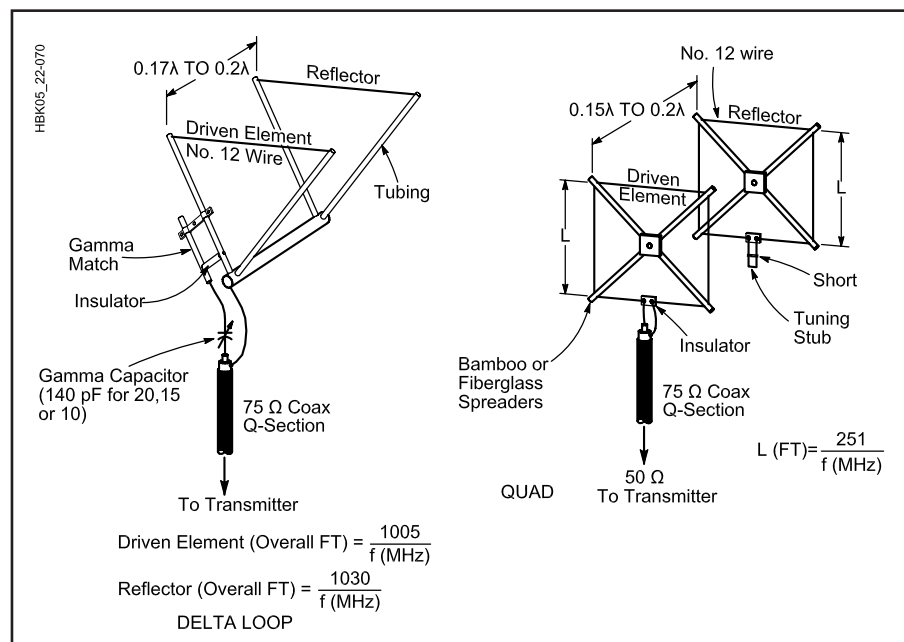

Fig 22.70 — Information on building a quad or a delta-loop antenna. The antennas are electrically similar, but the delta-loop uses plumber's delight construction. The $\lambda/4$ length of 75-Ω coax acts as a Q-section transformer from approximate 100-Ω feedpoint impedance of quad to 50-Ω feed line coax.

A FIVE-BAND, TWO-ELEMENT HF QUAD

Two quad designs are described in this article, both nearly identical. One was constructed by KC6T from scratch, and the other was built by Al Doig, W6NBH, using modified commercial triband quad hardware. The principles of construction and adjustment are the same for both models, and the performance results are also essentially identical. One of the main advantages of this design is the ease of (relatively) independent performance adjustments for each of the five bands. These quads were described by William A. Stein, KC6T, in *QST* for April 1992. Both models use 8-ft-long, 2-inch diameter booms, and conventional X-shaped spreaders (with two sides of each quad loop parallel to the ground).

THE FIVE-BAND QUAD AS A SYSTEM

Unless you are extraordinarily lucky, you should remember one general rule: Any quad must be adjusted for maximum performance after assembly. Simple quad designs can be tuned by pruning and re-stringing the elements to control front-to-rear ratio and SWR at the desired operating frequency. Since each element of this quad contains five concentric loops, this adjustment method could lead to a nervous breakdown!

Fig 22.71 shows that the reflectors and driven elements are each independently adjustable. After assembly, adjustment is simple, and although gamma-match components on the driven element and capacitors on the reflectors add to the antenna's parts count, physical construction is not difficult. The reflector elements are purposely cut slightly long (except for the 10-m reflector), and electrically shortened by a tuning capacitor. The driven-element gamma matches set the lowest SWR at the desired operating frequency.

As with most multiband directive antennas, the designer can optimize any two of the following three attributes at the expense of the third: forward gain, front-to-rear ratio and bandwidth (where the SWR is less than 2:1). These three characteristics are related, and changing one changes the other two. The basic idea behind this quad design is to permit (without resorting to trimming loop lengths, spacing or other gross mechanical adjustments):

- The forward gain, bandwidth and front-to-rear ratio may be set by a simple adjustment after assembly. The adjustments can be made on a band-by-band basis, with little or no effect on previously made adjustments on the other bands.

Fig 22.71 — Mechanical layout of the five-band quad. The boom is 8 ft long; see Table 22.19 for all other dimensions.

- Setting the minimum SWR in any portion of each band, with no interaction with previously made front-to-back or SWR adjustments.

The first of the two antennas described, the KC6T model, uses aluminum spreaders with PVC insulators at the element attachment points. (The author elected not to use fiberglass spreaders because of their high cost.) The second antenna, the W6NBH model, provides dimensions and adjustment values for the same antenna, but using standard triband-quad fiberglass spreaders and hardware. If you have a triband quad, you can easily adapt it to this design. When W6NBH built his antenna, he had to shorten the 20-m reflector because the KC6T model uses a larger 20-m reflector than W6NBH's fiberglass spreaders would allow. Performance is essentially identical for both models.

MECHANICAL CONSIDERATIONS

Even the best electrical design has no value if its mechanical construction is lacking. Here are some of the things that

contribute to mechanical strength: The gamma-match capacitor KC6T used was a small, air-variable, chassis-mount capacitor mounted in a plastic box (see Fig 22.72). A male UHF connector was mounted to the box, along with a screw terminal for connection to the gamma rod.

Fig 22.72 — Photo of one of the feed-point gamma-match capacitors.

The terminal lug and wire are for later connection to the driven element. The box came from a local hobby shop, and the box lid was replaced with a piece of 1/32-inch ABS plastic, glued in place after the capacitor, connector and wiring had been installed. The capacitor can be adjusted with a screwdriver through an access hole. Small vent (drain) holes were drilled near corresponding corners of each end.

Enclose the gamma-match capacitor in such a manner that you can tape unwanted openings closed so that moisture can't be directly blown in during wind and rainstorms. Also, smaller boxes and sturdy mounts to the driven element ensure that you won't pick up gamma capacitor assemblies along with the leaves after a wind storm.

Plastic gamma-rod insulators/standoffs were made from 1/32-inch ABS, cut 1/2-inch wide with a hole at each end. Use a knife to cut from the hole to the side of each insulator so that one end can be slipped over the driven element and the other over the gamma rod. Use about four such insu-

lators for each gamma rod, and mount the first insulator as close to the capacitor box as possible. Apply five-minute epoxy to the element and gamma rod at the insulator hole to keep the insulators from sliding. If you intend to experiment with gamma-rod length, perform this gluing operation after you have made the final gamma-rod adjustments.

ELEMENT INSULATORS

As shown in Fig 22.71, the quad uses insulators in the reflectors for each band to break the loop electrically, and to allow reflector adjustments. Similar insulators were used to break up each driven element so that element impedance measurements could be made with a noise bridge. After the impedance measurements, the driven-element loops are closed again. The insulators are made from 1/4 x 2 x 3/4-inch phenolic stock. The holes are 1/2-inch apart. Two terminal lugs (shorted together at the center hole) are used in each driven element. They offer a convenient way to open the loops by removing one screw.

Fig 22.73 shows these insulators and the gamma-match construction schematically. Table 22.19 lists the component values, element lengths and gamma-match dimensions.

ELEMENT-TO-SPREADER ATTACHMENT

Probably the most common problem with quad antennas is wire breakage at the element-to-spreader attachment points. There are a number of functional attachment methods; Fig 22.74 shows one of them. The attachment method with both KC6T and W6NBH spreaders is the same, even though the spreader constructions differ. The KC6T model uses #14 AWG, 7-strand copper wire; W6NBH used #18, 7-strand wire. At the point of element attachment (see Fig 22.75), drill a hole through both walls of the spreader using a #44 (0.086-inch) drill. Feed a 24-inch-long piece of antenna wire through the hole and center it for use as an attachment wire.

After fabricating the spider/spreader assembly, lay the completed assembly on a flat surface and cut the element to be installed to the correct length, starting with the 10-m element. Attach the element ends to the insulators to form a closed loop before attaching the elements to the spreaders. Center the insulator between the spreaders on what will become the bottom side of the quad loop, then carefully measure and mark the element-mounting-points with fingernail polish (or a similar substance). Do *not* depend on the at-rest position of the spreaders to guarantee that the mounting points will all be correct.

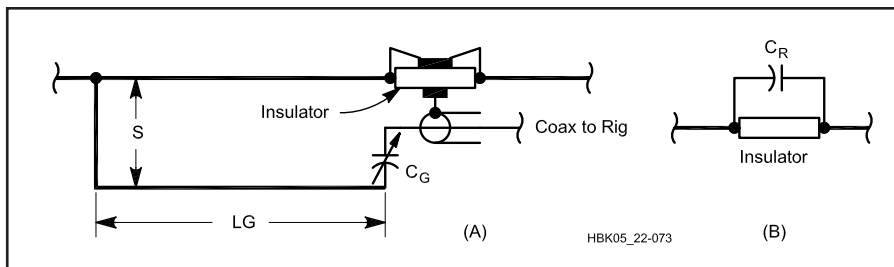

Fig 22.73 — Gamma-match construction details at A and reflector-tuning capacitor (C_R) attachment schematic at B. The gamma matches consist of matching wires (one per band) with series capacitors (C_G). See Table 22.19 for lengths and component specifications.

Table 22.19

Element Lengths and Gamma-Match Specifications of the KC6T and W6NBH Five-Band Quads

KC6T Model

Band (MHz)	Driven Element	Length (in.)	Gamma Match Spacing	C_G (pF)	Reflector Length (in.)	C_R (pF)
14	851.2	33	2	125	902.4	68
18	665.6	24	2	110	705.6	47
21	568	24	1.5	90	604.8	43

28	421.6	26.5	1	52	448.8	(jumper)

W6NBH Model

Band (MHz)	Driven Element	Length (in.)	Gamma Match Spacing	C_G (pF)	Reflector Length (in.)	C_R (pF)
14	851.2	31	2	117	890.4	120
18	665.6	21	2	114	705.6	56
21	568	26	1.5	69	604.8	58
24.9	483.2	15	1	75.5	514.4	54
28	421.6	18	1	41	448.8	(jumper)

Fig 22.74 — Attaching quad wires to the spreaders must minimize stress on the wires for best reliability. This method (described in the text) cuts the chances of wind-induced wire breakage by distributing stress.

Fig 22.75 — Spreader-drilling diagram and dimensions (in.) for the five-band quad. These dimensions apply to both spreader designs described in the text, except that most commercial spreaders are only a bit over 13 ft (156 inches) long. This requires compensation for the W6NBH model's shorter 20-m reflector as described in the text.

Holding the mark at the centerline of the spreader, tightly loop the attachment wire around the element and then gradually space out the attachment-wire turns as shown. The attachment wire need not be soldered to the element. The graduated turn spacing minimizes the likelihood that the element will flex in the same place with each gust of wind, thus reducing fatigue-induced wire breakage.

FEEDING THE DRIVEN ELEMENTS

Each driven element is fed separately, but feeding five separate feed lines down the tower and into the shack would be costly and mechanically difficult. The ends of each of these coax lines also require support other than the tension (or lack of thereof) provided by the driven element at the feed-point. It is best to use a remote coax switch on the boom approximately 1 ft from the driven-element spider-assembly attachment point.

At installation, the cables connecting the gamma-match capacitors and the coax switch help support the driven elements and gamma capacitors. The support can be improved by taping the cables together in several places. A single coaxial feed line (and a control cable from the remote coax switch, if yours requires one) is the only required cabling from the antenna to the shack.

THE KC6T MODEL'S COMPOSITE SPREADERS

If you live in an area with little or no wind, spreaders made from wood or PVC are practical but, if you live where winds can reach 60 to 80 mi/h, strong, lightweight spreaders are a must. Spreaders constructed with electrical conductors (in this case, aluminum tubing) can cause a myriad of problems with unwanted resonances, and the problem gets worse as the number of bands increases.

To avoid these problems, this version uses composite spreaders made from machined PVC insulators at the element-attachment points. Aluminum tubing is inserted into (or over) the insulators 2 inches on each end. This spreader is designed to withstand 80 mi/h winds. The overall insulator length is designed to provide a 3-inch center insulator clear of the aluminum tubing. The aluminum tubing used for the 10-m section (inside dimension "A" in Fig 22.75) is $1\frac{1}{8}$ -inch diameter \times 0.058-inch wall. The next three sections are $\frac{3}{4}$ -inch diameter \times 0.035-inch wall, and the outer length is made from $\frac{1}{2}$ -inch diameter \times 0.035-inch wall. The dimensions shown in Fig 22.75 are *attachment point* dimensions only.

Attach the insulators to the aluminum

using #6 sheet metal screws. Mechanical strength is provided by Devcon no. S 220 Plastic Welder Glue (or equivalent) applied liberally as the aluminum and plastic parts are joined. Paint the PVC insulators before mounting the elements to them. Paint protects the PVC from the harmful effects of solar radiation. As you can see from Fig 22.75, an additional spreader insulator located about halfway up the 10-m section (inside dimension "A") removes one of the structure's electrical resonances not eliminated by the attachment-point insulators. Because it mounts at a relatively high-stress point in the spreader, this insulator is fabricated from a length of heavy-wall fiberglass tubing.

Composite spreaders work as well as fiberglass spreaders, but require access to a well-equipped shop, including a lathe. The main objective of presenting the composite spreader is to show that fiberglass spreaders aren't a basic requirement—there are many other ways to construct usable spreaders. If you can lay your hands on a used multiband quad, even one that's damaged, you can probably obtain enough spreaders to reduce construction costs considerably.

GAMMA ROD

The gamma rod is made from a length of #12 solid copper wire (W6NBH used #18, 7-strand wire). Dimensions and spacings are shown in Table 22.19. If you intend to experiment with gamma-rod lengths and capacitor settings, cut the gamma-rod lengths about 12 inches longer than the length listed in the table. Fabricate a sliding short by soldering two small alligator clips back-to-back such that they can be clipped to the rod and the antenna element and easily moved along the driven element. Note that gamma-rod spacing varies from one band to another. When you find a suitable shorting-clip position, mark the gamma rod, remove the clip, bend the gamma rod at the mark and solder the end to the element.

THE W6NBH MODEL

As previously mentioned, this model uses standard 13-ft fiberglass spreaders, which aren't quite long enough to support the larger 20-m reflector specified for the KC6T model. The 20-m W6NBH reflector loop is cut to the dimensions shown in Table 22.19, 12 inches shorter than that for the KC6T model. To tune the shorter reflector, a 6-inch-long stub of antenna wire (spaced 2 inches) hangs from the reflector insulator, and the reflector tuning capacitor mounts on another insulator at the end of this stub.

GAMMA-MATCH AND REFLECTOR-TUNING CAPACITOR

Use an air-variable capacitor of your choice for each gamma match. Approximately 300 V can appear across this capacitor (at 1500 W), so choose plate spacing appropriately. If you want to adjust the capacitor for best match and then replace it with a fixed capacitance, remember that several amperes of RF will flow through the capacitance. If you choose disc-ceramic capacitors, use a parallel combination of at least four 1-kV units of equal value. Any temperature coefficient is acceptable. NP0 units are not required. Use similar components to tune the reflector elements.

ADJUSTMENTS

Well, here you are with about 605 ft of wire. Your antenna will weigh about 45 pounds (the W6NBH version is slightly lighter) and have about 9 square ft of wind area. If you chose to, you can use the dimensions and capacitance values given, and performance should be excellent. If you adjust the antenna for minimum SWR at the band centers, it should cover all of the lower four bands and 28 to 29 MHz with SWRs under 2:1; front-to-rear ratios are given in **Table 22.20**.

Instead of building the quad to the dimensions listed and hoping for the best, you can adjust your antenna to account for most of the electrical environment variables of your installation. The adjustments are conceptually simple: First adjust the reflector's electrical length for maximum front-to-rear ratio (if you desire good gain,

Table 22.20

Measured Front-to-Rear Ratios

<i>Band</i>	<i>KC6T Model</i>	<i>W6NBH Model</i>
14	25 dB	16 dB
18	15 dB	10 dB
21	25 dB	>20 dB
24.9	20 dB	>20 dB
28	20 dB	>20 dB

and are willing to settle for a narrower than maximum SWR bandwidth), or accept some compromise in front-to-rear ratio that results in the widest SWR bandwidth. You can make this adjustment by placing an air-variable capacitor (about 100-pF maximum) across the open reflector loop ends, one band at a time, and adjusting the capacitor for the desired front-to-rear ratio. The means of doing this will be discussed later.

During these reflector adjustments, the driven-element gamma-match capacitors may be set to any value and the gamma rods may be any convenient length (but the sliding-short alligator clips should be installed somewhere near the lengths specified in Table 22.19). After completing the front-to-rear adjustments, the gamma capacitors and rods are adjusted for minimum SWR at the desired frequency.

ADJUSTMENT SPECIFICS

Adjust each band by feeding it separately. You can make a calibrated variable

capacitor (with a hand-drawn scale and wire pointer). Calibrate the capacitor using your receiver, a known-value inductor and a dip meter (plus a little calculation).

To adjust front-to-rear ratio, simply clip the (calibrated) air-variable capacitor across the open ends of the desired reflector loop. Connect the antenna to a portable receiver with an S meter. Point the back of the quad at a signal source, and slowly adjust the capacitor for a dip in the S-meter reading.

After completing the front-to-rear adjustments, replace the variable capacitor with an appropriate fixed capacitor sealed against the weather. Then move to the driven-element adjustments. Connect the coax through the SWR bridge to the 10-m gamma-match capacitor box. Use an SWR bridge that requires only a watt or two (not more than 10 W) for full-scale deflection in the calibrate position on 10 m. Using the minimum necessary power, measure the SWR. Go back to receive and adjust the capacitor until (after a number of transmit/receive cycles) you find the minimum SWR. If it is too high, lengthen or shorten the gamma rod by means of the sliding alligator-clip short and make the measurements again.

Stand away from the antenna when making transmitter-on measurements. The adjustments have minimal effect on the previously made front-to-rear settings, and may be made in any band order. After making all the adjustments and sealing the gamma capacitors, reconnect the coax harness to the remote coax switch.

A SIMPLE QUAD FOR 40 METERS

Many amateurs yearn for a 40-m antenna with more gain than a simple dipole. While two-element rotary 40-m beams are available commercially, they are costly and require fairly hefty rotators to turn them. This low-cost, single-direction quad is simple enough for a quick Field Day installation, but will also make a home station very competitive on the 40-m band.

This quad uses a 2-inch outside diameter, 18-ft boom, which should be mounted no less than 60 ft high, preferably higher. (Performance tradeoffs with height above ground will be discussed later.) The basic design is derived from the N6BV 75/8 0-meter quad described in *The ARRL Antenna Compendium, Vol 5*. However, since this simplified 40-m version is unidirectional and since it covers only one portion of the band (CW or Phone, but not both), all the relay-switched components

used in the larger design have been eliminated.

The layout of the simple 40-m quad at a boom height of 70 ft is shown in **Fig 22.76**. The wires for each element are pulled out sideways from the boom with black 1/8-inch Dacron rope designed specifically to withstand both abrasion and UV radiation. The use of the proper type of rope is very important—using a cheap substitute is not a good idea. You will not enjoy trying to retrieve wires that have become, like Charlie Brown's kite, hopelessly entangled in nearby trees, all because a cheap rope broke during a windstorm! At a boom height of 70 ft, the quad requires a *wingspread* of 140 ft for the side ropes. This is the same wingspread needed by an inverted-V dipole at the same apex height with a 90° included angle between the two legs.

The shape of each loop is rather unusual,

since the bottom ends of each element are brought back close to the supporting tower. (These element ends are insulated from the tower and from each other). Having the elements near the tower makes fine-tuning adjustments much easier—after all, the ends of the loop wires are not 9 feet out, on the ends of the boom! The feed-point resistance with this loop configuration is close to 50 Ω, meaning that no matching network is necessary. By contrast, a more conventional diamond or square quad-loop configuration exhibits about a 100-Ω resistance.

Another bonus to this loop configuration is that the average height above ground is higher, leading to a slightly lower angle of radiation for the array and less loss because the bottom of each element is raised higher above lossy ground. The drawback to this unusual layout is that

Fig 22.76 — Layout of 40-meter quad with a boom height of 70 feet. The four stay ropes on each loop pull out each loop into the desired shape. Note the 10-foot separator rope at the bottom of each loop, which helps it hold its shape. The feed line is attached to the driven element through a choke balun, consisting of 10 turns of coax in a 1-foot diameter loop. You could also use large ferrite beads over the feed-line coax, as explained in Chapter 21. Both the driven element and reflector loops are terminated in SO-239 connectors tied back to (but insulated from) the tower. The reflector SO-239 has a shorted PL-259 normally installed in it. This is removed during fine-tuning of the quad, as explained in the text.

four more *tag-line* stay ropes are necessary to pull the elements out sideways at the bottom, pulling against the 10-foot separator ropes shown in Fig 22.76.

CONSTRUCTION

You must decide before construction whether you want coverage on CW (centered on 7050 kHz) or on Phone (centered on 7225 kHz), with roughly 120 kHz of coverage between the 2:1 SWR points. If the quad is cut for the CW portion of the band, it will have less than about a 3.5:1 SWR at 7300 kHz, as shown in Fig 22.77. The pattern will deteriorate to about a 7 dB F/B at 7300 kHz, with a reduction in gain of almost 3 dB from its peak in the CW band. It is possible to use a quad tuned for CW in the phone band if you use an antenna tuner to reduce the SWR and if you can take the reduction in performance. To put things in perspective, a quad tuned for CW but operated in the phone band will still work about as well as a dipole.

Next, you must decide where you want to point the quad. A DXer or contester in the USA might want to point this single-

Fig 22.77 — Plot of SWR versus frequency for a quad tuned for CW operation.

direction design to cover Europe and North Africa. For Field Day, a group operating on the East Coast would simply point it west, while their counterparts on the West Coast would point theirs east.

The mechanical requirements for the boom are not severe, especially since a top truss support is used to relieve stress on the boom due to the wires pulling on it from below. The boom is 18 ft long, made

of 2-inch diameter aluminum tubing. You can probably find a suitable boom from a scrapped triband or monoband Yagi. You will need a suitable set of U-bolts and a mounting plate to secure the boom to the face of a tower. Or perhaps you might use lag screws to mount the boom temporarily to a suitable tree on Field Day! On a 70-ft high tower, the loop wires are brought back to the tower at the 37.5-ft level and tied there using insulators and rope. The lowest points of the loops are located about 25 ft above ground for a 70-ft tower. Fig 22.78 gives dimensions for the driven element and reflector for both the CW and the Phone portions of the 40-m band.

GUY WIRES

Anyone who has worked with quads knows they are definitely three-dimensional objects! You should plan your installation carefully, particularly if the supporting tower has guy wires, as most do. Depending on where the guys are located on the tower and the layout of the quad with reference to those guys, you will probably have to string the quad loops over

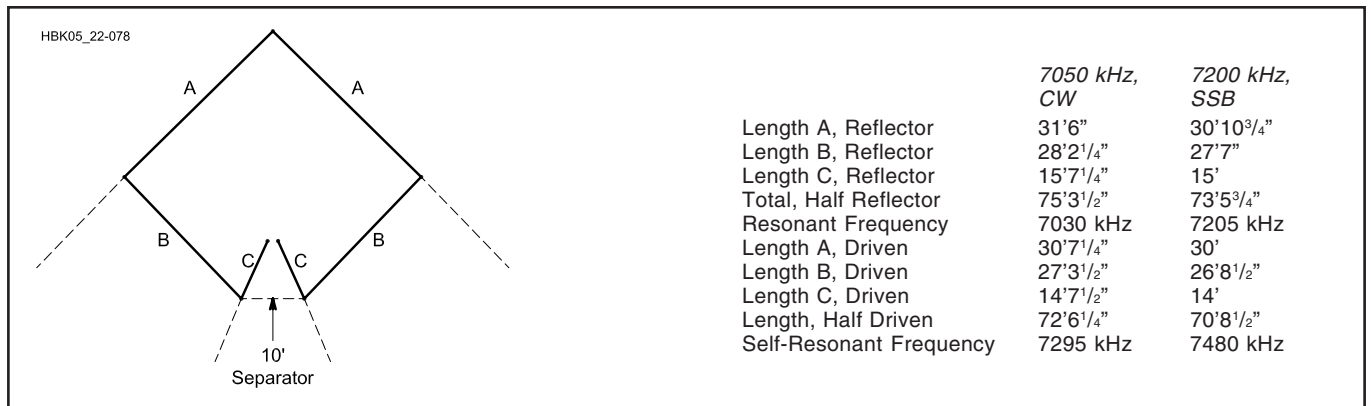

Fig 22.78 — Dimensions of each loop, for CW or Phone operation.

certain guys (probably at the top of the tower) and under other guys lower down.

It is very useful to view the placement of guy wires using the VIEW ANTENNA function in the EZNEC modeling program. This allows you to visualize the 3-D layout of an antenna. You can ROTATE yourself around the tower to view various aspects of the layout. EZNEC will complain about grounding wires directly but will still allow you to use the View Antenna function. Note also that it is best to insulate guy wires to prevent interaction between them and the antennas on a tower, but this may not be necessary for all installations.

FINE TUNING, IF NEEDED

We specify stranded #14 hard-drawn copper wire for the elements. During the course of installation, however, the loop wires could possibly be stretched a small amount as you pull and yank on them, trying to clear various obstacles. This may shift the frequency response and the performance slightly, so it is useful to have a tuning procedure for the quad when it is finally up in the air.

The easiest way to fine-tune the quad while on the tower is to use a portable, battery-operated SWR indicator (such as the Autek RF-1 or the MFJ-259) to adjust the reflector and the driven element lengths for specific resonant frequencies. You can eliminate the influence of mutual coupling to the other element by open-circuiting the other element.

For convenience, each quad loop should be connected to an SO-239 UHF female connector that is insulated from but tied close to the tower. You measure the driven

element's resonant frequency by first removing the shorted PL-259 normally inserted into the reflector connector. Similarly, the reflector's resonant frequency can be determined by removing the feed line normally connected to the driven element's feed point.

Obviously, it's easiest if you start out with extra wire for each loop, perhaps 6 inches extra on each side of the SO-239. You can then cut off wire in 1/2-inch segments equally on each side of the connector. This procedure is easier than trying to splice extra wire while up on the tower. Alligator clips are useful during this procedure, but just don't lose your hold on the wires! You should tie safety strings from each wire back to the tower. Prune the wire lengths to yield the resonant frequencies (± 5 kHz) shown in Fig 22.78 and then sol-

der things securely. Don't forget to reinsert the shorted PL-259 into the reflector SO-239 connector to turn it back into a reflector.

HIGHER IS BETTER

This quad was designed to operate with the boom at least 60 ft high. However, it will work considerably better for DX work if you can put the boom up even higher. Fig 22.79 shows the elevation patterns for four antennas: a reference inverted-V dipole at 70 ft (with a 90° included angle between the two legs), and three quads, with boom height of 70, 90 and 100 ft respectively. At an elevation angle of 20°, typical for DX work on 40 m, the quad at 100 ft has about a 5 dB advantage over an inverted-V dipole at 70 ft, and about a 3 dB advantage over a quad with a boom height of 70 ft.

Fig 22.79 — Comparisons of the elevation patterns for quads at boom heights of 70, 90 and 100 ft, referenced to an inverted-V dipole at 70 ft.

A SIMPLE LOOP ANTENNA FOR 28 MHZ

With the large number of operators and wide availability of inexpensive, single-band radios, the 10-m band could well become the hangout for local ragchewers that it was before the advent of 2-m FM, even at a low point in the solar cycle.

This simple antenna provides gain over a dipole or inverted V. It is a resonant loop with a particular shape. It provides 2.1 dB gain over a dipole at low radiation angles when mounted well above ground. The antenna is simple to feed—no matching network is necessary. When fed with 50-Ω coax, the SWR is close to 1:1 at the design frequency, and is less than 2:1 from 28.0-28.8 MHz for an antenna resonant at 28.4 MHz.

The antenna is made from #12 AWG wire (see Fig 22.80) and is fed at the center of the bottom wire. Coil the coax into a few turns near the feedpoint to provide a simple balun. A coil diameter of about a foot will work fine. You can support the antenna on a mast with spreaders made of bamboo, fiberglass, wood, PVC or other nonconducting material. You can also use aluminum tubing both for support and

conductors, but you may have to readjust the antenna dimensions for resonance.

This rectangular loop has two advantages over a resonant square loop. First, a square loop has just 1.1 dB gain over a dipole. This is a power increase of only 29%. Second, the input impedance of a square loop is about 125 Ω. You must use a matching network to feed a square loop with 50-Ω coax. The rectangular loop achieves gain by compressing its radiation pattern in the elevation plane. The azimuth plane pattern is slightly wider than that of a dipole (it's about the same as that of an inverted V). A broad pattern is an advantage for a general-purpose, fixed antenna. The rectangular loop provides a bidirectional gain over a broad azimuth region.

Mount the loop as high as possible. To provide 1.7 dB gain at low angles over an inverted V, the top wire must be at least 30 ft high. The loop will work at lower heights, but its gain advantage disappears. For example, at 20 ft the loop provides the same gain at low angles as an inverted V.

Fig 22.80 — Construction details of the 10-m rectangular loop antenna.

HF Mobile Antennas

This section is by Jack Kuecken, KE2QJ. Jack is an antenna engineer who has written a number of articles for ARRL publications.

An ideal HF mobile antenna is:

1. Sturdy. Stays upright at highway speeds.
2. Mechanically stable. Sudden stops or sharp turns do not cause it to whip about, endangering other vehicles.
3. Flexibly mounted. Permits springing around branches and obstacles at slow speeds.
4. Weatherproof. Handles the impact of wind, rain, snow and ice at high speed.
5. Tunable to all of the HF bands without stopping the vehicle.
6. Mountable without altering the vehicle in ways which lower the resale value.
7. Efficient as possible.
8. Easily removed for sending the car through a car wash, etc.

For HF mobile operation, the ham must use an electrically small antenna. The possibility that the antenna might strike a fixed object places a limitation on its height. On Interstate highways, an antenna tip at 11.5 feet above the pavement is usu-

ally no problem. However, on other roads you may encounter clearances of 9.5 or 10 feet. You should be able to easily *tie down* the antenna for a maximum height of about 7 feet to permit passage through low-clearance areas. The antenna should be usable while in the tied-down position.

If the base of an antenna is 1 ft above the pavement and the tip is at 11.5 ft, the length is 10.5 ft which is 0.1λ at 9.37 MHz, and 0.25λ at 23.4 MHz. That means that the antenna will require a matching network for all of the HF bands except 10 and 12 m.

The power radiated by the antenna is equal to the radiation resistance times the square of the antenna current. The radia-

tion resistance of an electrically small antenna is given by:

$$R_r = 395 \times (h/\lambda)^2$$

where

h = radiator height in meters

λ = wavelength in meters = $300/\text{Freq}$ in MHz

The capacitance in pF of an electrically small antenna is given approximately by:

$$C = \frac{55.78 \times h}{((\text{den1}) \times (\text{den2}))}$$

where

(den1) = $(\ln(h/r) - 1)$

(den2) = $(1 - (f \times h/75)^2)$

Table 22.21
Characteristics of a 10.5-foot whip antenna

F (MHz)	C (pF)	R _r	Impedance	Efficiency	L (μH)
1.8	30.1	0.146	13.72 -j2716	0.01064	240
3.5	30.6	0.55	7.43 -j1375	0.074	62.5
7	32.8	2.2	7.04 -j644	0.312	14.6
10	36.5	4.5	6.5 -j408	0.692	6.49
14	46.5	8.8	10 -j232	0.88	2.64

Fig 22.81 — Relationship at 3.5 MHz between vertical radiator length and capacitance. The two curves show that the capacitance is not very sensitive to radiator diameter.

Fig 22.82 — Relationship between frequency and capacitance for a 3.2-meter vertical whip.

\ln = natural logarithm
 r = conductor radius in meters
 f = frequency in MHz

Characteristics of a 10.5-ft (3.2 m) whip with a 0.003 m radius and, assuming a base loading coil with a Q of 200 and coil stray capacitance of 2 pF, are given in **Table 22.21**.

Radiation resistance rises in a nonlinear fashion and the capacitance drops just as dramatically with increase in the ratio h/λ . **Fig 22.81** shows the relationship of capacitance to height. This can be used for estimating antenna capacitance for other heights.

Fig 22.82 shows that capacitance is not very sensitive to frequency for h/λ less than 0.075, 8 MHz in this case. However, the sensitivity increases rapidly thereafter.

Table 22.21 shows that at 3.5 MHz an inductance of 62.5 μH will cancel the capacitive reactance. This results in an impedance of 7.43 Ω which means that additional matching is required. In this case the radiation efficiency of the system is only 0.074 or 7.4%. In other words, nearly 93% of energy at the terminals is wasted in heating the matching coil.

System Q is controlled by the Q of the coil. The bandwidth between 2:1 SWR points of the system = $0.36 \times f/Q$. In this case, bandwidth = $0.36 \times 3.5/200 = 6.3$ kHz

If we could double the Q of the coil, the efficiency would double and the bandwidth would be halved. The converse is also true. In the interest of efficiency, the highest possible Q should be used!

Another significant factor arises from the high Q. Let's assume that we deliver 100 watts to the 7.43 Ω at the antenna terminals. The current is 3.67 A and flows through the 1375- Ω reactance of the coil

giving rise to $1375 \times 3.67 = 5046$ VRMS (7137 Vpeak) across the coil.

With only 30.6 pF of antenna capacitance, the presence of significant stray capacitance at the antenna base shunts currents away from the antenna. RG-58 has about 21 pF/foot. A 1.5-foot length would halve the radiation efficiency of our example antenna. For cases like the whip at 3.5 MHz, the matching network has to be right at the antenna!

BASE, CENTER OR DISTRIBUTED LOADING

There is no clear-cut advantage in terms of radiation performance for either base or center-loaded antennas for HF mobile. Antennas with distributed (or continuous) loading have appeared in recent use. How do they compare?

Base Loading

In the design procedure, one estimates the capacitance, capacitive reactance and radiation resistance as shown previously. One then calculates the expected loss resistance of the loading coil required to resonate the antenna. There is generally additional resistance amounting to about half of the coil loss which must be added in. As a practical matter, it is usually not possible to achieve a coil Q in excess of 200 for such applications.

Using the radiation resistance plus 1.5 times the coil loss and the power rating desired for the antenna, one may select the wire size. For high efficiency coils, a current density of 1000 A/inch² is a good compromise. For the 3.67 A of the example we need a wire 0.068-inch diameter, which roughly corresponds to #14 AWG. Higher current densities can lead to a melted coil.

Design the coil with a pitch equal to

twice the wire diameter and the coil diameter approximately equal to the coil length. These proportions lead to the highest Q in air core coils.

The circuit of **Fig 22.83** will match essentially all practical HF antennas on a car or truck. The circuit actually matches the antenna to 12.5 Ω and the transformer boosts it up to 50 Ω . Actual losses alter the required values of both the shunt inductor and the series capacitor. At a frequency of 3.5 MHz with an antenna impedance of 0.55 $-j1375 \Omega$ and a base capacitance of 2 pF results in the values shown in **Table 22.22**. Inductor and capacitor values are highly sensitive to coil Q. Furthermore, the inductor values are considerably below the 62.5 μH required to resonate the antenna.

Fig 22.83 — The base-matched mobile whip antenna.

Table 22.22

Values of L and C for the Circuit of Fig 22.83 on 3.5 MHz

Coil Q	L (μH)	C (pF)	System Efficiency
300	44	11.9	0.083
200	29.14	35	0.0372
100	22.2	58.1	0.014

This circuit has the advantage that the tuning elements are all at the base of the antenna. The whip radiator itself has minimal mass and wind resistance. In addition, the rig is protected by the fact that there is a dc ground on the radiator so any accidental discharge or electrical contact is kept out of the cable and rig. Variable tuning elements allow the antenna to be tuned to other frequencies.

Connect the antenna, L and C. Start with less inductor than required to resonate the antenna. Tune the capacitor to minimum SWR. Increase the inductance and tune for minimum SWR. When the values of L and C are right, the SWR will be 1:1.

For remote or automatic tuning the drive motors for the coil and capacitor and the limit switches can be operated at RF ground potential. Mechanical connections to the RF components should be through insulated couplings.

Center Loading

Center loading increases the current in the lower half of the whip as shown in Fig 22.84. One can start by calculating the capacitance for the section above the coil just as done for the base loaded antenna. This permits the calculation of the loading inductance. The center loaded antenna is often operated without any base matching in which case the resistive component can be assumed to be 50 Ω for purposes of calculating the current rating and selecting wire size for the inductor.

The reduced size top section results in reduced capacitance which requires a much larger loading inductor. Center loading requires twice as much inductive reactance as base loading. For equal coil Qs, loss resistance is twice as great for center loading. If the coil is above the center, the inductance must be even larger, and the loss resistance increases accordingly. These factors tend to negate the advantage of the improved current distribution.

Because of the high value of inductance required, optimum Q coils are very large. One manufacturer of this type coil does not recommend their use in rain or inclement weather. The large wind resistance necessitates a very sturdy mount for operation at highway speed. Owing to the Q of these large coils the use of a base matching element in the form of either a tapped inductor or a shunt capacitor is usually needed to match to 50 Ω .

Another manufacturer places the coil above the center and uses a small extendable *wand* for tuning. To minimize wind resistance, the coil lengths are several times their diameters. These antenna coils are usually close wound with enameled wire. The coils are covered with a heat-shrink sleeve. If used in heavy rain or snow for extended periods water may get under the sleeving and seriously detune and lower the Q of the coils. These antennas usually do not require a base matching element. The resistance seems to come out close enough to 50 Ω .

It is possible to make a center-loaded antenna that is remotely tunable across the HF bands; however, this requires a certain amount of mechanical sophistication. The drive motor, limit switches and position sensor can be located in a box at the antenna base and drive the coil tuning mechanism through an electrically isolated shaft. Alternatively, the equipment could be placed adjacent to the loading coil requiring all of the electrical leads to be choked off to permit RF feeding of the base. The latter choice is probably the most difficult to realize.

Continuously Loaded Antennas

Antennas consisting of a fiberglass sleeve with the radiator wound in a continuous spiral to shorten a CB antenna from 8.65 feet to 5 or 6 feet have been on the market for many years. This modest shortening has little impact on the efficiency but does narrow the bandwidth.

One line of mobile antennas uses periodic loading on a relatively small diameter tube. A series of taps along the length are used to select among the HF bands. An adjustable tip allows one to move about a single band. Because the length to diameter ratio is so large the loading coil Q is relatively low. The antenna is most effective above 20 meters.

THE SCREWDRIVER ANTENNA

The screwdriver antenna consists of a top whip attached to a long slender coil about 1.5 inches in diameter. The coil screws itself out of a base tube which has a set of contact fingers at the top. For lower frequencies more of the coil is screwed out of the base tube and at maximum frequency the coil is entirely *swallowed* by the base tube.

The antenna is tunable over a wide range of frequencies by remote control. It has the advantage that the drive mechanism is operated at ground potential with RF isolation in the mechanical drive shaft. On the other hand, the antenna is not easily extended to 10.5 foot length for maximum efficiency on 80 and 40 meters. Because of its shape, coil Q will not be very high.

Fig 22.84 — Relative current distribution on a base-loaded antenna is shown at A and for a center-loaded antenna at B.

DIGITAL VERSUS ANALOG COUPLERS

Digital HF antenna couplers were first used by the military about 1960 for radios with Automatic Link Establishment. In this mode, the military radio has a list of frequencies ranging 2 to 30 MHz. It will try these in some sequence and will *lock* on the frequency giving the best reception. During the search, frequencies change much too fast to permit the use of conventional roller coils and motor driven vacuum capacitors. By comparison the digital coupler can jump from one memory setting to another in milliseconds.

For matching a mobile whip, the circuit shown in Fig 22.85 will suffice. The inductor and capacitor can each be made up of about 8 binary sequenced steps. For example, at 3.5 MHz, the 10.5-foot antenna has an impedance of about $0.55 -j1684 \Omega$. From Table 22.22 we see that we could use a series inductance sequence of 20, 10, 5, 2.5, 1.25, 0.625, 0.32 and 0.16 μH . We can use a relay to short unwanted elements. In this way we could theoretically produce any value of inductance between 0 and 39.84 μH in steps of 0.16 μH . In reality you will never reach a zero inductance. With all of the relays shorted, the wiring inductance and contact inductance of 8 relays appear in series. Also, each of the coils will have the open circuit capacitance of a relay contact across it in addition to the normal stray capacitance.

With most relays it does not make sense to switch less than 2 pF. For that reason, the capacitance chain would consist of 2, 4, 8, 16, 32, 64, 128 and possibly 256 pF. This would give a maximum of 510 pF and a step size of 2 pF. Each relay has an open circuit capacitance of about 1 pF, and that gives a minimum capacitance of 8 to 9 pF. As a practical matter, there is also the stray capacitance between the relay contacts and the coil windings.

In a high Q matching circuit that handles 100 W, the individual relays must handle 4 or 5 kV with the contacts open and several amperes of RF with the contacts closed. If we can unkey the transmitter so that the coupler will not have to switch under power, we'll still need some sizeable relays. If the inductors have lower Q, the voltages and currents will be correspondingly lower. Some military couplers use Jennings vacuum latching relays. This is expensive, as each of the 16 or 17 relays costs more than \$100.

If coil and antenna Qs are kept or forced low, the voltages and currents become more reasonable. However, if the antenna size is restricted this reduction comes only at the cost of decreased efficiency. A commercially available ham/marine digital

Fig 22.85 — A digital coupler based on the circuit shown in Fig 22.83. Capacitive and inductive elements are organized in a binary sequence with each being twice the value of the next lower value.

coupler employs RF reed relays rated for 5 kV and 1 A, and restricts the power at low frequencies if the antenna is small. Another ham/marine unit uses small relays in series where voltage requirements are great and in parallel where current requirements are great—not good engineering practice. A third offering is not too specific about the power rating with very high Q loads.

There are no successful examples of 100 W plus couplers that use PIN diode switching. Their use is highly problematic given the high-Q loads they would handle.

A REMOTELY TUNED ANALOG ANTENNA COUPLER

KE2QJ built an antenna coupler designed for 100-W continuous-duty operation that will tune an antenna 10 feet or longer to any frequency from 3.5 to 30 MHz. With longer antennas, the power rating is higher and the lowest frequency is lower. The design requires only hand tools to build; however, access to a drill press and a lathe could save labor.

The roller coils and air variable capaci-

tors to be used are not widely manufactured these days. Tube-type linear amplifiers still use air variable capacitors but these are generally built on order for the manufacturer and are not readily available to consumers in small quantity.

Until the 1970s, E. F. Johnson manufactured roller coils and air variable capacitors that were suitable for kilowatt amplifier finals and high power antenna couplers. On occasion one or more of these may be found in the original box, but they tend to be expensive. Ten Tec and MFJ both manufacture antenna couplers and offer some components in small quantities.

The following data refer to generic motors, capacitors and inductors. The descriptions are intended to aid the builder in selecting items from surplus, hamfest flea market offerings or salvage of old equipment.

THE MOTORS

Two motors are required, one to drive the inductor and one to drive the capacitor. The design employs permanent mag-

net dc gearhead motors with a nominal 12-V rating. A permanent magnet (PM) motor can be reversed by simply reversing the polarity of the drive voltage, and its speed can be controlled over a wide range by pulsing the power on and off with a variable duty cycle. The motor should have an output shaft speed on the order of 60 to 180 r/min (1 to 3 r/s) although this is not critical. New, such motors, can cost as

much as \$65 to \$150 in small quantities. However, they can be found surplus and in repair shops for a few dollars.

The motor you are looking for is 1 to 1.5 inches in diameter and perhaps 2.5 inches long. It might be rated 12 or 24 V and have a 1/4-inch diameter output shaft. At 12 V it should have enough torque to make it hard to stop the shaft with your fingers. Tape recorders, fax machines, film projectors,

windshield wipers and copiers often use this type of motor.

LIMIT SWITCHES

On a remotely operated unit it is usually necessary to have limit switches to prevent the device from *crashing* into the ends. On an external roller coil these can be microswitches with paddles mounted on each end of the coil. As the coil is wound to one end, the roller operates the paddle and opens the limit switch which stops the motor.

Fig 22.86A illustrates a simple motor control circuit. Relay K1 is arranged as a DPDT polarity reversing switch. If switch CCW is pressed, the motor rotates CCW and the steering diode D2 prevents the relay from operating. If CW is pressed, relay K1 operates reversing the polarity of the motor. The motor is energized through the steering diode.

Fig 22.86B shows how to add limit switches. The diodes across the switches are called anti-jam diodes. When a switch opens, the diode permits current to flow in the reverse direction and the motor to move the roller away from the open switch.

The photograph of **Fig 22.87** shows the mounting of the switches on the coil. The diode should be a power rectifier type rated for several times the motor current and at least 60 V.

POSITION READER

While not necessary, it is worthwhile to

Fig 22.86 — At A, motor control circuit used by KE2QJ. This circuit uses pulse modulation for speed control with good starting torque. Direction of rotation is controlled by the relay. At B, how to add limit switches to the circuit. See text.

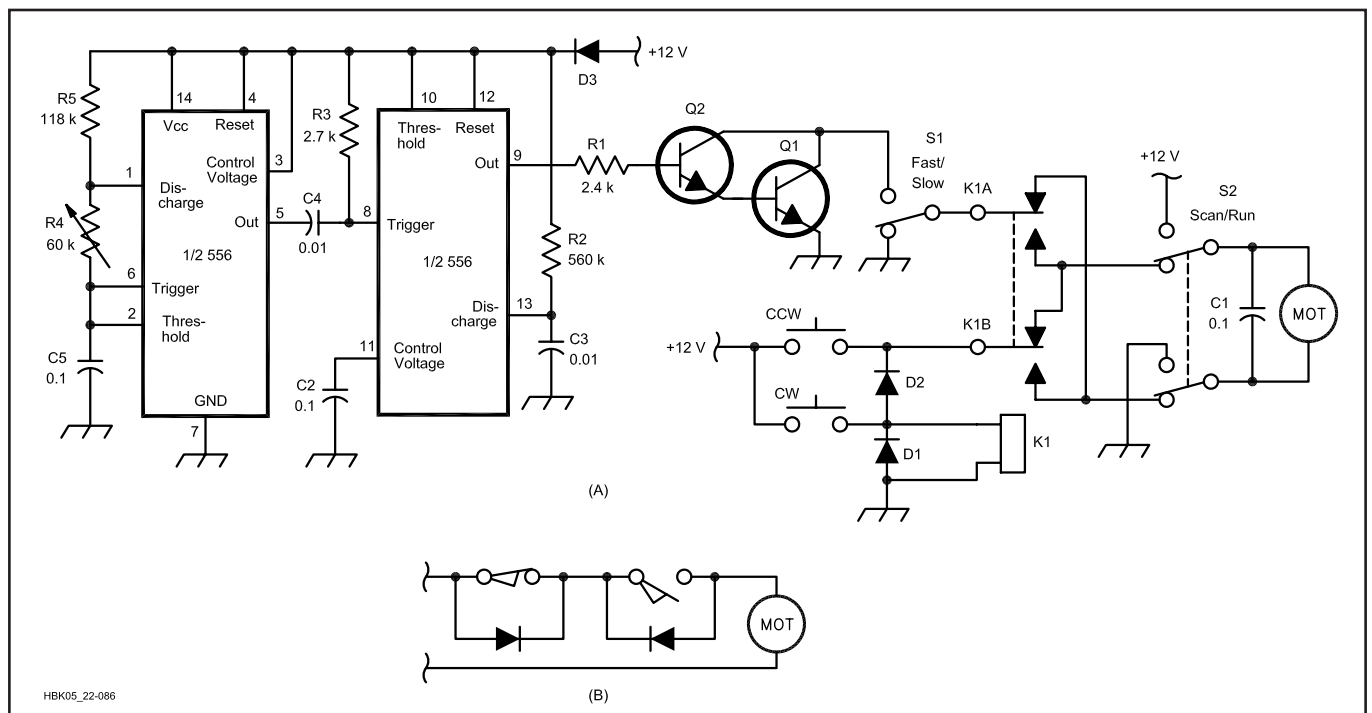

Fig 22.87 — Photo of the inductor drive assembly from KE2QJ's antenna coupler.

have a way to determine inductor position. An easy way to do this is to couple a 10-turn potentiometer to the coil shaft or drive gears. Make sure that the potentiometer turns less than 10 turns between limits. Don't try to make it come out exact.

Because the potentiometer is a light mechanical load, a belt drive reduction works well and won't slip if properly tensioned. Fig 22.87 shows the potentiometer and the gear drive.

You may be able to find suitable gears. However, a belt drive requires less precise shaft positioning than fine tooth gears. With a lathe, pulleys can be made in almost any ratio. Vacuum cleaner belts and O rings make handy belts.

COUPLINGS

In this coupler circuit, both ends of the capacitor are *hot* with RF although the end adjacent to the transformer is at relatively low voltage. Nevertheless, the capacitor shaft must be insulated from the motor shaft. The coil can be driven from the grounded end. Insulation is not necessary, but use a coupler between the motor shaft and the coil to compensate for any misalignment. Universal joints and insulating couplings are available from most electronics supply houses. You can make a coupling from a length of flexible plastic tubing which fits snugly over the shafts. Clamp the tubing to the shafts to avoid slippage.

THE CAPACITOR

The easiest capacitor to use is an air variable. It should have a range of approximately 10 to 250 pF. The plate spacing should be 2 mm ($1/16$ inch) or more, and the plate edges should be smooth and rounded. The capacitor should be capable of continuous 360° rotation, and it would be nice if it had ball bearings. The straight-line capacitance design is best for this application. Several capacitors of this type are available in military surplus ARC-5 series transmitters. These are approximately 2 × 2 × 3 inches.

The capacitor must be mounted on stand-off insulators although high voltage will not be present on the frame. A cam that briefly operates a microswitch when the capacitor goes through minimum can be used to flash an LED on the remote control panel. This provides an indication that the capacitor is turning.

THE INDUCTOR

As calculated earlier, and assuming an inductor Q a bit under 300 is attainable, the roller inductor for this coupler should have a maximum inductance on the order of 40 μH. The wire should be at least #14

Table 22.23
Data for 40 μH Coils

Diameter	Length	Turns
2.3 inch (58 mm)	5.625 inch (143 mm)	45
2.8 inch (71 mm)	4.25 inch (108 mm)	34
3.3 inch (84 mm)	3.375 inch (86 mm)	27

AWG wound about 8 t/inch.

You can use **Table 22.23** as a guide to buy a roller coil at a hamfest. The seller may not know the inductance of the coil. The antenna loading coil from an ARC-5 transmitter will work, but the wire is a bit small.

You could make the loading coil by threading 2, 2.5 or 3-inch diameter white, thick-wall PVC pipe with 8 t/inch. If the pipe is threaded in a lathe, the wire can be wound into the threads under consider-

able tension. This helps to prevent the wires from coming loose with wear or temperature.

THE TRANSFORMER

The transformer consists of a bifilar winding on an Amidon FT-114-61 core. Start with two 2-foot lengths of #18 insulated wire; Teflon insulation is preferable. Twist the wire with a hand drill until there are about 5 t/inch (not critical). Wind 12 turns onto the core. This should about fill it up. Attach the starting end of one wire to the finish end of the other. This is the 12.5-Ω tap. One of the free ends is grounded and the other is the 50-Ω tap. Mount the coil on a plastic or wooden post through the center of the coil. A metal screw can be used as long as it does not make a complete turn around the core.

CONSTRUCTION

For ease of service, mount the inductor, its drive motor, position sensing poten-

Fig 22.88 — At A, the chassis for the coupler mounting box. At B, the box cover.

tiometer and limit switch assembly on a single aluminum plate. A plug and socket assembly permits rapid disconnection and removal. Make a similar assembly for the capacitor, its drive motor, transformer and the interrupter. Both assemblies should be made on $\frac{1}{16}$ to $\frac{1}{4}$ -inch thick aluminum. These individual assemblies make it easier to fix problems.

The chassis shown in **Fig 22.88A** is made of a single piece $\frac{1}{16}$ to $\frac{3}{32}$ -inch aluminum bent in an L shape. Two chassis-stiffening braces are riveted in place. Alternatively, the chassis can be made of flat sheets with aluminum angles riveted around the edge.

Mount the coil and capacitor assemblies parallel to the long leg of the L. Punch a 1-inch hole in the center of the short end of the L. Cover the hole with an insulator made of PVC, Teflon or other suitable material.

The rest of the case is a 4-sided wooden assembly as shown in **Fig 22.88B**. The back wall of the box is drilled to accept the two pivot pins. The box is slid over the chassis and the pivot pins engaged. The tie-down screw secures the box. For service, remove the tie-down screw and slide off the cover. The works of the coupler are very easy to get at!

The box is made of $\frac{1}{4}$ -inch exterior grade plywood except for the back plate, which is $\frac{3}{8}$ or $\frac{1}{2}$ -inch plywood. The sides, top and back should overlap the flanges on the chassis by $\frac{1}{2}$ inch. The inside corner seams of the box should be reinforced with $\frac{1}{2}$ or $\frac{3}{4}$ -inch square strips. Assembly can be with any water resistant glue.

Finish the box, inside and out, with several coats of clear urethane varnish, sanding lightly between coats. This leaves a smooth plastic finish. This can be sprayed with an exterior paint that matches your car's color.

If the sides of the box fit closely over the flanges, no fastening beside the tie-down screw is required. A nearly perfect seal will leak out hot air when the sun shines on it and will draw in cold damp air in the evening, trapping moisture inside. A moderate fit will keep rain and snow out and permit the box to *breathe* freely, thereby keeping the inside dry.

MOUNTING THE WHIP AND THE BOX

Plastics in bumpers and bodies makes the mounting of a mobile whip antenna problematic. Modern bumpers are covered with plastic and the bumper is attached to the car unibody through a 5-MPH shock absorber. The latter item is an unreliable ground.

The arrangement of **Fig 22.89** solves many of these problems. It uses a $\frac{1}{4}$ -inch

Fig 22.89 — Antenna mounting detail. At A, the overall plan. At B, detail of the mount plate.

aluminum plate 6 to 8 inches wide and long enough to fit between a reasonably strong place on the unibody and the place behind the bumper where the antenna wants to be. This plate is fitted with an angle bracket for the lower bolt on the shock/bumper mounting. This plate is stiffened with a length of $1 \times 1 \times \frac{1}{4}$ inch aluminum angle bolted in several places.

Near the forward edge of the plate, two $\frac{1}{2}$ -inch diameter aluminum shear posts are fitted. The bottom of each is tapped 10-32 and bolted through the mount plate with a stainless 10-32 screw. At the top of these shear posts another piece of $1 \times 1 \times \frac{1}{2}$ -inch angle is attached which is screwed to the unibody with three or four #10 stainless sheet metal screws. A bracket attaches the mount plate to the bumper's shock absorber. The angle bracket may either be welded to the plate or bolted with angle stock. In the event that the car is hit from behind or backs into an obstacle, the two

10-32 screws will shear off, thereby preventing the mount from defeating the 5 MPH crushable shock absorber. The part protruding behind the bumper may be cut down in width to 3 inches and rounded for appearance and safety.

Any type of base insulator may be used, but try to bring the base of the antenna to the height of the coupler output terminal. You can make a good base insulator from thick-wall white PVC $1\frac{1}{2}$ -inch pipe. Reinforce each end. Start with a $1\frac{1}{2}$ -inch length of pipe. Remove a $\frac{5}{8}$ -inch wide strip so the remaining portion can be rolled and pressed into the open end of the insulator. Apply PVC pipe glue just before pressing in the piece; this gives the insulator a double wall thickness at each end. Aluminum plugs can be turned for a snug fit and tapped for $\frac{3}{8}$ -24 hardware. The plugs can be held in place with 8-32 stainless screws.

The upper antenna brace has an aluminum plate at one end that goes under the

trunk lid (see Fig 22.89). A length of 1/2-inch diameter heavy-wall white PVC pipe, which serves as an insulator, is screwed to this. At the other end of the insulator, another aluminum piece is bent to form a saddle for the antenna which is clamped to the saddle. This clamp should be as high as convenient above the mount plate, preferably not less than a foot. The mount plate should be sturdy enough for you to stand on and with the brace will easily hold a whip upright at 70 MPH or more.

The coupler box mounting is shown in Fig 22.90. Brackets can be made of 1/8 x 2-inch aluminum with a brace going perhaps 2 inches from the corner. The brackets bolt or rivet to the chassis. The bracket reaches through the gap between the trunk lid and the plastic top of the bumper. For reinforcement, a pair of reinforcement plates 1.5 x 2 x 1/4-inch thick are bolted to the plastic on the under side of the bumper. Ground the reinforcement plates to the unibody with some 3/4 or 1 inch ground braid.

Two 10-32 stainless screws hold each reinforcement plate to the plastic bumper and a central 1/4-20 tapped hole holds down the box bracket. One need only remove two screws to get the box off the car for car wash, etc. You have to open the trunk to remove the antenna coupler, and this provides a measure of security.

THE SPRING AND WHIP

A section of 1-inch diameter aluminum tubing extends from the top of the insulator to the base of the spring. It's usually best to have the spring about 4 ft above the pavement. The type used for CB whips works well. A 7-ft whip brings the top to about 11.5 ft above the pavement. The 7-ft whip can be a cut down CB unit. Don't use the type with helical winding. When the antenna is tied down, the bow of the whip should be about 7 ft above the pavement.

TUNING

It is best to initially tune the antenna using low power. A power attenuator just after the transceiver will limit SWR, but your SWR indicator must be on the antenna side of the attenuator.

For a first tune-up, set the capacitor control to SCAN and slowly advance the inductor from minimum inductance toward maximum. As the inductor approaches the correct value the SWR will start to kick down. At this point take the capacitor off of SCAN and JOG it to a best tune. Next, JOG the inductor and repeat; the SWR should go down. Continue until a 1:1 SWR is obtained. Record the potentiometer setting. The next time you want to use this frequency run the coil directly

Fig 22.90 — Box mounting detail. At A, mounting-bracket design. At B, photo of KE2QJ's installation.

to the logged setting.

In the SCAN position the capacitor motor runs at full voltage. When you JOG the capacitor for low SWR you will find the speed far too fast for sharp tuning. The slow speed tuning is provided by using duty-factor modulation of the motor current. The circuit of Fig 22.86A supplies fixed width pulses with variable timing. At the slowest speed, the unit will supply about one pulse per second and the motor shaft will rotate one degree or so per pulse. The full voltage pulse provides good starting torque.

If the SWR cannot be brought to 1:1, examine the coil and capacitor to see whether either is at maximum or minimum. At high frequencies above 24 MHz it may be necessary to place a capacitor between the coupler and the antenna base.

RADIATION PATTERNS

At the lower frequencies the pattern tends to be essentially round in azimuth. At 20 meters the pattern tends to become more and more directive. The patterns in

Fig 22.91 — At A, elevation pattern of the KE2QJ mobile antenna. The pattern is in the plane that runs diagonal through the car. At B, azimuth pattern at 25° elevation for the same antenna. The operating frequency is 18.130 MHz.

Fig 22.91 were calculated using EZNEC. The frequency is 18.13 MHz and the antenna is mounted at the left rear corner of a mid-size sedan. It may be seen that the pattern has more than 10 dB maximum-to-minimum ratio with the broad maximum along the diagonal of the vehicle occupied by the antenna. If the antenna were mounted in the center of the vehicle, the omnidirectional characteristics would be improved. However, the antenna would have to be much shorter to stay under 11.5 feet. The shorter antenna would likely be weaker in its best direction than the taller antenna is in its worst.

VHF/UHF Antennas

Improving an antenna system is one of the most productive moves open to the VHF enthusiast. It can increase transmitting range, improve reception, reduce interference problems and bring other practical benefits. The work itself is by no means the least attractive part of the job. Even with high-gain antennas, experimentation is greatly simplified at VHF and UHF because an array is a workable size, and much can be learned about the nature and adjustment of antennas. No large investment in test equipment is necessary.

Whether we buy or build our antennas, we soon find that there is no one *best* design for all purposes. Selecting the antenna best suited to our needs involves much more than scanning gain figures and prices in a manufacturer's catalog. The first step should be to establish priorities.

GAIN

As has been discussed previously, shaping the pattern of an antenna to concentrate radiated energy, or received signal pickup, in some directions at the expense of others is the only possible way to develop gain. Radiation patterns can be controlled in various ways. One is to use two or more driven elements, fed in phase. Such arrays provide gain without markedly sharpening the frequency response, compared to that of a single element. More gain per element, but with some sacrifice in frequency coverage, is obtained by placing parasitic elements into a Yagi array.

RADIATION PATTERN

Antenna radiation can be made omnidirectional, bidirectional, practically unidirectional, or anything between these conditions. A VHF net operator may find an omnidirectional system almost a necessity but it may be a poor choice otherwise. Noise pickup and other interference problems tend to be greater with omnidirectional antennas. Maximum gain and low radiation angle are usually prime interests of the weak-signal DX aspirant. A clean pattern, with lowest possible pickup and radiation off the sides and back, may be important in high-activity areas, where the noise level is high, or when challenging modes like EME (Earth-Moon-Earth) are employed.

HEIGHT GAIN

In general, the higher a VHF antenna is installed, the better will be the results. If raising the antenna clears its view over nearby obstructions, it may make dramatic improvements in coverage. Within reason,

greater height is almost always worth its cost, but height gain must be balanced against increased transmission-line loss. Line losses can be considerable at VHF, and they increase with frequency. The best available line may be none too good, if the run is long in terms of wavelength. Consider line losses in any antenna planning.

PHYSICAL SIZE

A given antenna design for 432 MHz, say a 5-element Yagi on a $1-\lambda$ boom, will have the same gain as one for 144 MHz, but being only one-third the size it will intercept only one-ninth as much energy in receiving. Thus, to be equal in communication effectiveness, the 432-MHz array should be at least equal in physical size to the 144-MHz one, requiring roughly three times the number of elements. With all the extra difficulties involved in going higher in frequency, it is well to be on the big side in building an antenna for the UHF bands.

DESIGN FACTORS

Having sorted out objectives in a general way, we face decisions on specifics, such as polarization, type of transmission line, matching methods and mechanical design.

POLARIZATION

Whether to position the antenna elements vertically or horizontally has been a question since early VHF pioneering. Tests show little evidence on which to set up a uniform polarization policy. On long paths there is no consistent advantage, either way. Shorter paths tend to yield higher signal levels with horizontal in some kinds of terrain. Man-made noise, especially ignition interference, tends to be lower with horizontal. Verticals, however, are markedly simpler to use in omnidirectional systems and in mobile work.

Early VHF communication was largely vertical, but horizontal gained favor when directional arrays became widely used. The major trend to FM and repeaters, particularly in the 144-MHz band, has tipped the balance in favor of verticals in mobile work and for repeaters. Horizontal predominates in other communication on 50 MHz and higher frequencies. It is well to check in advance in any new area in which you expect to operate, however, as some localities may use vertical polarization. A circuit loss of 20 dB or more can be expected with cross-polarization.

TRANSMISSION LINES

There are two main categories of trans-

mission lines used at HF through UHF: balanced and unbalanced. Balanced lines include *open-wire lines* separated by insulating spreaders, and *twin-lead*, in which the wires are embedded in solid or foamed insulation. Unbalanced lines are represented by the family of coaxial cables, commonly called *coax*. Line losses in either types of line result from ohmic resistance, radiation from the line and deficiencies in the insulation.

Large conductors, closely spaced in terms of wavelength, and using a minimum of insulation, make the best balanced lines. Characteristic impedances are between 300 to 500 Ω . Balanced lines work best in straight runs, but if bends are unavoidable, the angles should be as gentle as possible. Care should also be taken to prevent one wire from coming closer to metal objects than the other.

Properly built open-wire line can operate with very low loss in VHF and even UHF installations. A total line loss under 2 dB per hundred ft at 432 MHz is readily obtained. A line made of #12 wire, spaced $\frac{3}{4}$ inch or less with Teflon spreaders, and running essentially straight from antenna to station, can be better than anything but the most expensive *Hardline* coax, at a fraction of the cost. This assumes the use of high-quality baluns to match into and out of the balanced line, with a short length of low-loss coax for the rotating section from the top of the tower to the antenna. A similar 144-MHz setup could have a line loss under 1 dB.

Small coax such as RG-58 or RG-59 should never be used in VHF work if the run is more than a few feet. Half-inch lines (RG-8 or RG-11) work fairly well at 50 MHz, and are acceptable for 144-MHz runs of 50 ft or less. If these lines have foam rather than solid insulation they are about 30% better. Aluminum-jacket *Hardline* coaxial cables with large inner conductors and foam insulation are well worth their cost. *Hardline* can sometimes even be obtained for free from local Cable TV operators as *end runs*—pieces at the end of a roll. The most common CATV variety is $\frac{1}{2}$ -inch OD 75- Ω *Hardline*. Waterproof commercial connectors for *Hardline* are fairly expensive, but enterprising amateurs have *home-brewed* low-cost connectors. If they are properly waterproofed, connectors and *Hardline* can last almost indefinitely. Of course, a disadvantage implied by their name is that *Hardline* must not be bent too sharply, because it will kink. See *The ARRL Antenna Book* for details on *Hardline* connectors.

Effects of weather on transmission lines

should not be ignored. A well-constructed open-wire line works well in nearly any weather, and it stands up well. TV type twin-lead is almost useless in heavy rain, wet snow or icing. The best grades of coax are impervious to weather. They can be run underground, fastened to metal towers without insulation, or bent into almost any convenient position, with no adverse effects on performance. However, beware of *bargain* coax. Lost transmitter power can be made up to some extent by increasing power, but once lost, a weak signal can never be recovered in the receiver.

IMPEDANCE MATCHING

Theory and practice in impedance matching are given in detail in the **Transmission Lines** chapter, and in theory, at least, is the same for frequencies above 50 MHz. Practice may be similar, but physical size can be a major modifying factor in choice of methods.

Delta Match

Probably the first impedance match was made when the ends of an open line were fanned out and tapped onto a half-wave antenna at the point of most efficient power transfer, as in Fig 22.92A. Both the side length and the points of connection either side of the center of the element must be adjusted for minimum reflected power in the line, but the impedances need not be known. The delta makes no provision for tuning out reactance, so the length of the dipole is pruned for best SWR.

Once thought to be inferior for VHF applications because of its tendency to radiate if adjusted improperly, the delta has come back to favor now that we have good methods for measuring the effects of matching. It is very handy for phasing multiple-bay arrays with low-loss open lines, and its dimensions in this use are not particularly critical.

Gamma and T Matches

The gamma match is shown in Fig 22.92C, and the T match is shown in Fig 22.92D. These matches are covered in more detail in the **Transmission Lines** chapter. There being no RF voltage at the center of a half-wave dipole, the outer conductor of the coax is connected to the element at this point, which may also be the junction with a metallic or wooden boom. The inner conductor, carrying the RF current, is tapped out on the element at the matching point. Inductance of the arm is canceled by means of C1. Both the point of contact with the element and the setting of the capacitor are adjusted for zero reflected power, with a bridge connected in the coaxial line.

Fig 22.92 — Matching methods commonly used in VHF antennas. In the delta match, A and B, the line is fanned out to tap on the dipole at the point of best impedance match. The gamma match, C, is for direct connection of coax. C1 tunes out inductance in the arm. Folded dipole of uniform conductor size, D, steps up antenna impedance by a factor of four. Using a larger conductor in the unbroken portion of the folded dipole, E, gives higher orders of impedance transformation.

The capacitor can be made variable temporarily, then replaced with a suitable fixed unit when the required capacitance value is found, or C1 can be mounted in a waterproof box. Maximum capacitance should be about 100 pF for 50 MHz and 35 to 50 pF for 144 MHz. The capacitor and arm can be combined with the arm connecting to the driven element by means of a sliding clamp, and the inner end of the arm sliding inside a sleeve connected to the inner conductor of the coax. It can be constructed from concentric pieces of tubing, insulated by plastic sleeving or shrink tubing. RF voltage across the capacitor is low, once the match is adjusted properly, so with a good dielectric, insulation presents no great problem, if the initial adjustment is made with low power. A clean, permanent, high-conductivity bond between arm and element is important, as the RF current is high at this point.

Because it is inherently somewhat unbalanced, the gamma match can sometimes introduce pattern distortion, particularly on long-boom, highly direc-

tive Yagi arrays. The T-match, essentially two gamma matches in series creating a balanced feed system, has become popular for this reason. A coaxial balun like that shown in Fig 22.92B is used from the balanced T-match to the unbalanced coaxial line going to the transmitter.

Folded Dipole

The impedance of a half-wave antenna broken at its center is 72 Ω. If a single conductor of uniform size is folded to make a half-wave dipole, as shown in Fig 22.92D, the impedance is stepped up four times. Such a folded dipole can thus be fed directly with 300-Ω line with no appreciable mismatch. Coaxial line of 70 to 75 Ω impedance may also be used if a 4:1 balun is added. Higher impedance step-up can be obtained if the unbroken portion is made larger in cross-section than the fed portion, as in Fig 22.92E.

BALUNS

Conversion from balanced loads to unbalanced lines, or vice versa, can be per-

Fig 22.93 — Conversion from unbalanced coax to a balanced load can be done with a half-wave coaxial balun, A. Electrical length of the looped section should be checked with a dip meter, with ends shorted, B. The half-wave balun gives a 4:1 impedance step up.

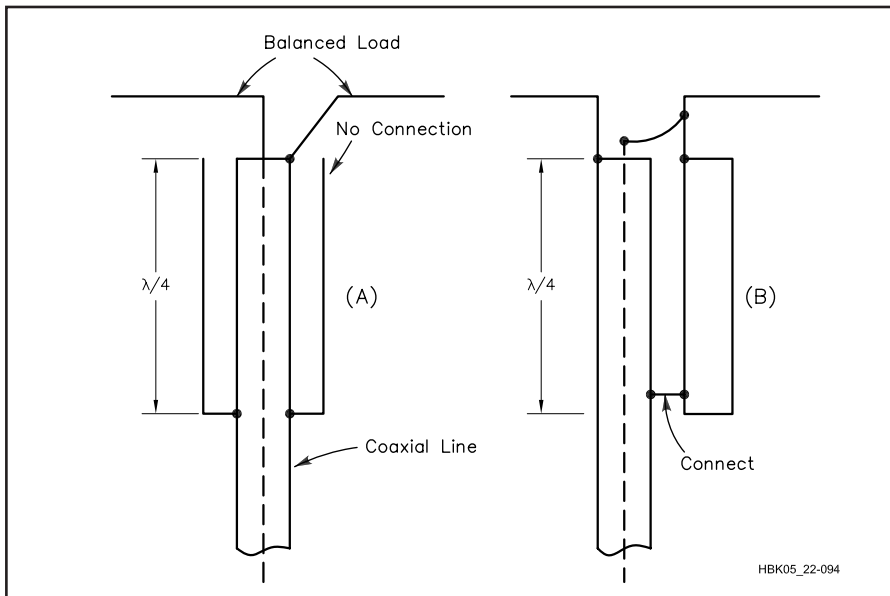

Fig 22.94 — The balun conversion function, with no impedance change, is accomplished with quarter-wave lines, open at the top and connected to the coax outer conductor at the bottom. The coaxial sleeve shown at A is preferred.

formed with electrical circuits, or their equivalents made of coaxial line. A balun made from flexible coax is shown in **Fig 22.93A**. The looped portion is an electrical half-wave. The physical length depends on the propagation factor of the line used, so it is well to check its resonant frequency, as shown at B. The two ends are shorted, and the loop at one end is coupled to a dip-meter coil. This type of balun gives an impedance step-up of 4:1, 50 to 200 Ω , or 75 to 300 Ω typically.

Coaxial baluns giving a 1:1 impedance transfer are shown in **Fig 22.94**. The coaxial sleeve, open at the top and connected to the outer conductor of the line at the lower end (A) is the preferred type. A conductor of approximately the same size as the line is used with the outer conductor to form a quarter-wave stub, in B. Another piece of coax, using only the outer con-

ductor, will serve this purpose. Both baluns are intended to present an infinite impedance to any RF current that might otherwise tend to flow on the outer conductor of the coax.

STACKING YAGIS

Where suitable provision can be made for supporting them, two Yagis mounted one above the other and fed in phase may be preferable to one long Yagi having the same theoretical or measured gain. The pair will require a much smaller turning space for the same gain, and their lower radiation angle can provide interesting results. On long ionospheric paths a stacked pair occasionally may show an apparent gain much greater than the 2 to 3 dB that can be measured locally as the gain from stacking.

Optimum spacing for Yagis with booms

Fig 22.95 — A method for feeding a stacked Yagi array. Note that baluns at each antenna are not specifically shown. Modern-day practice is to use current (choke) baluns made up of ferrite beads slipped over the outside of the coax and taped to prevent movement. See the Transmission Lines chapter for details.

longer than 1λ is one wavelength, but this may be too much for many builders of 50-MHz antennas to handle. Worthwhile results are possible with as little as $\frac{1}{2} \lambda$ (10 ft), but $\frac{5}{8} \lambda$ (12 ft) is markedly better. The difference between 12 and 20 ft may not be worth the added structural problems involved in the wider spacing, at 50 MHz at least.

The closer spacings give lowered measured gain, but the antenna patterns are cleaner (less power in the high-angle elevation lobes) than with one-wavelength spacing. Extra gain with wider spacings is usually the objective on 144 MHz and higher bands, where the structural problems are not quite as severe as on 50 MHz.

One method for feeding two 50- Ω antennas, as might be used in a stacked Yagi array, is shown in **Fig 22.95**. The transmission lines from each antenna, with a balun feeding each antenna (not shown in the drawing for simplicity), to the common feedpoint must be equal in length and an odd multiple of a quarter wavelength. This line acts as a quarter-wave (Q-section) impedance transformer and raises the feed impedance of each antenna to 100 Ω . When the coaxes are connected

in parallel at the coaxial T fitting, the resulting impedance is close to 50 Ω.

CIRCULAR POLARIZATION

Polarization is described as *horizontal* or *vertical*, but these terms have no meaning once the reference of the Earth's surface is lost. Many propagation factors can cause polarization change—reflection or refraction and passage through magnetic fields (Faraday rotation), for example. Polarization of VHF waves is often ran-

dom, so an antenna capable of accepting any polarization is useful. Circular polarization, generated with helical antennas or with crossed elements fed 90° out of phase, will respond to any linear polarization.

The circularly polarized wave in effect threads its way through space, and it can be left- or right-hand polarized. These polarization senses are mutually exclusive, but either will respond to any plane (horizontal or vertical) polarization. A

wave generated with right-hand polarization, when reflected from the moon, comes back with left-hand polarization, a fact to be borne in mind in setting up EME circuits. Stations communicating on direct paths should have the same polarization sense.

Both senses can be generated with crossed dipoles, with the aid of a switchable phasing harness. With helical arrays, both senses are provided with two antennas wound in opposite directions.

SIMPLE, PORTABLE GROUNDPLANE ANTENNA

This utility antenna is built on a coaxial connector. UHF connectors work well, but you may prefer to use type N or BNC connectors. With only two radials, it is essentially two dimensional, which makes it easier to store when not in use.

If the antenna is sheltered from weather, copper wire is sufficiently rigid for the

radiating element and radials. Antennas exposed to the wind and weather can be made from brazing rod, which is available at welding supply stores. Alternatively, #12 or #14 copper-clad steel wire could be used to construct this antenna.

The ground-plane antenna is shown in Fig 22.96 and uses a female chassis-mount

connector to support the element and two radials. To eliminate sharp ends, it's a good idea to bend the element and radial ends into a circle or to terminate them with a solder lug. See Fig 22.97. The solder lug approach is easier with stiff wire. Crimp and then solder the lug to the wire. Make the overall length of the element and radials the same as shown in Fig 22.96, measuring to the outer tip of the loop or lug.

Radials may be attached directly to the mounting holes of the coaxial connector. Bend a hook at one end of each radial for insertion through the connector. Solder the radials to the connector using a large soldering iron or propane torch.

Solder the element to the center pin of the connector. If the element does not fit inside the solder cup, use a short section of brass tubing as a coupler (a slotted 1/8-inch-ID tube will fit over an SO-239 or N-receptacle center pin).

Tune the antenna by adjusting the radial droop angle for best SWR. If necessary, you can also prune the element length.

One mounting method for fixed-station antennas appears in Fig 22.96. The feed line and connector are inside the mast, and a hose clamp squeezes the slotted mast end to tightly grip the plug body. Once the antenna is mounted and tested, thoroughly seal the open side of the coaxial connector with RTV sealant, and weatherproof the connections with rust-preventative paint.

Fig 22.96 — A simple groundplane antenna for the 144, 222 or 440-MHz bands. The feed line and connector are inside the mast, and a hose clamp squeezes the slotted mast end to tightly grip the plug body. Element and radial dimensions given in the drawing are good for the entire band.

Fig 22.97 — Alternate methods for terminating element and radial tips on the simple groundplane antenna. See text. [Photo by K8CH]

DUAL-BAND ANTENNA FOR 146/446 MHZ

This nifty project by Wayde Bartholomew, K3MF (ex-WA3WMG), first appeared in *The ARRL Antenna Compendium, Volume 5*. This mobile whip antenna won't take long to build, works well and only requires one feed line for the two-band coverage.

Wayde used a commercial NMO-style base and magnetic mount. For the radiator and decoupling stub, He used brazing rod, which he coated with a rust inhibitor after all the tuning was done. You can start with a 2-m radiator that's 20.5 inches long. This is an inch longer than normal so that it may be pruned for best SWR.

Next tack on the 70-cm decoupling stub, which is 6.5 inches long. Trim the length of the 2-m radiator for best SWR at 146 MHz and then tune the 70-cm stub on 446 MHz, moving it up and down for best SWR. There should be no significant interaction between the adjustments for either frequency.

Final dimensions are shown in Fig 22.98. The SWR in the repeater portions of both bands is less than 2:1.

ADAPTING WA3WMG'S MOBILE ANTENNA FOR FIXED-STATION USE

You can use the WA3WMG dual-band mobile whip as the radiating element for the groundplane antenna in Fig 22.96. Don't change the 2-m radials. Instead, add two 70-cm radials at right angles to the 2-m set. See Fig 22.99. The antenna is no longer two dimensional, but you do have two bands with one feed line *and* automatic band switching.

Fig 22.98 — Diagram of WA3WMG's dual-band 146/446-MHz mobile whip. Brazing rod is used for the 2-m radiator and for the 70-cm decoupling stub.

Fig 22.99 — WA3WMG's whip can be used to make a dual-band groundplane antenna. Separate radials for 2-m and 70-cm simplifies tuning. [Photo by K8CH]

A QUICK ANTENNA FOR 223 MHZ

William Bruce Cameron, WA4UZM, built the antenna for 223 MHz shown in Fig 22.100. It took less than an hour to build. To make one, you'll need 9 feet of #10 copper wire, 6 inches of small-diameter copper tubing, and a 10-foot length of PVC pipe or some other physical support.

Bend the antenna from one piece of wire. Slide the copper tubing over the top end of the antenna, and adjust how far it extends beyond the wire to get the lowest SWR. (Don't handle the antenna while transmitting—make adjustments only while receiving.) For more precision, you can move the coaxial feed line taps on the antenna's matching stub (the 12-inch section at the bottom) about an eighth of an inch at a time. The antenna shows an SWR of 1.2 at 223 MHz.

Fig 22.100 — WA4UZM's quick 223-MHz antenna gets you going on 1¹/₄ meters in a hurry. The text explains how to adjust it for minimum SWR. To support the antenna, lash it to a piece of PVC pipe with UV-resistant nylon cable ties.

AN ALL-COPPER 2-M J-POLE

Rigid copper tubing, fittings and assorted hardware can be used to make a really rugged J-pole antenna for 2 m. When copper tubing is used, the entire assembly can be soldered together, ensuring electrical integrity, and making the whole antenna weatherproof. This material came from an article by Michael Hood, KD8JB, in *The ARRL Antenna Compendium, Vol. 4*.

No special hardware or machined parts are used in this antenna, nor are insulating materials needed, since the antenna is always at dc ground. Best of all, even if the parts aren't on sale, the antenna can be built for less than \$15. If you only build one antenna, you'll have enough tubing left over to make most of a second antenna.

CONSTRUCTION

Copper and brass is used exclusively in this antenna. These metals get along together, so dissimilar metal corrosion is

eliminated. Both metals solder well, too. See Fig 22.101. Cut the copper tubing to the lengths indicated. Item 9 is a 1¹/₄-inch nipple cut from the 20-inch length of 1/2-inch tubing. This leaves 18³/₄ inches for the λ/4-matching stub. Item 10 is a 3¹/₄-inch long nipple cut from the 60-inch length of 3/4-inch tubing. The 3/4-wave element should measure 56³/₄ inches long. Remove burrs from the ends of the tubing after cutting, and clean the mating surfaces with sandpaper, steel wool, or emery cloth.

After cleaning, apply a very thin coat of flux to the mating elements and assemble the tubing, elbow, tee, endcaps and stubs. Solder the assembled parts with a propane torch and rosin-core solder. Wipe off excess solder with a damp cloth, being careful not to burn yourself. The copper tubing will hold heat for a long time after you've finished soldering. After soldering, set the assembly aside to cool.

Flatten one each of the 1/2-inch and

3/4-inch pipe clamps. Drill a hole in the flattened clamp as shown in Fig 22.101B. Assemble the clamps and cut off the excess metal from the flattened clamp using the unmodified clamp as a template. Disassemble the clamps.

Assemble the 1/2-inch clamp around the 1/4-wave element and secure with two of the screws, washers, and nuts as shown in Fig 22.101B. Do the same with the 3/4-inch clamp around the 3/4-wave element. Set the clamps initially to a spot about 4 inches above the bottom of the J on their respective elements. Tighten the clamps only finger tight, since you'll need to move them when tuning.

TUNING

The J-Pole can be fed directly from 50 Ω coax through a choke balun (3 turns of the feed coax rolled into a coil about 8 inches in diameter and held together with electrical tape). Before tuning, mount the

antenna vertically, about 5 to 10 ft above the ground. A short TV mast on a tripod works well for this purpose. When tuning VHF antennas, keep in mind that they are sensitive to nearby objects—such as your body. Attach the feed line to the clamps on the antenna, and make sure all the nuts and screws are at least finger tight. It really doesn't matter to which element ($3/4$ -wave element or stub) you attach the coaxial center lead. Tune the antenna by moving

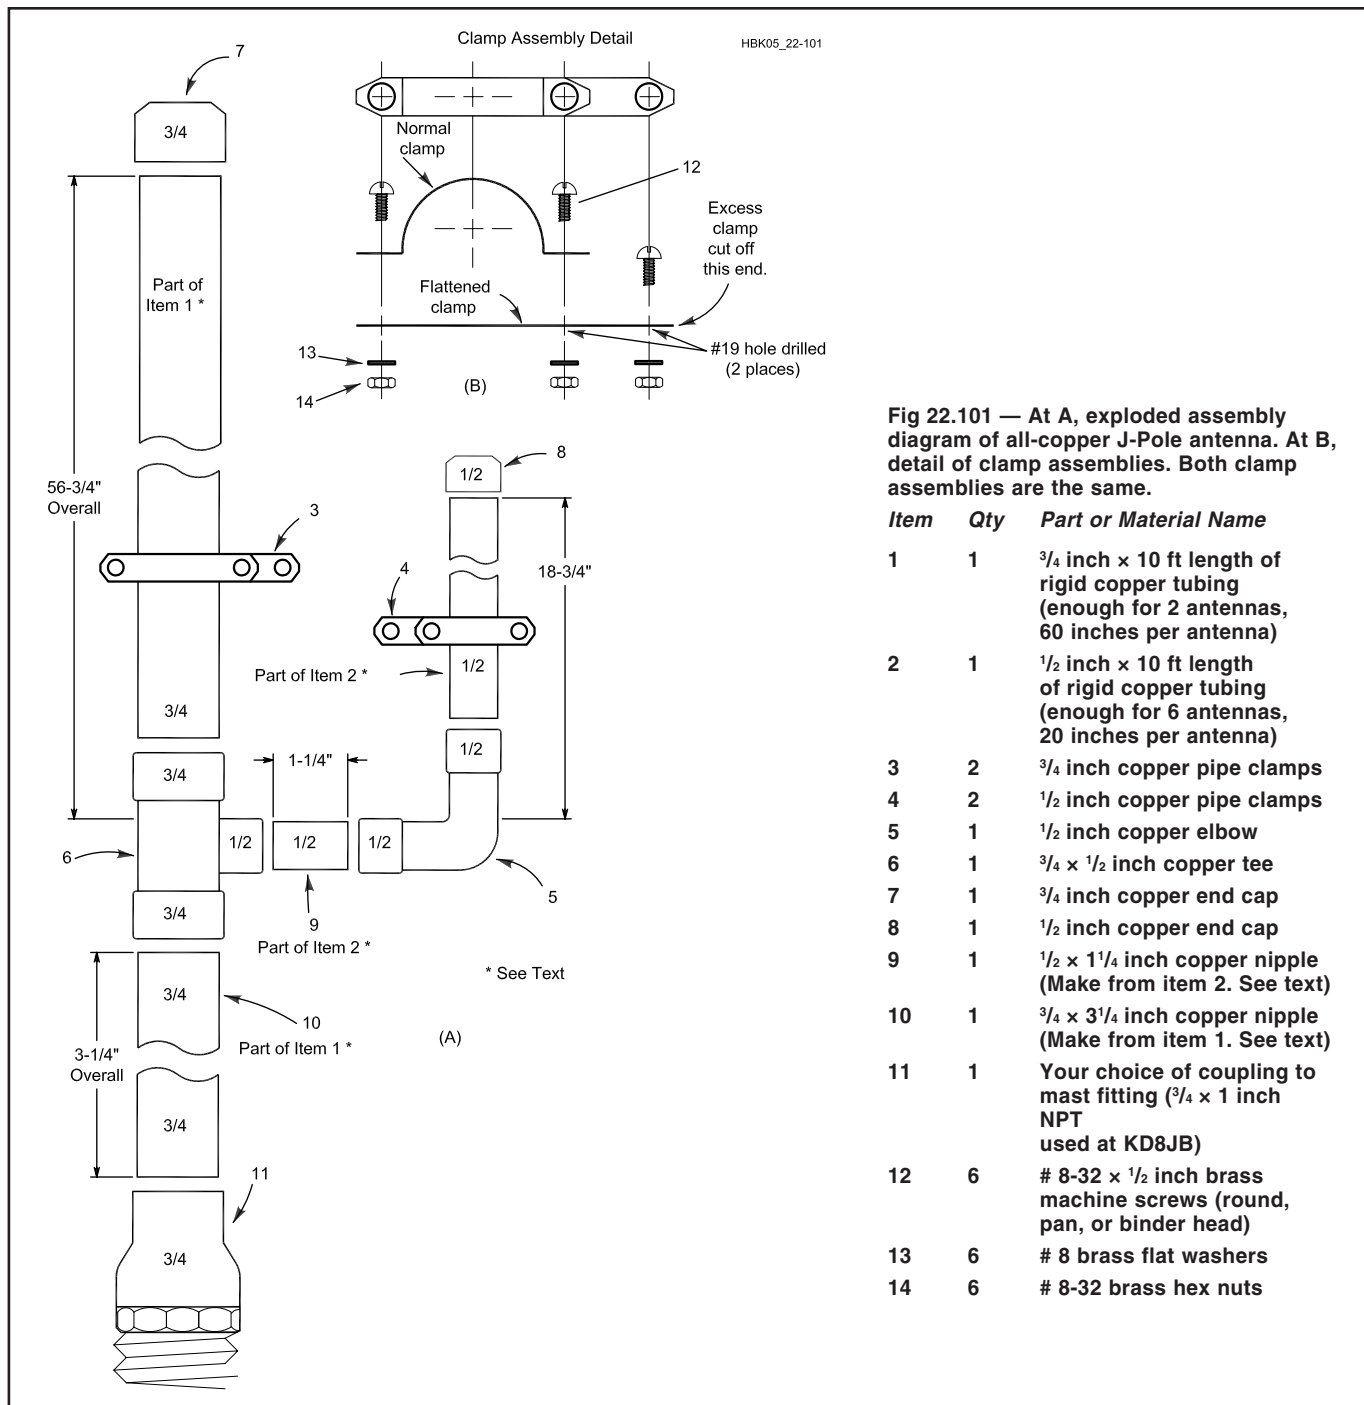

the two feed-point clamps equal distances a small amount each time until the SWR is minimum at the desired frequency. The SWR will be close to 1:1.

FINAL ASSEMBLY

The final assembly of the antenna will determine its long-term survivability. Perform the following steps with care. After adjusting the clamps for minimum SWR, mark the clamp positions with a pencil and

then remove the feed line and clamps. Apply a very thin coating of flux to the inside of the clamp and the corresponding surface of the antenna element where the clamp attaches. Install the clamps and tighten the clamp screws.

Solder the feed line clamps where they are attached to the antenna elements. Now, apply a small amount of solder around the screw heads and nuts where they contact the clamps. Don't get solder on the screw

threads! Clean away excess flux with a non-corrosive solvent.

After final assembly and erecting/mounting the antenna in the desired location, attach the feed line and secure with the remaining washer and nut. Weather-

seal this joint with RTV. Otherwise, you may find yourself repairing the feed line after a couple years.

ON-AIR PERFORMANCE

The author had no problem working

various repeaters around town with a 1/4-wave antenna, but simplex operation left a lot to be desired. The J-Pole performs just as well as a Ringo Ranger, and significantly better than the 1/4-wave ground-plane vertical.

VHF/UHF Yagis

Without doubt, the Yagi is king of home-station antennas these days. Today's best designs are computer optimized. For years amateurs as well as professionals designed Yagi arrays experimentally. Now we have

powerful (and inexpensive) personal computers and sophisticated software for antenna modeling. These have brought us antennas with improved performance, with little or no element pruning required.

A more complete discussion of Yagi design can be found earlier in this chapter. For more coverage on this topic and on stacking Yagis, see the most recent edition of *The ARRL Antenna Book*.

3 AND 5-ELEMENT YAGIS FOR 6 M

Boom length often proves to be the deciding factor when one selects a Yagi design. ARRL Senior Assistant Technical Editor Dean Straw, N6BV, created the designs shown in **Table 22.24**. Straw generated the designs in the table for convenient boom lengths (6 and 12 ft). The 3-element design has about 8 dBi gain, and the 5-element version has about 10 dBi gain. Both antennas exhibit better than 22 dB front-to-rear ratio, and both cover 50 to 51 MHz with better than 1.6:1 SWR.

Element lengths and spacings are given

in the table. Elements can be mounted to the boom as shown in **Fig 22.102**. Two muffler clamps hold each aluminum plate to the boom, and two U bolts fasten each element to the plate, which is 0.25 inches thick and 4.4 inches square. Stainless steel is the best choice for hardware, however, galvanized hardware can be substituted. Automotive muffler clamps do not work well in this application, because they are not galvanized and quickly rust once exposed to the weather.

The driven element is mounted to the boom on a Bakelite plate of similar dimension to the other mounting plates. A 12-inch piece of Plexiglas rod is inserted into

the driven element halves. The Plexiglas allows the use of a single clamp on each side of the element and also seals the center of the elements against moisture. Self-tapping screws are used for electrical connection to the driven element.

Refer to **Fig 22.103** for driven element and Hairpin match details. A bracket made from a piece of aluminum is used to mount the three SO-239 connectors to the driven element plate. A 4:1 transmission-line balun connects the two element halves, transforming the 200-Ω resistance at the Hairpin match to 50 Ω at the center connector. Note that the electrical length of the balun is $\lambda/2$, but the physical length

Fig 22.102 — The element-to-boom clamp. Galvanized U bolts are used to hold the element to the plate, and 2-inch galvanized muffler clamps hold the plates to the boom.

Table 22.24
Optimized 6-m Yagi Designs

	Spacing From Reflector (in.)	Seg 1 Length (in.)	Seg 2 Length (in.)	Midband Gain F/R
306-06				
Refl	0	36	22.500	8.1 dBi
DE	24	36	16.000	28.3 dB
Dir 1	66	36	15.500	
506-12				
OD		0.750	0.625	
Refl	0	36	23.625	10.0 dBi
DE	24	36	17.125	26.8 dB

Dir 2	80	36	18.250	
Dir 3	138	36	15.375	

Note: For all antennas, telescoping tube diameters (in inches) are: Seg1=0.750, Seg2=0.625. See figure 22.66 for element details.

Fig 22.103 — Detailed drawing of the feed system used with the 50-MHz Yagi. Balun lengths: For cable with 0.80 velocity factor — 7 ft, 10³/₈ in. For cable with 0.66 velocity factor — 6 ft, 5³/₄ in.

will be shorter due to the velocity factor of the particular coaxial cable used. The Hairpin is connected directly across the element halves. The exact center of the hairpin is electrically neutral and should be fastened to the boom. This has the advantage of placing the driven element at

dc ground potential.

The Hairpin match requires no adjustment as such. However, you may have to change the length of the driven element slightly to obtain the best match in your preferred portion of the band. Changing the driven-element length will not ad-

versely affect antenna performance. *Do not adjust the lengths or spacings of the other elements—they are optimized already.* If you decide to use a gamma match, add 3 inches to each side of the driven element lengths given in the table for both antennas.

A MEDIUM GAIN 2-M YAGI

This project was designed and built by L. B. Cebik, W4RNL. Practical Yagis for 2 meters abound. What makes this one a bit different is the selection of materials. The elements, of course, are high-grade aluminum. However, the boom is PVC and there are only two #6 nut-bolt sets and two #8 sheet metal screws in the entire antenna. The remaining fasteners are all hitch-pin clips. The result is a very durable 6-element Yagi that you can disassemble with fair ease for transport.

THE BASIC ANTENNA DESIGN

The 6-element Yagi presented here is a derivative of the *optimized wide-band antenna* (OWA) designs developed for HF use by NW3Z and WA4FET. **Fig 22.104** shows the general outline. The reflector and first director largely set the impedance. The next 2 directors contribute to

setting the operating bandwidth. The final director (Dir. 4) sets the gain. This account is over-simplified, since every element plays a role in every facet of Yagi performance. However, the notes give some idea of which elements are most sensitive in adjusting the performance figures.

Designed on *NEC-4*, the antenna uses 6 elements on a 56 inch boom. **Table 22.25** gives the specific dimensions for the version described in these notes. The parasitic elements are all ³/₁₆-inch aluminum rods. For ease of construction, the driver is ¹/₂-inch aluminum tubing. Do not alter the element diameters without referring to a source, such as RSGB's *The VHF/UHF DX Book*, edited by Ian White, G3SEK, (Chapter 7), for information on how to recalculate element lengths.

The driver is the simplest element to readjust. Table 22.25 shows an alternative

driver using ³/₁₆-inch diameter material. Of all the elements, the driver is perhaps the only one for which you may extrapolate reasonable lengths for other diameters from the two lengths and diameters shown. However, the parasitic elements may require more work than merely substituting one diameter and length for another. The lower portion of the table shows the design adjusted for ¹/₈-inch elements throughout. Not all element lengths change by the same amount using any single formula.

The OWA design provides about 10.2 dBi of free-space gain with better than 20 dB front-to-back (or front-to-rear) ratio across the entire 2-m band. Azimuth (or E-plane) patterns show solid performance across the entire band. This applies not only to forward gain but rejection from the rear.

One significant feature of the OWA design is its direct 50-Ω feedpoint impedance that requires no matching network. Of course, a choke balun to suppress any currents on the feedline is desirable, and a simple bead-choke of W2DU design works well in this application. The SWR, shown in Fig 22.105, is very flat across the band and never reaches 1.3:1. The SWR and the pattern consistency together create a very useful utility antenna for 2 m, whether installed vertically or horizontally. The only remaining question is how to effectively build the beam in the average home shop.

THE BEAM MATERIALS

The boom is Schedule 40, 1/2-inch nominal PVC. Insulated booms are good for test antennas, since they do not require recalculating the element lengths due to the effects of a metal boom.

White PVC stands up for a decade of exposure in Tennessee, but apparently does not do as well in every part of the US. You may wish to use the gray electrical conduit version. If you use any other material for your boom, be sure that it is UV-protected. You'll find a parts list in Table 22.26. Sources for the parts are given in the table. However, you are encouraged to develop your own sources for antenna materials.

along the 56-inch boom. Centering the first element hole 1 inch from the rear end of the boom results in a succession of holes for the $\frac{3}{16}$ -inch pass-through parasitic elements. Only the driver requires special treatment. We shall use a $\frac{3}{8}$ -inch hole to carry a short length of fiberglass rod that will support the two sides of the driver element. Note that I used a BNC connector, mounted on a small plate that we shall meet along the way.

The boom is actually a more complex structure than initially meets the eye. You need a support for the elements, and a means of connecting the boom to the mast. If you break the boom in the middle to install a Tee connector for the mast junction, you come very close to the 2nd director. **Fig 22.107** shows how to avoid the predicament.

Before drilling the boom, assemble it from common Schedule 40 $\frac{1}{2}$ -inch fittings and insert the lengths of PVC pipe. Fig 22.107 shows the dimensions for the center section of the boom assembly. However, PVC dimensions are always *nominal*, that is, meeting certain minimum size standards. So you may have to adjust the lengths of the linking pieces slightly to come up with a straight and true boom assembly.

Use scrap lumber to help keep everything aligned while cementing the pieces together. A 1x4 and a 1x6 nailed together

along the edges produces a very good platform with a right-angle. Start with the two upper Tees and the Ls below each one. Dry-fit scrap PVC into the openings except for the short link that joins the fitting. Cement these in place and align them using the dry-fit pieces as guides to keep everything parallel. Next, cement the two short ($2\frac{3}{4}$ -inch) links into the third Tee. Then, cement one link into its L, using the dry-fit tube in the upper Tee as an alignment guide.

Before proceeding further, carefully measure the required length of PVC for the boom section between Tees. How well you measure here will determine whether the boom will be straight or whether it will bow up or down. Now, cement both the L and the Tee at the same time, pressing the cemented sections into the 2-board jig to assure alignment.

The final step in the process is to add the 23-inch boom end pieces to the open ends of the upper Tees. For the brief period in which the PVC cement is wet, it is possible to misalign the tubing. Dry-fit end caps on the boom ends and do the cement work using the 2-board jig. By pressing the assembly into the right angle of the boards, you can assure that you have a very true boom. When you've put the PVC cement back onto its shelf, your boom should be ready to drill.

Consider the boom-to-mast connection.

The lower Tee in Fig 22.107 receives a short length of $\frac{1}{2}$ -inch nominal Schedule 40 PVC. This material has an outside diameter of about $\frac{7}{8}$ -inch, not a useful size for joining to a mast. However, PVC fittings have a handy series of threaded couplers that allow you to screw-fit a series of ever-larger sizes until you reach a more useful size. As **Fig 22.108B** shows, enough of these fittings will finish off with a $1\frac{1}{4}$ -inch threaded female side and a $1\frac{1}{4}$ -inch cement-coupling side. To this fitting, cement a length of $1\frac{1}{4}$ -inch tubing that slides over a length of common TV mast. For a tight fit, wrap the TV mast with several layers of electrical tape in two places—one near the upper end of the PVC pipe section and the other close to where the PVC pipe ends. You may then use stainless steel through-bolts or set-screws to prevent the PVC assembly from turning.

BOOM AND ELEMENTS

Before installing the elements, you need to drill the holes in the boom. The two-board jig comes in handy once more. The key goals in the drilling process are to: A) precisely position the holes; B) create holes that are a fairly tight fit for the rod elements; and C) keep the elements aligned in a flat plane. For this purpose, a drill press is almost a necessity for all but those with the truest eyes.

Use the jig and a couple of clamps to

Fig 22.107 — Details of a parallel PVC pipe structure for the Yagi boom and mount.

hold the boom assembly in place. Because the assembly has two parallel sections, laying it flat will present the drill press with the correct angle for drilling through the PVC in one stroke. Drill the holes at premarked positions, remembering that the driver hole is $\frac{3}{8}$ inch while all the others are $\frac{3}{16}$ inch. Clean the holes, but do not enlarge them in the process.

(A)

(B)

Fig 22.108 — The completed Yagi is shown at A. A close-up view of the parallel PVC boom and mount, the sequence of threaded fittings, and the hitch-pin clips used to secure parasitic elements is shown at B.

By now you should have the rod and tube stock in hand. For antenna elements, don't rely on questionable materials that are designed for other applications. Rather, obtain 6063-T832 tubing and 6061-T6 rods from mail order sources, such as Texas Towers, McMasters-Carr, and others. These materials are often not available at local hardware depots.

Cut the parasitic elements to length and smooth their ends with a fine file or sandpaper. Find the center of each element and carefully mark a position about $\frac{1}{16}$ " outside where the element will emerge from each side of the boom. You'll drill small holes in these locations. You may wish to very lightly file a flattened area where the hole is to go to prevent the drill bit from slipping as you start the hole.

Drill $\frac{1}{16}$ -inch holes at each marked location all the way through the rod. De-burr the exit ends so that the rod will pass through the boom hole. These holes are the locations for hitch-pin clips. **Fig 22.109** shows the outline of a typical hitch-pin clip, which is also called a hair-pin cotter pin in some catalogs and stores. Obtain stainless steel pins whose bodies just fit tightly over the rod when installed. Initially, install 1 pin per parasitic element. Slide the element through the correct boom hole and install the second pin. Although the upper part of the drawing shows a bit of room between the boom and pin, this space is for clarity. Install the pins as close to each side of the boom as you can.

Pins designed for a $\frac{3}{16}$ -inch rod are small enough that they add nothing significant to the element, and antenna tests showed that they did not move the performance curve of the antenna. Yet, they have held securely through a series of shock tests given to the prototype. These pins—in various sizes—offer the home builder a handy fastener that

Fig 22.109 — The parasitic element mounting system, showing the placement of the hitch-pin clips and the shape of the clips.

is applicable to many types of portable or field antennas. Although you may wish to use better fasteners when making permanent metal-to-metal connections, for joining sections of Field Day and similar antennas, the hitch-pin clips perform the mechanical function, while clean tubing sections themselves provide adequate electrical contact for a limited period of use.

THE DRIVER AND FEEDLINE CONNECTOR

The final construction step is perhaps the one requiring the most attention to detail, as shown in **Fig 22.110**. The driver and feedpoint assembly consists of a 4- to 6-inch length of $\frac{3}{8}$ -inch fiberglass or other non-conductive rod, two sections of the driver element made from $\frac{1}{2}$ -inch aluminum tubing, a BNC connector, a homemade mounting plate, two sets of stainless steel #6 nuts, bolts, and lock-washers, and two stainless steel #8 sheet metal screws. Consult both the upper and lower portions of the figure, since some detail has been omitted from each one to show other detail more clearly.

First, trial fit the driver tubing and the fiberglass rod, marking where the rod exits the boom. Now pre-drill $\frac{9}{64}$ -inch holes through the tubing and the fiberglass rod. Do not use larger hardware, since the resulting hole will weaken the rod, possibly to the breaking point. If you use an alternative plastic material, observe the same caution and be certain that the rod remains strong after drilling. Do not use wooden dowels for this application, since they do not have sufficient strength. Position the holes about $\frac{1}{4}$ to $\frac{3}{8}$ inch from the tubing end where it presses against the boom. One hole will receive a solder lug and the other will connect to an extension of the BNC mounting plate.

Second, install the fiberglass rod through the boom. You can leave it loose, since the elements will press against boom and hold it in place. Alternatively, you may glue it in place with a 2-part epoxy. Slide the driver element tubes over the rod and test the holes for alignment by placing the #6 bolts in them.

Next, cut and shape the BNC mounting plate from $\frac{1}{16}$ -inch thick aluminum. I made my fitting from a scrap of L-stock 1 inch on a side. Before cutting the stock, I drilled the $\frac{3}{8}$ -inch hole needed for the BNC connector. Then I cut the vertical portion. The horizontal portion requires a curved tab that reaches the bolt on one side of the boom. I used bench vise to bend the tab in a curve and then flatten it for the bolt-hole. It takes several tries to get the shape and tab exact, so be patient. When the squared-edge piece found its perfect

Fig 22.110 — Details of the feedpoint of the Yagi, showing the BNC connector, mounting plate, and connections to the 1/2-inch driver element halves placed over a central 3/8-inch fiberglass rod.

shape, I took it to a disk sander and rounded the vertical piece to follow the connector shape. I also tapered the tap edges to minimize excess material. The last step is to drill the mounting holes that receive the #8 sheet metal screws.

Mounting the assembly involves loosely attaching both the #6 and #8 hardware and alternatively tightening up all pieces. Be certain that the side of the BNC connector that receives the coax points toward the mast. Next, mount the BNC connector. The shield side is already connected to one side of the driver. Mount the other side of the driver, placing a solder lug under the bolt head. Connect a short wire as directly as possible from the solder lug to the center pin of the BNC connector. After initial testing, you may coat all exposed connections with Plasti-Dip for weather protection.

TUNE-UP

Testing and tuning the antenna is a

simple process if you build carefully. The only significant test that you can perform is to ensure that the SWR curve comes close to the one shown in Fig 22.105. If the SWR is high at 148 MHz but very low at 144 MHz, then you will need to shorten the driver ends by a small amount—no more than 1/8 inch per end at a time. I found that shaving the ends with a disk sander was most effective.

Using the antenna with vertical polarization will require good spacing from any support structure with metal vertical portions. One of the easiest ways to devise such a mounting is to create a PVC structure that turns the entire boom by 90 degrees. If you feel the need for added support, you can create an angular brace by placing 45-degree connectors in both the vertical and horizontal supports and running a length of PVC between them.

As an alternative, you can let the rear part of the boom be slightly long. To this end you can cement PVC fixtures—in-

cluding the screw-thread series to enlarge the support pipe size. Create a smooth junction that you attach with a through-bolt instead of cement. By drilling one side of the connection with two sets of holes, 90-degrees apart, you can change the antenna from horizontal polarization to vertical and back in short order.

The 6-element OWA Yagi for 2 meters performs well. It serves as a good utility antenna with more gain and directivity than the usual 3-element general-use Yagi. When vertically polarized, the added gain confirms the wisdom of using a longer boom and more elements. With a length under 5 feet, the antenna is still compact. The ability to disassemble the parts simplifies moving the antenna to various portable sites.

Space Communications

An Amateur Satellite Primer

Most amateurs are familiar with repeater stations that retransmit signals to provide wider coverage. Repeaters achieve this by listening for signals on one frequency and immediately retransmitting whatever they hear on another frequency. Thanks to repeaters, small, low-power radios can communicate over thousands of square kilometers. Unfortunately, many amateurs are *not* familiar with the best repeaters that have ever existed. These are the amateur satellites that hams have been using for 40 years. (See the sidebar “Tired of the Same Old QSOs?”)

This is essentially the function of an amateur satellite as well. Of course, while a repeater antenna may be up to a few hundred meters above the surrounding terrain, the satellite is hundreds or thousands of *kilometers* above the surface of the Earth. The area of the Earth that the satellite’s signals can reach is therefore much larger than the coverage area of even the best Earth-bound repeaters. It is this characteristic of satellites that makes them attractive for communication. Most amateur satellites act as analog repeaters, retransmitting CW and voice signals exactly as they are received, as packet store-and-forward systems that receive whole messages from ground stations for later relay, or as specialized Earth-looking camera systems that can provide some spectacular views. See Fig 23.2, an image of a town in the western US.

Amateur satellites have a long history of performing worldwide communications

N1JEZ

Fig 23.1—N1JEZ’s portable microwave satellite station.

services for amateurs. See the sidebar “Amateur Satellite History.”

LINEAR TRANSPONDERS AND THE PROBLEM OF POWER

Most analog satellites are equipped with *linear transponders*. These are devices

that retransmit signals within a band of frequencies, usually 50 to 250 kHz wide, known as the *passband*. Since the linear transponder retransmits the entire band, a number of signals may be retransmitted simultaneously. For example, if three SSB signals (each separated by as little

Tired of the Same Old QSOs? Break out of Orbit and Set your Course for the “Final Frontier”

Satellite-active hams comprise a relatively small segment of our hobby, primarily because of an unfortunate fiction that has been circulating for many years—the myth that operating through amateur satellites is overly difficult and expensive.

Like any other facet of Amateur Radio, satellite hamming is as expensive as you allow it to become. If you want to equip your home with a satellite communication station that would make a NASA engineer blush, it will be expensive. If you want to simply communicate with a few low-Earth-orbiting birds using less-than-state-of-the-art gear, a satellite station is no more expensive than a typical HF or VHF setup. In many cases you can communicate with satellites using your present station equipment—no additional purchases are necessary.

Does satellite hamming impose a steep learning curve? Not

really. You have to do a bit of work and invest some brain power to be successful, but the same can be said of DXing, contesting, traffic handling, digital operating or any other specialized endeavor. You are, after all, communicating with a *spacecraft!*

The rewards for your efforts are substantial, making satellite operating one of the most exciting pursuits in Amateur Radio. There is nothing like the thrill of hearing someone responding to your call from a thousand miles away and knowing that he heard you through a satellite. (The same goes for the spooky, spellbinding effect of hearing your own voice echoing through a spacecraft as it streaks through the blackness of space.) Satellite hamming will pump the life back into your radio experience and give you new goals to conquer.

Fig 23.2—UO-36 captured this image of a well-known city in the western US. Need a hint? Think “Caesar’s Palace.”

as 5 kHz) were transmitted to the satellite, the satellite would retransmit all three signals—still separated by 5 kHz each (see Fig 23.3). Just like a terrestrial repeater, the retransmissions take place on frequencies that are different from the ones on which the signals were originally received.

Some linear transponders invert the uplink signals. In other words, if you trans-

Fig 23.3—A linear transponder acts much like a repeater, except that it relays an entire group of signals, not just one signal at a time. In this example the satellite is receiving three signals on its 23-cm uplink passband and retransmitting them on its 13-cm downlink passband.

mit to the satellite at the *bottom* of the uplink passband, your signal will appear at the *top* of the downlink passband. In addition, if you transmit in lower sideband (LSB), your downlink signal will be in upper sideband (USB). See Fig 23.4. Satellite passbands are usually operated according to the courtesy band plan, as shown. Transceivers designed for satellite use usually include features that cope with this confusing flip-flop.

Over the years, the number of amateur bands available on satellites has increased. To help in easily identifying these bands, a system of “Modes” has been created. In the early years reference to these Modes was by a single letter (Mode A, Mode B, etc), but with the launch of more satellites the opportuni-

ties greatly increased and it was necessary to show both the uplink and downlink bands. See Table 23.1, Satellite Operating Modes.

Linear transponders can repeat any type of signal, but those used by amateur satellites are primarily designed for SSB and CW. The reason for the SSB and CW preference has a lot to do with the hassle of generating power in space. Amateur satellites are powered by batteries, which are recharged by solar cells. “Space rated” solar arrays and batteries are very expensive. They are also heavy and tend to take up a substantial amount of space. Thanks to meager funding, hams don’t have the luxury of launching satellites with large power systems such as those used by commercial birds. We have to do the best we

Table 23.1

Satellite Operating Modes

Frequency Band	Letter Designation	New Designation (Transmit, First Letter; Receive, Second Letter)	Old Designation
HF, 21-30 MHz	H	Mode U/V	Mode B
VHF, 144-148 MHz	V	Mode V/U	Mode J
UHF, 435-438 MHz	U	Mode U/S	Mode S
1.26-1.27 GHz	L	Mode L/U	Mode L
2.40-2.45 GHz	S	Mode V/H	Mode A
5.6 GHz	C	Mode H/S	
10.4 GHz	X	Mode L/S	
24 GHz	K	Mode L/X	
		Mode C/X	

Fig 23.4—The OSCAR satellite band plan allows for CW-only, mixed CW/SSB, and SSB-only operation. Courteous operators observe this voluntary band plan at all times.

can within a much more limited “power budget.”

So what does this have to do with SSB or any other mode? Think *duty cycle*—the amount of time a transmitter operates at full output. With SSB and CW the duty cycle is quite low. A linear satellite transponder can retransmit many SSB and CW signals while still operating within the power generating limitations of an amateur satellite. It hardly breaks a sweat.

Now consider FM. An FM transmitter operates at a 100% duty cycle, which means it is generating its full output with every transmission. Imagine how much power a linear transponder would need to retransmit, say, a dozen FM signals—all demanding 100% output!

Having said all that, there *are* a few, very popular FM repeater satellites. However, they do not use linear transponders. They retransmit only one signal at a time.

FINDING A SATELLITE

Before you can communicate through a satellite, you have to know what satellites are available and when they are available. (See sidebar “Current Amateur Satellites.”) This isn’t quite as straight-

forward as it seems.

Amateur satellites do not travel in geostationary orbits like many commercial and military spacecraft. Satellites in geostationary orbits cruise above the Earth’s equator at an altitude of about 35,000 kilometers. From this vantage point the satellites can “see” almost half of our planet. Their speed in orbit matches the rotational speed of the Earth itself, so the satellites appear to be “parked” at fixed positions in the sky. They are available to send and receive signals 24 hours a day over an enormous area.

Of course, amateur satellites *could* be placed in geostationary orbits. The problem isn’t one of physics; it’s money and politics. Placing a satellite in geostationary orbit and keeping it on station costs a great deal of money—more than any one amateur satellite organization can afford. An amateur satellite group could ask similar groups in other areas of the world to contribute money to a geostationary satellite project, but why should they? Would you contribute large sums of money to a satellite that may never “see” your part of the world? Unless you are blessed with phenomenal generosity, it would seem unlikely!

Fig 23.5—An example of a satellite in a high, elliptical orbit.

Instead, all amateur satellites are either low-Earth orbiters (LEO), or they travel in very high, elongated orbits. See **Fig 23.5**. Either way, they are not in fixed positions in the sky. Their positions relative to your station change constantly as the satellites zip around the Earth. This means that you need to predict when satellites will appear in your area, and what paths they’ll take as they move across your local sky.

You’ll be pleased to know that there is software available that handles this prediction task very nicely. A bare-bones program will provide a schedule for the satellite you choose. A very simple schedule might look something like **Fig 23.6**, showing the antenna pointing angles for each minute of a pass for AO-16.

The time is usually expressed in UTC.

ORBIT NO. 20988 EPOCH: 30.219444444384									
UTC	Az	El	D/L Dplr	U/L Dplr	Range	Height	SSP Lat	SSP Long	MA

Amateur Satellite History

The Amateur Radio satellite program began with the design, construction and launch of OSCAR I in 1961 under the auspices of the Project OSCAR Association in California. The acronym "OSCAR," which has been attached to almost all Amateur Radio satellite designations on a worldwide basis, stands for *Orbiting Satellite Carrying Amateur Radio*. Project OSCAR was instrumental in organizing the construction of the next three Amateur Radio satellites—OSCARs II, III and IV. *The Radio Amateur's Satellite Handbook*, published by ARRL has details of the early days of the amateur space program.

In 1969, the Radio Amateur Satellite Corporation (AMSAT) was formed in Washington, DC. AMSAT has participated in the vast majority of amateur satellite projects, both in the United States and internationally, beginning with the launch of OSCAR 5. Now, many countries have their own AMSAT organizations, such as AMSAT-UK in England, AMSAT-DL in Germany, BRAMSAT in Brazil and AMSAT-LU in Argentina. All of these organizations operate independently but may cooperate on large satellite projects and other items of interest to the worldwide Amateur Radio satellite community. Because of the many AMSAT organizations now in existence, the US AMSAT organization is frequently designated AMSAT-NA.

Beginning with OSCAR 6, amateurs started to enjoy the use of satellites with lifetimes measured in years as opposed to weeks or months. The operational lives of OSCARs 6, 7, 8 and 9, for example, ranged between four and eight years. All of these satellites were low Earth orbiting (LEO) with altitudes approximately 800-1200 km. LEO Amateur Radio satellites have also been launched by other groups not associated with any AMSAT organization such

as the Radio Sputniks 1-8 and the ISKRA 2 and 3 satellites launched by the former Soviet Union.

The short-lifetime LEO satellites (OSCARs I through IV and 5) are sometimes designated the *Phase I* satellites, while the long-lifetime LEO satellites are sometimes called the *Phase II* satellites. There are other conventions in satellite naming that are useful to know. First, it is common practice to have one designation for a satellite before launch and another after it is successfully launched. Thus, OSCAR 40 (discussed later) was known as Phase 3D before launch. Next, the AMSAT designator may be added to the name, for example, AMSAT-OSCAR 40, or just AO-40 for short. Finally, some other designator may replace the AMSAT designator such as the case with Japanese-built Fuji-OSCAR 29 (FO-29).

In order to provide wider coverage areas for longer time periods, the high-altitude Phase 3 series was initiated. Phase 3 satellites often provide 8-12 hours of communications for a large part of the Northern Hemisphere. After losing the first satellite of the Phase 3 series to a launch vehicle failure in 1980, AO-10 was successfully launched and became operational in 1983. AO-13, the follow-up to the AO-10 mission, was launched in 1988 and re-entered the atmosphere in 1996. The successor to AO-13, AO-40 was launched on November 16, 2000 from Kourou, French Guiana.

Satellites providing store-and-forward communication services using packet radio techniques are generically called *PACSATs*. Files stored in a PACSAT message system can be anything from plain ASCII text to digitized pictures and voice.

The first satellite with a digital store-and-forward feature was UoSAT-OSCAR 11. UO-11's

Digital Communications Experiment (DCE) was not open to the general Amateur Radio community although it was utilized by designated "gateway" stations. The first satellite with store-and-forward capability open to all amateurs was the Japanese Fuji-OSCAR 12 satellite, launched in 1986. FO-12 was succeeded by FO-20, launched in 1990, and FO-29, launched in 1996.

By far the most popular store-and-forward satellites are the *PACSATs* utilizing the PACSAT Broadcast Protocol. These PACSATs fall into two general categories — the *Microsats*, based on technology developed by AMSAT-NA, and the *UOSATs*, based on technology developed by the University of Surrey in the UK. While both types are physically small spacecraft, the Microsats represent a truly innovative design in terms of size and capability. A typical Microsat is a cube measuring 23 cm (9 in) on a side and weighing about 10 kg (22 lb). The satellite will contain an onboard computer, enough RAM for the message storage, two to three transmitters, a multichannel receiver, telemetry system, batteries and the battery charging/power conditioning system.

Amateur Radio satellites have evolved to provide three primary types of communication services — analog transponders for real-time CW and SSB communication, digital store-and-forward for non real-time communication, and direct "bent-pipe" single-channel FM repeaters. Which of these types interest you the most will probably depend on your current Amateur Radio operating habits. Whatever your preference, this section should provide the information to help you make a successful entry into the specialty of amateur satellite communications.

AO-16 will appear above your horizon beginning at 0516 UTC on January 30. The bird will “rise” at an azimuth of 164°, or approximately south-southeast of your station. The elevation refers to the satellite’s position above your horizon in

degrees—the higher the better. A zero-degree elevation is right on the horizon; 90° is directly overhead.

By looking at this schedule you can see that the satellite will appear in your south-southeastern sky at 0516 UTC and will rise

quickly to an elevation of 70° by 0524. The satellite’s path will curve further to the east and then directly to the north as it rises. Notice how the azimuth shifts from 164° at 0516 UTC to 0° at 0524. This is nearly a direct overhead pass of AO-16 and it sets in the north-northwest at 348°.

The more sophisticated the software, the more information it usually provides in the schedule table. The software may also display the satellite’s position graphically as a moving object superimposed on a map of the world. Some of the displays used by satellite prediction software are visually stunning! This view, **Fig 23.7**, is provided by *Nova* for *Windows*, from Northern Lights Software Associates.

Satellite prediction software is widely available on the Web. Some of the simpler programs are freeware. The AMSAT-NA Web site has the largest collection of satellite software for just about any computer you can imagine. Most AMSAT software isn’t free, but the cost is reasonable and the funds support amateur satellite programs.

Whichever software you choose, there are two key pieces of information you must provide before you can use the programs:

(1) **Your position.** The software must have your latitude and longitude before it can crank out predictions for your sta-

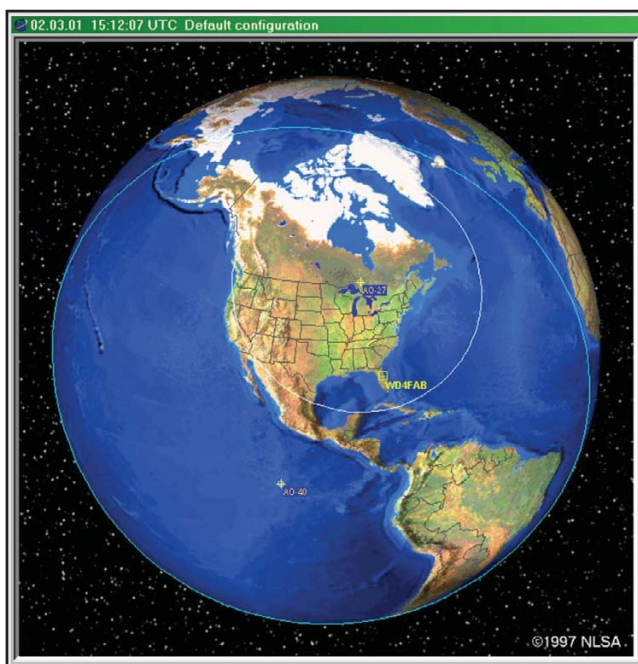

Fig 23.7—The communications range circles, or “footprints” over North America.

Current Operational Amateur Satellites

OSCAR 7, AO-7, was launched November 15, 1974 by a Delta 2310 from Vandenberg, CA. AO-7’s operating status is semi-operational in sunlight only. After being declared dead in mid 1981 due to battery failure, AO-7 has miraculously sprung back to life. It will only be on when in sunlight and off in eclipse. AO-7 will reset each orbit and may not turn on each time.

OSCAR 11, UO-11, a scientific/educational low-orbit satellite, was built at the University of Surrey in England and launched on March 1, 1984. This UoSat spacecraft has also demonstrated the feasibility of store-and-forward packet digital communications and is operational with telemetry downlinks only.

OSCAR 16, AO-16, also known as PACSAT, was launched in January 1990. A digital store-and-forward packet radio file server, it has an experimental S-band beacon at 2401.143 MHz. AO-16 is only semi-operational with the 1200-baud digipeater for APRS service.

OSCAR 26, IO-26, was launched on September 26, 1993 is semi-operational and now serves as a

1200-baud digipeater for APRS service.

RS 15, launched in December 1994, is a Mode V/H spacecraft; its uplink is on the 2m band, and its downlink is on 10m.

OSCAR 27, AO-27, was launched in September 1993 along with OSCAR 26. It features a mode V/U analog FM repeater. Because of the need to conserve power, OSCAR 27 is usually only available during daylight passes.

OSCAR 29, FO-29, launched from Japan in 1996, in a low earth orbit. It operates with a mode V/U analog transponder.

OSCAR 44, NO-44, also known as PCSAT was launched on September 30, 2001 from Kodiak, Alaska. PCSAT is a 1200-baud APRS digipeater designed for use by stations using hand-held or mobile transceivers. The operational status of PCSAT is uncertain and subject to change due to power availability.

OSCAR 50, SO-50 also known as SAUDISAT-1C, was launched December 20, 2002 aboard a converted Soviet ballistic missile

from Baikonur Cosmodrome. SO-50 carries several experiments, including a mode U/V FM amateur repeater. The repeater is available to amateurs as power permits, using a 67.0 Hz uplink tone for on-demand activation.

OSCAR 51, also known as *Echo*, was launched on June 29, 2004 from the Baikonur Cosmodrome. Echo carries a FM repeater capable of 144 MHz and/or 1.2 GHz uplink with a 435 MHz and/or 2.4GHz downlink. The satellite also includes an AX.25 digital PACSAT BBS and a PSK31 uplink on 28 MHz.

VUSat-OSCAR 52 was launched on May 5, 2005. Within 24 hours its Mode U/V transponder was open for business and hams were reporting excellent signals. The first Indian Amateur Radio satellite carries two 1-W linear transponders for SSB and CW communication, although only one transponder is operational at a time. OSCAR 52 travels in a polar sun-synchronous orbit at an altitude of 632 × 621 km with an inclination of 97.8 deg with respect to the equator.

tion. The good news is that your position information doesn't need to be extremely accurate. Just find out the latitude and longitude of your city or town (the public library would have this data, as would any nearby airport) and plug it into the program.

(2) **Orbital elements.** This is the information that describes the orbits of the satellites. You can find orbital elements (often referred to as *Keplerian elements*) at the AMSAT Web site, and through many other sources on the Internet. You need to update the elements every few months. Many satellite programs will automatically read in the elements if they are provided as ASCII text files. The less sophisticated programs will require you to enter them by hand. Automatically updated software is highly recommended; it's too easy to make a mistake with manual entries.

GETTING STARTED WITH THE FM BIRDS

Do you like elevated FM repeaters with wide coverage areas? Then check out the AO-27 and AO-51 FM repeater satellites. From their low-Earth orbits these satellites can hear stations within a radius of 2000 miles in all directions.

You can operate the FM satellites with a basic dual band VHF/UHF FM transceiver and even a good FM HT, as some amateurs have managed. Assuming that the transceiver is reasonably sensitive, you can use a good "rubber duck" antenna as in **Fig 23.8**. Some amateurs have even managed to work the FM birds with HTs

Fig 23.8—W2RS shows another popular LEO FM antenna for hand-held operations.

coupled to multi-element directional antennas such as the popular Arrow Antenna, **Fig 23.9**. Of course, this means they must aim their antennas at the satellites as they cross overhead.

High quality omnidirectional antennas for LEO service come in quite a number of forms and shapes. M² Enterprises has their EB-144 and EB-432 Eggbeater antennas, **Fig 23.10** and **Fig 23.11**, which have proven to be very useful and do not require any rotators for control. The Quadrifilar omnidirectional antenna, **Fig 23.12**, has been around for a long time, as has the turnstile-over-reflector antenna, **Fig 23.13**.

For even better performance, at the modest cost of a simple TV antenna rotator, check out the fixed elevation Texas Potato Masher antenna by K5OE, **Fig 23.14**. This antenna provides a dual band solution for medium gain directional antennas for LEO satellite operations. This is a considerable improvement over omnidirectional antennas and does not require an elevation control for good performance.

Start by booting your satellite tracking software. Check for a pass with a peak elevation of 30° or higher. As with all satellites, the higher the elevation, the better. If you plan to operate outdoors or away from home, either print the schedule to a printer or jot down the times on a piece of scrap paper that you can keep with you.

When the satellite comes into range, you'll be receiving its signal about 5 kHz higher than the published downlink frequency (see **Table 23.2**, Active Amateur Satellites: Frequencies and Modes) thanks to *Doppler shifting* (see the sidebar, "Down with Doppler"). So, begin listening on the higher frequency. If you suddenly hear the noise level dropping, chances are you are picking up the satellite's signal. At about the midpoint of the pass you'll need to shift your receiver down to the published frequency, and as the satellite is heading away you may wind up stepping down another 5 kHz. Some operators program these frequency steps into memory channels so that they can compensate for Doppler shift at the push of a button.

Once again, these FM satellites behave just like terrestrial FM repeaters. Only one person at a time can talk. If two or more people transmit simultaneously, the result is garbled audio or a squealing sound on the output. The trick is to take turns and keep the conversations short. Even the best passes will only give you about 15 minutes to use the satellite. If you strike up a conversation, don't forget that there are others waiting to use the bird.

The FM repeater satellites are a good way to get started. Once you get your feet

Fig 23.9—The hand-held "Arrow" gain antenna is popular for LEO FM operations. (Photo courtesy *The AMSAT Journal*, Sep/Oct 1998.)

Fig 23.10—Eggbeater antennas are popular for base station LEO satellite operation. This EB144 eggbeater is for 2 m.

Fig 23.11—This EB-432 eggbeater antenna for 70-cm operation is small enough to put in an attic. Antenna gain pattern is helped with the radials placed below the antenna.

Fig 23.12—W3KH suggests that quadrifilar antennas can serve well for omnidirectional satellite station antenna service.

Fig 23.13—The Turnstile Over Reflector antenna has served well for LEO satellite service for a number of years.

Fig 23.14—Jerry Brown, K5OE, uses his Texas Potato Masher antennas for LEO satellite operations.

Table 23.2 – Active Amateur Satellites: Frequencies and Modes

Satellite (SSB/CW)	Uplink (MHz)	Downlink (MHz)
FO-29	145.900-146.000	435.800-435.900 435.795 (CW beacon)
RS-15	145.858-145.898	29.354-29.394

wet, you'll probably wish you could access a satellite that wasn't so crowded, where you could chat for as long as the bird was in range. You may find that a very good assist will be given to you from the book *Working the Easy Sats*, by WA4YMZ and N1JEZ. This is available from AMSAT headquarters.³ But now it is time to move up!

MOVING UP TO OSCARS 29 AND 52

VUSat-OSCAR 52 carries a *Mode U/V* transponder, which means that it receives signals on the 70-cm band and retransmits on the 2-m band. Operating this satellite is done with the equipment and antenna setup shown in **Fig 23.15**.

Once you've determined when the satellite is due to rise above the horizon at your location, listen for the satellite's CW telemetry beacon. This signal is transmitted constantly by the satellite and carries information about the state of the satellite's systems, such as its battery voltage, solar-panel currents, temperatures and so on. You should hear it just as the satellite rises above the horizon. As soon as you can hear the beacon, start tuning across the downlink passband.

On an active day you should pick up several signals. They will sound like normal amateur SSB and CW conversations. Nothing unusual about them at all—except that the signals will be slowly drifting downward in frequency. That's the effect of Doppler shift.

Now tune your transmitter's frequency to the satellite's uplink passband. OSCAR 52 uses inverting transponders. If you transmit at the low end of the uplink pass-

band, you can expect to hear your signal at the high end of the downlink passband. Generally speaking, CW operators occupy the lower half of the transponder passband while SSB enthusiasts use the upper half, as was shown in **Fig 23.4**.

Assuming that you cannot hear your own signal from the satellite on a separate receiver, the best thing to do is make your best guess as to where your signal will appear on the downlink and set your receive frequency accordingly. Send several brief CQs ("CQ OSCAR 52, CQ OSCAR 52..."), tuning "generously" around your guesstimated receive frequency after each

Fig 23.15—Simple ground plane and Yagi antennas can be used for low-Earth-orbit (LEO) satellite contacts.

one. The station that is answering your call will also be making his or her best guess about where you are listening.

The Japanese Fuji OSCAR FO-29, is also a linear transponder bird that functions much like OSCAR 52. The main difference is that it listens on 2 m and retransmits on 70 cm, Mode V/U. (FO-29 also uses inverting transponders.) Few amateurs own receivers that can listen for 70 cm CW and SSB, so this satellite is not very active. During weekend passes, however, you should be able to hear several conversations taking place.

Station Requirements for the OSCAR 29 and 52 Satellites

To work OSCAR 52 you'll need, at minimum, a multiband VHF/UHF SSB or CW transceiver. You *do not* need an amplifier; 50 W is more than enough power for the uplink. In fact, even 50 W may be too much in many instances. The rule of thumb is that your signal on the downlink should never be stronger than the satellite's own telemetry beacon.

The ability to hear yourself simultaneously on the downlink is a tremendous asset for working any satellite. It allows you to operate full duplex as you listen to the Doppler shifting of your own signal,

giving you the opportunity to immediately tweak your transmit frequency to compensate (rather than fishing for contacts using the haphazard half-duplex procedure described earlier).

To work OSCAR 52 in Mode U/V, you'll need a 2-m multimode transceiver that can operate in CW or SSB. Remember that OSCAR 52 is listening for signals on 70 cm and retransmitting on 2 m. This means that also need a 70 cm transceiver. Choose your radios carefully. A number of modern HF transceivers also include 2 m and even 70 cm. The problem, however, is that some

Fig 23.17—The Yaesu FT-847's satellite mode provides the user with a full featured satellite transceiver. As a bonus, it also covers all the HF bands!

Fig 23.16—VUSat-OSCAR 52 heads for orbit!

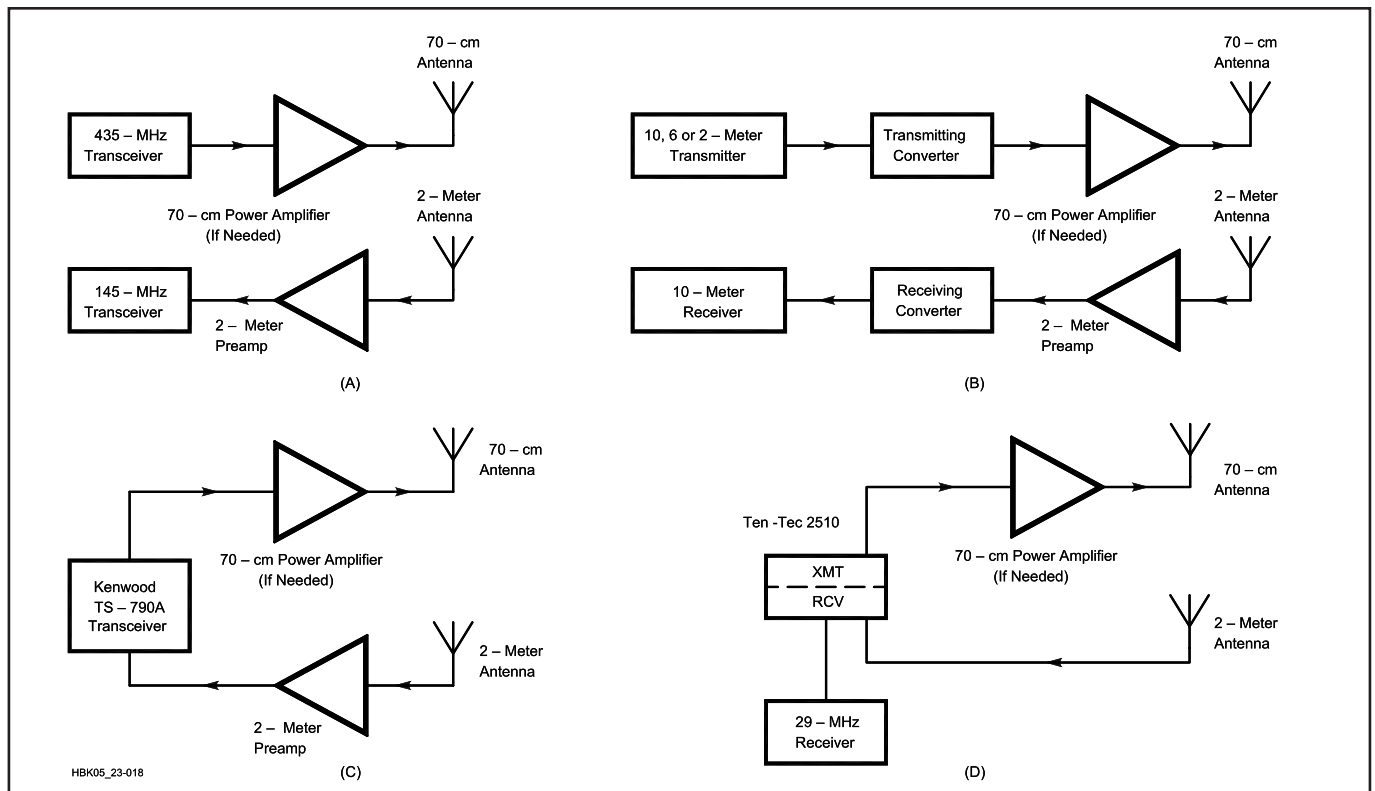

Fig 23.18—Several different Mode-U/V satellite-station configurations for OSCAR 52 are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, a multimode, multiband transceiver can perform both transmitting and receiving function, full duplex, in one package. The Ten-Tec 2510 shown at D contains a 435-MHz transmitter and a 2-m to 10-m receiving converter.

of these radios do not allow *crossband splits* between VHF and HF. That is, they won't allow you to transmit on 70 cm and receive on 2 m. At the very least they won't allow you to do this simultaneously. One solution that will provide full duplex service for Mode U/V is the Yaesu FT-847 transceiver, **Fig 23.17**, all in one neat package.

Omnidirectional antennas for 2 m are sufficient for listening to OSCAR 52. A beam on 2 m would be even better, but then you incur the cost of an antenna rotator that can move the antenna up and down as well as side to side—the so-called *azimuth/elevation rotator*, or Az-El rotators.

For FO-29 the ability to transmit and

receive simultaneously is a must. The Doppler effect is pronounced on the 70 cm downlink. You need to listen to your own signal continuously, making small adjustments to your 2-m uplink so your voice or CW note does not slide rapidly downward in frequency. To achieve this you will need separate 2-m and 70-cm transceivers (such as a couple of used rigs), or a dual band transceiver specifically designed for satellite use. **Fig 23.18** and **Fig 23.19** show several possible combinations of equipment for satellite operations on 2 m and 70 cm. Kenwood, ICOM and Yaesu have such radios in their product lines. These wondrous rigs make satellite operating a

breeze, although their price tags may give you a bit of sticker shock (about \$1600). They feature full crossband duplex, meaning that you can transmit on 2 m at the same time you are listening on 70 cm. They even have the ability to work with inverting transponders automatically. That is, as you move your receive frequency down, the transmit VFO will automatically move up (and vice versa)!

Although beam antennas and azimuth/elevation rotators are not strictly necessary to work FO-29, they vastly improve the quality of your signal. A good compromise, medium-gain antenna for 2 m and 70 cm is shown in Fig 23.14. If you decide

Down with Doppler

The relative motion between you and the satellite causes *Doppler shifting* of signals. As the satellite moves toward you, the frequency of the downlink signals will increase as the velocity of the satellite adds to the velocity of the transmitted signal. As the satellite passes overhead and starts to move away from you, the frequency will drop, much the same way as the tone of a car horn or a train whistle drops as the vehicle moves past the observer.

The Doppler effect is different for stations located at different distances from the satellite because the relative velocity of the satellite with respect to the observer is dependent on the observer's distance from the satellite. The result is that signals passing through the satellite transponder shift slowly around the published downlink frequency. Your job is to tune your uplink transmitter—not your receiver—to compensate for Doppler shifting and keep your frequency relatively stable on the downlink. That's why it is helpful to hear your own signal coming through the satellite. If you and the station you're talking to both compensate correctly, your conversation will stay at one frequency on the downlink throughout the pass. If you don't compensate, your signals will drift through the downlink passband as you attempt to "follow" each other. This is highly annoying to others using the satellite because your drifting signals may drift into their conversations.

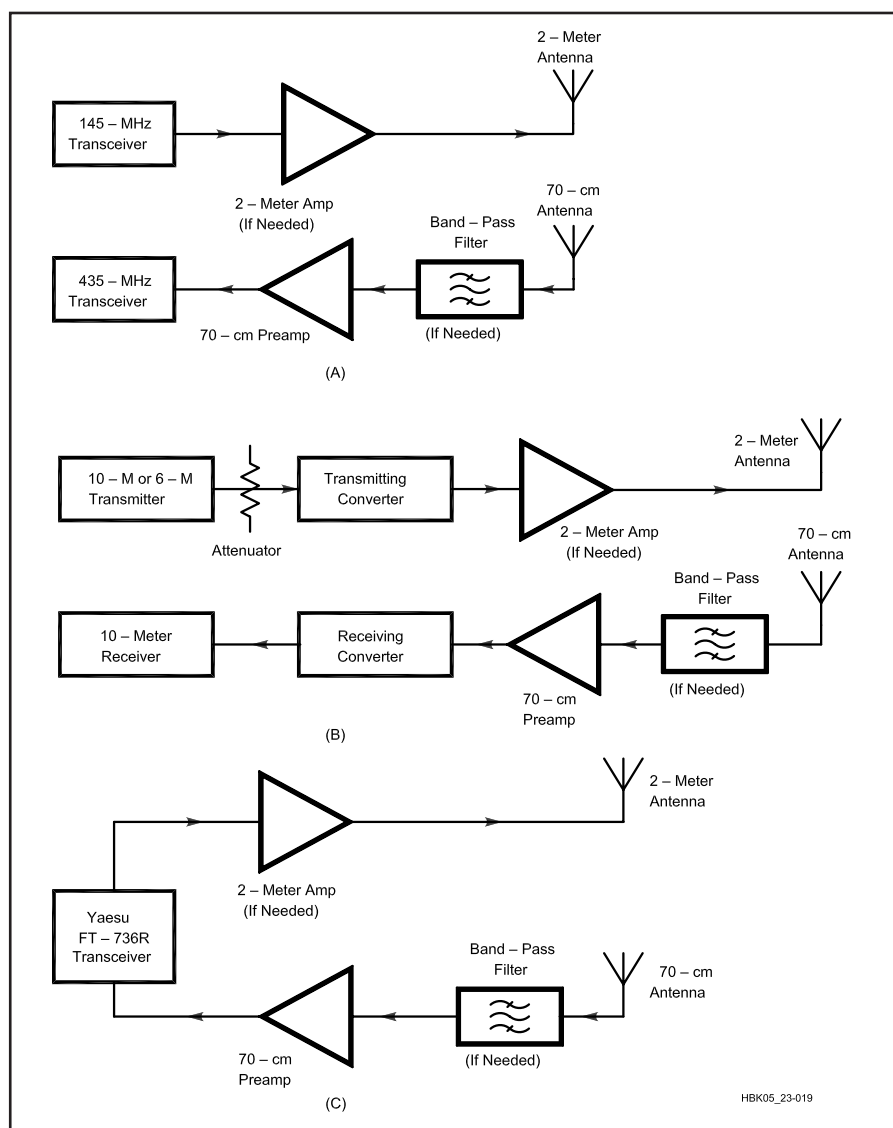

Fig 23.19—Several different Mode-V/U satellite-station configurations for OSCAR 29 are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, a multimode, multiband transceiver can perform both transmitting and receiving functions, full duplex, in one package.

to go the omnidirectional route, you'll need to add a 70-cm receive preamp at the antenna to boost the downlink signal.

PHASE 3E—THE NEXT GENERATION

The next Phase 3-series satellite planned is Phase 3E or P3E. It is built on a P3C (AO-13) platform. As this *Handbook* went to press, P3E is expected to launch within the next two years. Currently, the planned transmit RF operations on P3E are R Band (47 GHz) very low power — 0.5 W PEP; K Band (24 GHz) moderate power — 5 W PEP; X Band (10.5 GHz) very low, medium and high power — up to 10 W; S Band (2.4 GHz) high power — 25 W PEP, and V Band (145 MHz) high power. Generally, *high power* here means RF output from the satellite in the 5- to 25-W PEP range using mostly linear transmitters that incorporate HELAPS technology. Very low power on X Band is to simulate the signal strength that Earth stations will see from a P5A (Mars mission) transmitter near the red planet. There are other modules on board — such as a star sensor — that are prototypes for the upcoming P5A mission. Receive frequencies on P3E will be in C Band (5.6 GHz); S Band (2.45 GHz); L Band (1.2 GHz), and U Band (435 MHz). Updates and other useful information on P3E can be found on the German AMSAT website at: www.amsat-dl.org/p3e.

SATELLITE GROUND STATIONS

The keys to your enjoyable satellite communications are in the details of your station. One such station is illustrated in **Fig 23.20** and **Fig 23.21**, showing only some of the ways that you can achieve this enjoyable ham radio operation. The following sections will describe that station and the options that are open for you to construct your own satellite station, including discussions of equipment and techniques for transmitting, receiving, antennas, and station accessories, such as audio processing and antenna pointing control.

Transmitting

The 23-cm (L) band is the highest band for which commercial amateur transceivers are readily available. Kits and converters are also available. Commercial equipment, such as the ICOM IC-910H, **Fig 23.22**, with a 23-cm module, the popular Yaesu FT-736R, **Fig 23.23**, with a 23-cm module, and the new Kenwood TS-2000, **Fig 23.24**, with a 23-cm module, all provide about 10 watts of RF output power. Of course multimode transceivers, such as the ICOM IC-821H, **Fig 23.25**, with an outboard 23-cm up-converter will

Fig 23.20—WD4FAB's station is typical of a full-featured HF and satellite operation. On the bottom row, L-R are: IC-746 HF to 2 meter transceiver, IC-821H VHF-UHF multimode transceiver topped by a home-brew power meter, KLM 1200GU 1.2-GHz transverter, home-brew multi-antenna rotator controller on top of the station accessory control box. On the top row, L-R are: G3RUH AO-13 Telemetry Demodulator, PacComm SPIRIT2 high performance packet controller, Timewave DSP-599zx audio DSP unit for the VHF-microwave operations through the IC-821H and the TAPR EasyTrak antenna command unit for interfacing the computer tracking to the antenna controller.

also serve the satellite station very well. See **Table 23.3** for a listing of suppliers of equipment of interest to satellite operators.

Stations that do not have one of the newer transceivers, with their built-in 1.2 GHz band modules, can use a separate transverter or transmitting up-converter to achieve the L-band uplink. Commonly these up-converters employ a 2-m IF for their drive. This generally means that a separate 2-m receiver is needed along with the VHF/UHF transceiver, as often the S-band down-converter also has a 2-m IF. The station shown in **Fig 23.20** is of this type, using the 2-m features of the base HF transceiver to provide the IF for the S-band down-converter. Transmitting functions use the VHF/UHF transceiver for uplinks on U band and L band through an up-converter. There are a few L-band-transmitting up-converters on the market just for satellite service. Among these are units from Down East Microwave, with its 1268-144TX; and from SSB-USA, with its MKU130TX; and from Parabolic AB. When you assemble your station, be sure to take the necessary steps to set the RF power drive level needed for your up-converter. This may mean the need for a power attenuator inserted between the transceiver and up-converter.

Operating experience with L-band uplinks has shown that the power and antenna requirements for communications at altitudes up to 40,000 km can be satisfied with 10 W of power *delivered* to a 12-turn helix antenna. This experience has also shown that L-band power levels of 40 W-PEP, or higher, *delivered to the antenna*, along with antenna gains of greater than 20 dBi (4000-5600 W-PEP EIRP) are very workable for operations at the highest altitudes, depending upon the satellite squint angle. A pretty compact L-band antenna arrangement with two 22-element antennas in a stacked array is shown in **Fig 23.21**. These antennas have a combined gain of about 21.5 dBi. Some other experiences with L-band dish antennas have shown that a 1.2-m offset-fed dish with a helix feed and 10-W of RF power can also provide a superb uplink. This dish antenna will have a practical gain of about 21 dBic, giving an uplink of only 1400 W-PEP EIRP but with RHCP. Circular polarization for L band makes a real uplink difference. These uplinks will provide the user a downlink that is 10-15 dB above the transponder noise floor. In more practical terms this is an S7 to S8 signal over a S3 transponder noise floor in the illustrated station, a very comfortable copy for the capable station.

Fig 23.21—Station antennas at WD4FAB. Mounted are T-B: M2 436-CP30, two stacked M² 23CM22EZ, modified PrimeStar dish with homebrew seven-turn Helix feed antenna. The M² 2M-CP22 antenna is off the bottom of the photo. See Fig 23.41 for details of the center section.

For the illustrated station, the remotely mounted 23-cm amplifier (see “Double Brick Amplifier Construction”) is contained in a tower-mounted-box. The regulated dc power requirements for this amplifier are of too high a current at 13.8 V-dc to bring it up from the ground, as the voltage loss of any reasonable cable would be excessive. Instead, 24 V dc unregulated power is taken from the station power supply before its regulator. This power is brought up the tower and regulated to 13.8 V where it is needed. This power regulator is borrowed from Chapter 17, “28-V, High-Current Power Supply”, using only the regulator circuitry, and adjusting the output voltage down to 13.8 V dc.

Much of your station’s uplink performance strongly depends upon the satellite’s antenna off-pointing, or *squint* angle. L-band and U-band receiving antennas are usually high-gain arrays, with measured gains of 16 dBic and 15 dBic, respectively. This means that the antenna half-power-beamwidth (HPBW) of these arrays are relatively narrow, calculated to be $HPBW = 28.5^\circ$ and 32.0° , respectively. When a satellite’s main axis (+Z axis) is off pointed from your ground station that off-pointing angle is known as the squint angle. If the squint angle is less than half of the HPBW, the ground station will be within the spacecraft antenna nominal beam width. It is one of the information outputs from most of the newer computer satellite tracking programs. With the weaker signals from birds at higher altitudes, the effects of the squint angle are

Fig 23.22—ICOM’s IC-910H, a recent entry into the multi band VHF/UHF transceiver world, has an available 23-cm module.

Fig 23.23—The Yaesu FT-736R is a multi-mode transceiver for 2 m (144-148 MHz) and 70 cm (430-450 MHz). It can be used for full-duplex receiving and transmitting on Mode U/V and V/U. An optional 23-cm module covers 1230-1300 MHz (Mode L/U). Approximate power output: 20 W on 2 m and 70 cm, and 10 W on 23 cm.

Fig 23.24—Kenwood’s TS-2000 is an all-band, multi-mode transceiver that covers HF, 6 m, 2 m, and 70 cm. A 23-cm (1240-1300 MHz) module is optional. Typical power output is 35-45 W on 144 MHz, 30-40 W on 430 MHz and 10 W on 1240 MHz.

Fig 23.25—ICOM’s IC-821H is another full-featured transceiver designed for satellite use.

more pronounced; making the HPBW values sometimes seem even smaller.

SOME L-BAND PROBLEMS AND SOLUTIONS

An examination of an efficient operating system must include all of the various

parts of that system, and how they best fit together. The trick is in turning negatives into positives, as shown by K9EK. For L-band transmitting, the problems are more physical than electronic. Fig 23.26 illustrates this approach.

First is the fact that transmitters and

Fig 23.26—L-Band Transmitting: an integrated approach.

antennas are usually in separate places with a long length of coaxial cable connecting the transmitter to the antenna. Coaxial cable is an imperfect RF conductor and with losses increasing with frequency and length of cable. Common (and reasonably priced) coaxial cables have unwanted losses at 1270 MHz. The old standby, RG-8U, loses almost 13 dB per 100 feet at 1270 MHz. A 100-foot feedline would only have 0.5 W coming out from 10 W going in. Of course, we could increase transmitter power by 20 times to compensate, but those are quite expensive watts to be used for heating coaxial cable! Coaxial cable “hardline” is a good but an expensive solution, and even it has significant loss. Low-loss L-band waveguide is much too large and expensive to be considered.

What is needed are methods of getting all of the transmitter power to the antenna. You may not want to remotely mount your entire L-band transmitter at the antenna, although some manufacturers are offering transmitting converters for that service. A much better solution would be to split the transmit power generation into two stages, and integrate the antenna and final amplifier stage by mounting a final amplifier very near the antenna feedpoint. This will greatly reduce the transmitter to antenna feed-line

loss by eliminating most of the feed line. Fortunately, an elegant solution exists for the “final amplifier stage” of this integration. This is the M57762 hybrid linear amplifier module. This 1-W input, 10-18 W output “brick” has 50-Ω input and output impedance and requires only the addition of connectors, a heat sink and simple dc power circuitry. A second design of amplifier is also offered, using two of these M57762 modules for higher output power.

There is still the problem of the feed-line loss between the shack transmitter and the final amplifier stage, but there are ways to use this to an advantage. Most L-band transmitters use the M57762 brick as part of their output stage, and are rated for 10 W (+40 dBm) RF output. The remotely mounted final amplifier stage requires only 1 W (+30 dBm) RF input, so some method of reducing the transmitter output to match the amplifier input. A very satisfactory way to do this is to use the loss qualities of a length of small coaxial cable as an attenuator. For this feed, a 10-dB loss between the transmitter and amplifier is needed. Referring to cable manufacturer’s data, a length of coaxial cable can be determined that will give the required 10-dB attenuation, then use it to connect the transmitter and amplifier.

SINGLE BRICK L-BAND AMPLIFIER

The amplifier of Fig 23.27 was constructed by K9EK by mounting the M57762 module directly to a heat sink (no insulator required; but thermal compound is highly recommended), then using an etched circuit board, slipped under the leads of the module, to provide both RF and dc connections. The schematic for this amplifier is shown in Fig 23.28. The board is made from 0.062-inch thick, G10 board. Keep the input and output lines 0.10-inch wide to main-

Fig 23.27—The matching brick amplifier can be mounted on the counterbalance side of the Helix antenna boom.

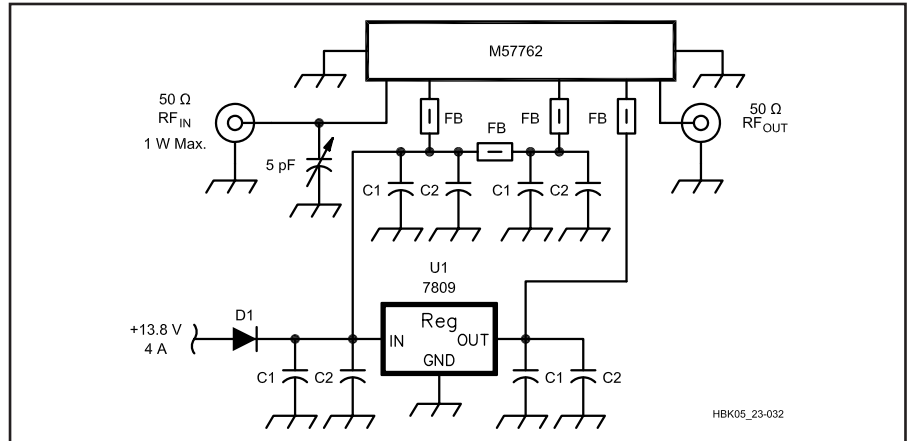

Fig 23.28—Just a handful of parts are needed to connect the brick amplifier module. All capacitor pairs are 10 μ F/35 V chip or tantalum units in parallel with 1 nF chip capacitors. D1 is a 4-A (minimum) 50-V power rectifier such as Digi-Key G1820CT-ND. It prevents damage due to reverse connection of the power leads. U1 is a 7809 voltage regulator (9-V, 1-A). Check RF Parts and Down East Microwave for pricing and availability of the amplifier module.

tain the 50- Ω input and output impedance. The type N connectors should be mounted on the end of the heat sink in such a manner that the center conductors lie directly on the board traces. Ensure that the circuit board is well grounded to the heat sink by drilling and tapping several holes through the circuit board as shown.

This amplifier operates in class AB linear, and therefore draws some (about

400 mA) dc current when not transmitting. It was decided that the additional circuit complexity to cut the amplifier off completely was not warranted. You just turn off the dc supply during long standby periods. The full load current is approximately 4A.

A template, with additional construction details and a PC board layout, is available from the ARRL. See the *Handbook CD-ROM Templates* section for details.

DOUBLE BRICK L-BAND AMPLIFIER

This second L-band amplifier is more complex, offering considerably more output power (≈ 40 W), and was originally constructed for terrestrial 1296-MHz service by WD4FAB. This amplifier also operates in class AB linear. As the amplifier is pretty broad-banded, it can serve the satellite service as well as for the original terrestrial service plans; all is the matter of not pointing your antenna into the sky for that 1296-MHz contact! The inspirational credit for using the M57762 module and getting this unit started is given to the North Texas Microwave Society. NTMS has a lot of good ideas flowing through their newsletters.

Fig 23.29 shows this completed assembly, as it was just removed from the tower box, for the purpose of the picture taking. This assembly is composed of two flanged extruded heat sinks mounted face-to-face, with the brushless dc blower moving cool-

Fig 23.29—This is an alternate, more powerful, design of the L-band brick amplifier. This is a pair of heat sinks mounted face to face with a dc motor cooling fan; the electronics are mounted on each side with the combiner and relay circuitry on the near side. From left to right: output 3-dB hybrid coupler, directional coupler for power measurement, the four-port relay, and the input 3-dB hybrid coupler.

ing air through the finned chamber of the heat sinks. The identical M57762 module “brick” amplifiers and their bias circuitry PCB assemblies are mounted on the troughs of each heat sink on the opposite sides of the assembly.

Fig 23.30 and Fig 23.31 provide the schematic information for this amplifier assembly. The following notes will give the constructor details that may not be obvious from the photographs and schematics. Considerable care is needed in making the RF connections between these module amplifiers and their respective input and output 3-dB hybrid couplers. Slight differences in getting really equal length lines here can make a large difference in the overall performance. Notice in Fig 23.29 that the input coaxial lines, on the right, are of flexible Teflon 50- Ω cable, while the output lines, on the left, are of the semi-rigid UT141 copper jacketed co-

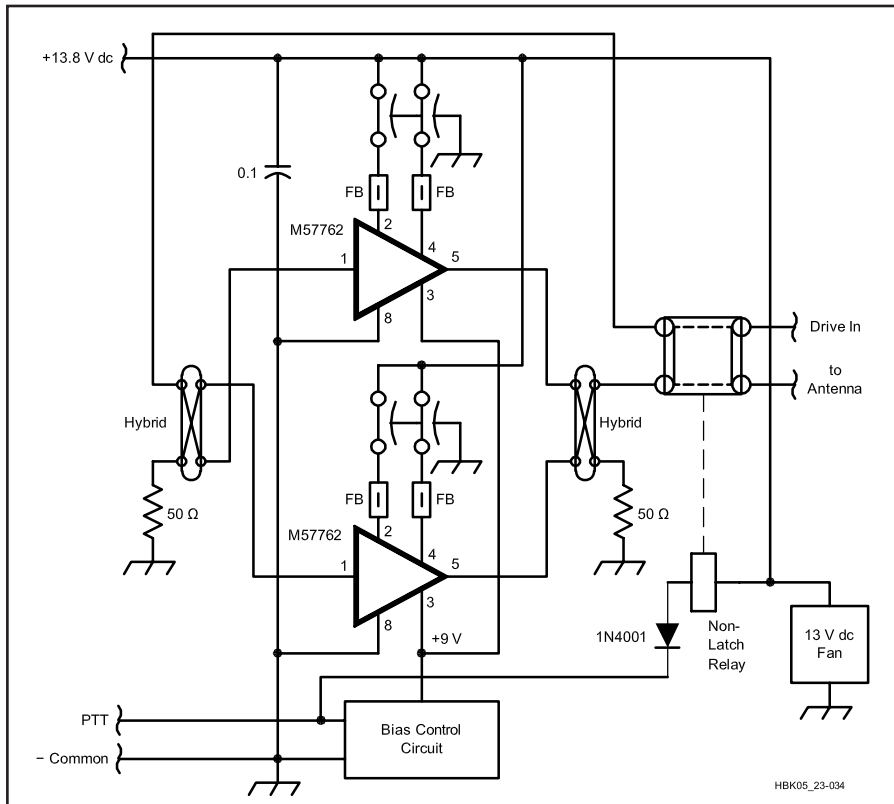

Fig 23.30—Schematic diagram of the more powerful L-band amplifier assembly.

axial cable, selected because of the higher power level at this point. Each end of the UT141 cables is terminated in an SMA connector, for ease of handling and uniformity of cable length.

Also shown along the facing side of the heat sink assembly is a collection of RF parts, which from left to right are output hybrid coupler, directional coupler for power measurement, the four-port relay

and the input hybrid coupler. Having a four-port relay of this type surely makes life easier, as it handles both input and output switching. The output from the directional coupler is converted to a dc signal by a diode and capacitor right at the SMA connector (not shown) that mounts to the coupled port. That dc signal is sent back to the station to give a very useful indication of the output power. Note also

the 50-ohm load terminations that are SMA-connector-mounted to the couplers. These loads absorb any unbalanced power from the amplifiers through the hybrid couplers. While the input coupler did not need such a large load, it was easier to buy two identical loads.

For the M57762 module assemblies, Fig 23.32, there are a number of details that are not so obvious, some mechanical and some electrical. First is to note that measures are taken to insure that the module is very thoroughly clamped to the heat sink, through the use of a pair of 6.4-mm (0.25-inch) square brass bars. Using screws alone would provide insufficient clamping forces. The module must have heat sink compound used between it and the heat sink and that interface must be smooth and flat for reasonably decent heat transfer. These bars are elongated to serve additional purposes as the bar at the output end of the module (at the right) has a two-hole SMA connector embedded in it so as to get a very close termination to the wire lead of the RF output of the module. This bar also serves as a low-resistance dc connection for the power ground lead to the module, thereby not depending upon a casual connection through mounting screws and the heat sink. For the input end, the coaxial cable is fed through a hole in the bar (at the left) to also get the close connection to the module RF input. Note the short, exposed RF leads at these points.

There are three other wire leads to the module, two for +13.8 V and one for the +9 V bias power. These leads are individually filtered with FB43101 ferrite beads, and with the leads running across the top of a 1nF trapezoidal filter capacitor soldered to the PCB. The PCB is a double-sided G10

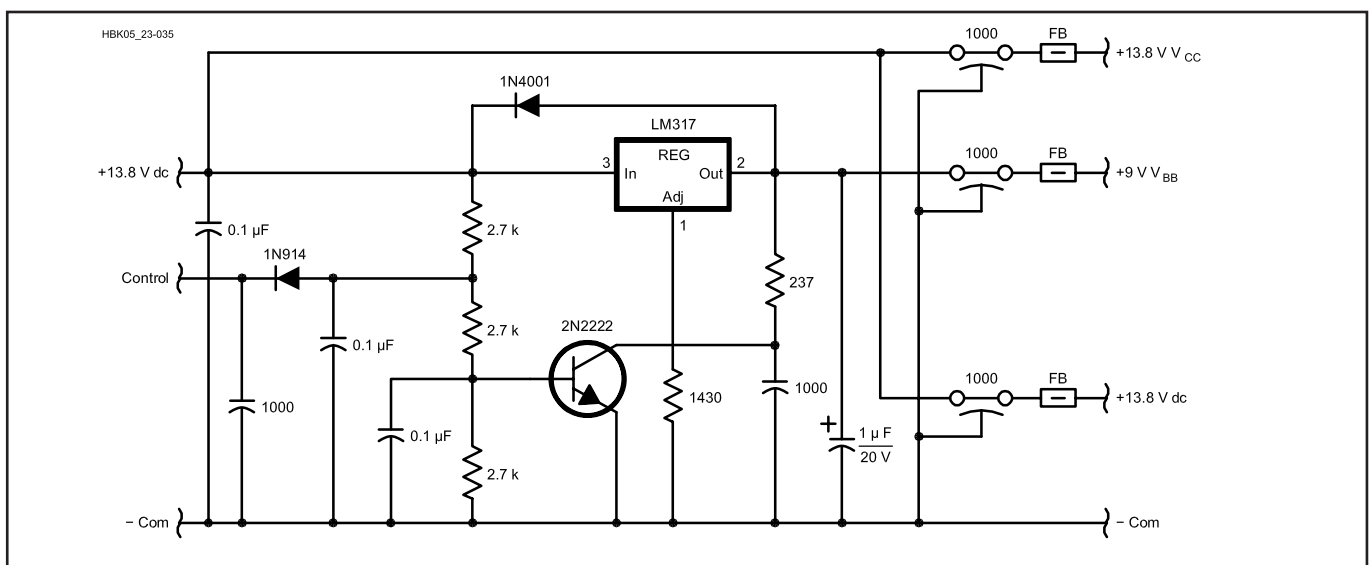

Fig 23.31—Schematic diagram of bias circuitry for the L-band amplifier assembly.

Fig 23.32—One side of the amplifier assembly, showing the brick amplifier and the one-sided PC board with bias regulator and filter circuitry. Note that the input and output coaxial cables are soldered to the brass clamp bars so that the center conductor is closely “presented” to the input and output terminations of the brick amplifier.

board, 0.062-inches thick, with only the topside formed into circuit patterns. The reverse side of the PCB is only used as the ground plane for the power circuits. The two sides of the PCB are connected with copper or brass foil wrapped around the edges at selected locations.

This bias circuitry operates to shut off the bias to the module when not transmitting, through a conventional grounding-on-PTT control line that comes up from the station. This same line, which is controlled by a sequencer in the station, also operates the four-port T/R relay. It was determined necessary to turn off the module to prohibit it from having any possible emissions while the station is in its most

Fig 23.33—A close-up view of one of the 3-dB hybrid coupler assemblies (the two are identical) showing its construction using Sage Wireline®, four 2-hole SMA connectors, spacers and screw hardware. Note the 50-Ω terminated port.

sensitive receiving condition, although this is unproven.

Operation of the bias circuitry is through the diode isolated control line shutting off the bias to a saturated 2N2222, which, in turn, unclamps the LM317 regulator reference lead. It is interesting what tricks can

be done with these adjustable regulators. All of the additional capacitive filtering needed for the regulator is added.

One of the two identical 3-dB hybrid coupler assemblies is shown in Fig 23.33, with drawing details shown in Fig 23.34. The neat tricks of constructing these couplers using the Sage Wireline and SMA connectors was learned from KE3D, who probably “borrowed” it from S57MV. Proper wiring of the Wireline to the SMA connectors is very important here, as is having equal lengths of equal-properties coaxial lines from the amplifiers to the couplers. Careful attention to small details here pay great dividends in performance. Also note the “reversal” of the input lines from the coupler to the amplifiers, needed to compensate for 90° phase shifts of the hybrids. Without this input crossover, there would be no RF output! The first assembly of this unit had ignored that phase shift and the amplifier input lines had to be “patched” with extension cables to correct for that bit of forgetfulness.

Templates with additional construction details and PC board layouts are available for each of these two amplifiers on the CD included with this book.

RECEIVING, PREAMPLIFIERS AND RECEIVE CONVERTERS

Receiving Phase-3E downlinks will require equipment for the microwave bands. Operating experience with AO-40

Fig 23.34—Details of the construction of the 3-dB hybrid coupler assemblies.

has shown that receiving antenna gains need to be 22 dBic, minimum. On S band this has clearly been shown to require the use of a dish antenna with at least a diameter of 600 mm. As there are no commercial base-station S band receivers, outboard S band down-converters need to be used and have become available in recent years, with a lot of interest in soaking up the surplus market units provided by Drake and others, **Fig 23.35**. Commercial Amateur S band receive converters have been coming on the market from SSB-USA, with their UEK-3000SAT; from Down East Microwave (DEM), with their 2400-144RX and 2400-432RX (see **Fig 23.36**); from Parabolic AB, with their “Mode S Down-converter”; and from other sources. Amateur microwave operation is not a “strange” activity relegated just to the specialists anymore, as satellite enthusiasts have been exploring these S band downlinks for some time and manufacturers have responded by increasing the supply of useable equipment for S band.

No discussion of satellite receiving systems would be complete without mentioning preamplifiers and their location. The mast mounting of sensitive electronic equipment has been a fact of life for the serious VHF/UHF operator for years, although it may seem to be a strange or difficult technology for HF operators. While a preamplifier can be added at the receiver in the station, it will do no good there. Vastly better results will be obtained if the preamp is mounted *directly* to the antenna. To get the most out of your VHF/UHF satellite station, you’ll need to mount a low-noise preamplifier or receive

Fig 23.35—S-band converter that was available from Drake, and easily modified for satellite service.

Fig 23.36—This SSB Electronic unit (left) is one of several solutions for mast-mounted S-band receive converters. Other manufacturers, including Down East Microwave (top), have similar offerings.

converter on the tower or mast near the antenna, see **Fig 23.37**, so that feed-line losses do not degrade low-noise performance. Feed-line losses ahead of the preamplifier or converter add directly to

receiver noise figure. Antenna mounting the preamplifier or down-converter will overcome these noise figure problems. For S band, placing either a preamp or the receiving down-converter *on* your antenna feed point is essential. Not even mast mounting the preamplifier will suffice here.

Low-noise front ends for down-converters or preamps are essential for receiving weak satellite signals, especially as the operating frequency goes higher. Multimode rigs and most down-converters will hear much better with the addition of a preamplifier employing GaAs FET or PHEMT technology ahead of the front end, albeit at the expense of the reduction in the third-order intercept point of the receiver. DEM provides a weather-resistant assembly in their 13ULNA unit. See photos of S-band dish antennas for views of this DEM product. Other very qualified preamplifier units are available from SSB-USA.

Table 23.3 lists other sources of commercially built preamplifiers and receive converters for most all VHF, UHF and microwave bands. These are available in several configurations. Many models are designed for mounting in a receive-only line for use with a receiving converter or transverter. Others, designed with multimode transceivers in mind, have built-in relays and circuitry that automatically switch the preamplifier or converter out of the antenna line during transmit. Most of these models are housed, with relays, in weatherproof enclosures that mount right at the antenna. For the equipment builder, several suitable designs appear in *The Radio Amateur’s Satellite Handbook*.

Fig 23.37—Details of WD4FAB’s tower cluster of satellite antennas, including a home-brew elevation rotator. Top to bottom: M² 436-CP30, a CP U-band antenna; two each M² 23CM22EZA antennas shown in a CP array for L band; “FABStar” dish antenna with helix feed for S band; M² 2M-CP22, a CP V-band antenna (only partially shown.) To left of dish antenna is a NEMA4 equipment box with an internal 40W L-band amplifier, and also hosts externally-mounted preamplifiers.

ACCESSORIES

Receiver audio output noise on these higher satellite bands is often quite disturbing to many operators, taking away from the “listenability”, or the “arm chair” quality of the QSO audio on these bands. Some of this disruption can also be from the in-band use of such equipment as microwave ovens and the modern spread-spectrum 2.4-GHz cordless telephones that are becoming common in our households. Modern receivers and accessory equipment comes to the rescue here, and is the reason for the use of the HF transceiver (an IC-746) in receiving the S-band signals of the station shown in Fig 23.20. Newer model HF transceivers provide IF DSP and other features that provide very useable “Noise Reduction” and “Noise Blanker” functions. The noise blanker, in particular, removed all the observed noise from a 2.4-GHz Spread-Spectrum cordless telephone near the illustrated station, even with the very high sensitivity of the S-band receiving equipment. In the illustrated station an outboard audio DSP unit (a Timewave DSP599zx) is very helpful to remove the audio “Random Noise” that is not removed by the IF DSP. The combination of the equipment shown does provide “arm-chair” quality comfortable listening. Some of the other most recently available Amateur transceivers may incorporate both the audio and IF DSP noted above, possibly eliminating the need for an outboard audio DSP unit.

Great caution by the operator must be exhibited when using a transceiver for receiving the S-band signals, as even the slightest inadvertent moment of transmitter operation into the “rear end” of a down-converter can make it an instant hot dog without a roll! SSBUSA offers a protection unit “The Protector” with a SSB power rating of 50 W. In the illustrated station with its IC-746 transceiver, the 2-m receive line was internally isolated from the transmitting circuits and brought out to a SMA connector at a convenient point on the rear panel. This separated receive capability on 2 m has saved the down-converter on several occasions.

One very helpful accessory for the station is the remote measurement of RF power. Such power meters are commercially available or easily constructed by the handy operator. This type of measurement is very meaningful for stations with long feed lines between the transmitter and the antennas, making the determination of EIRP more realistic. The illustrated station uses a moving-coil power meter of uncertain origin coupled with surplus or home made directional couplers for power sampling near the antennas in the equip-

Fig 23.38—KLM 2M-22C antenna CP switching relay with relocated balun. Protective cover is needed for rain protection; see text.

ment box on the tower.

Operators unfamiliar with microwave S-band operation may gain a greater confidence of their receivers with the addition of a 2101-MHz signal source. Such signal sources have been in the literature in recent years, and Down East Microwave offers a kit. An S-band signal source can also provide the user a convenient check for the station antennas and also as a calibrator for the S-band receiver S meter.

For stations using “crossed” Yagi antennas for CP operation, one feature that has been quite helpful for communicating through most of the LEO satellites, has been the ability to switch polarization from RHCP to LHCP. In some satellite operation this switchable CP ability has been essential.

The station shown has an all up capability for analog and digital satellite operations. Not shown just to the left of the photo is the station computer, which provides the satellite tracking information from the Northern Lights Software Association, NLSA, *Nova* for *Windows* tracking program. This provides output for the TAPR EasyTrak antenna controller, as well as providing the interface to the digital communications operations, using a PacComm SPIRIT-2 Packet Controller. Please note the warning sign in Fig 23.20, as it is right and proper for the unwary at that station.

EXPOSED ANTENNA RELAYS AND PREAMPLIFIERS

Experience with the exposed circularity switching relays and preamplifiers mounted

on antennas have shown that they are prone to failure caused by an elusive mechanism known as “diurnal pumping.” Often these relays are covered with a plastic case, and the seam between the case and PC board is sealed with a silicone sealant. Preamps may also have a gasket seal for the cover, while the connectors can easily leak air. None of these methods create a true hermetic seal and as a result the day/night temperature swings pump air and moisture in and out of the relay or preamp case. Under the right conditions of temperature and moisture content, moisture from the air will condense inside the case when the outside air cools down. Condensed water builds up inside the case, promoting extensive corrosion and unwanted electrical conduction, seriously degrading component performance in a short time.

A solution for those antennas with “sealed” plastic relays, such as the KLM CX series: you can avoid problems by making the modifications shown in Fig 23.38. Relocate the 4:1 balun as shown and place a clear polystyrene plastic refrigerator container over the relay. Notch the container edges for the driven element and the boom so the container will sit down over the relay, sheltering it from the elements. Bond the container in place with a few dabs of RTV adhesive sealant. Position the antenna in an “X” orientation, so neither set of elements is parallel to the ground. The switcher board should now be canted at an angle, and one side of the relay case should be lower than the other. An example for the protective cover for an S-band preamp can be seen in the discus-

Fig 23.39—Protection for tower-mounted equipment need not be elaborate. Be sure to dress the cables as shown so that water drips off the cable jacket before it reaches the enclosure.

sion on feeds for parabolic antennas.

For both the relay and preamp cases, carefully drill a $\frac{3}{32}$ -inch hole through the low side of the case to provide the needed vent. The added cover keeps rain water off the relay and preamp, and the holes will prevent any build-up of condensation inside the relay case. Relays and preamplifiers so treated have remained clean and operational over periods of years without problems.

Another example for the protection of remotely, tower mounted equipment is shown in Fig 23.37, illustrating the equipment box and “mast mounted” preamplifiers at the top of WD4FAB’s tower. The commercial NEMA4 rated equipment box is used to protect the 23-cm power amplifier and its power supply, as well as a multitude of electrical connections. This steel box is *very* weather resistant, with an exceptionally good epoxy finish, but it is not sealed and so it will *not* trap moisture to be condensed with temperature changes. Be sure to use a box with at least a NEMA3 rating for rainwater and dust protection. The NEMA4 rating is just a little better protection than the NEMA3 rating. Using a well-rated equipment box is very well worth the expense of the box. The box also provides some pretty good flanges to mount the “mast-mounted” preamplifiers for three bands. This box is an elegant solution for the simple need of

rain shelter for your equipment, as illustrated in Fig 23.39.

ELEVATION CONTROL

Satellite antennas need to have elevation control to point up to the sky, the “El” part of the needed Az-El control of satellite antennas. Generally, elevation booms for CP satellite antennas need to be non-conducting so that the boom does not affect the radiation pattern of the antenna. In the example shown, the elevation boom center section is a piece of extra heavy wall $1\frac{1}{2}$ -inch pipe (for greater strength) coupled with a tubular fiberglass-epoxy boom extension on the 70-cm end and a home-brew long extension (not shown in the photo) on the 2-m end, using large PVC pipe reinforced with four braces of Phillystran non-metallic guy cable. (PVC pipe is notoriously flexible, but the Phillystran cables make a quite stiff and strong boom of the PVC pipe.) For smaller installations, a continuous piece of fiberglass-epoxy boom can be placed directly through the elevation rotator.

Elevation boom motion needs to be powered, and one solution, Fig 23.40, uses a surplus jackscrew drive mechanism. One operator, VE5FP, found a solution for his Az-El needs by using two low-cost, lightweight TV rotators.¹ See Fig 23.41.

Operators through the years have employed many methods for the control of their antenna positions, ranging from true “arm-strong” manual positioning, to manual operation of the powered antenna azimuth and elevation rotators, and to fully automated computer control of the rotators. While computer control of the rotators is not essential, life is greatly assisted with the use of your computer. Fully automated control of your rotators is possible for such tasks as digital message uploading and downloading. For many years, one of the keystone control units for rotators has been the Kansas City Tracker (KCT) board installed in your computer. Most satellite tracking programs can connect to the KCT with ease. There are other options, these days, to replace the KCT unit.

A recent trend for amateur antenna control has been evolving, however, in the form of a standalone controller that translates computer antenna position information into controller commands with an understanding of antenna position limits. These boxes, represented by the new EasyTrak unit, Fig 23.42, from the Tucson Amateur Packet Radio (TAPR) group, have made this capability readily available for many amateurs. One of the EasyTrak units is also shown in Fig 23.20. The station computer, to the left and out of the photo, is used to upload antenna posi-

tions to EasyTrak. The computer can also control the operation of your station transceiver through the radio interface provided in EasyTrak; you will not need any other radio interface.

ANTENNAS

Antennas have always been favorite subjects for amateur operators. Everyone

Fig 23.42—The EasyTrak automated antenna rotator and radio controller by TAPR.

Fig 23.43—This L-band helix antenna was designed to be home-brewed without any special tools or shop equipment. It is mounted on a 4-foot-long fiberglass tube.

is an expert! Fig 23.21 shows the example of the antennas for one station. The Yagi antennas are used for the U and L-band uplinks, while the S-band dish antenna is for the downlink. These satellite antennas are tower mounted at 63 feet to avoid pointing into the many nearby trees and suffering from the “green attenuation” provided by those trees. Satellite antennas otherwise do not need to be mounted so high. If the satellite antennas are mounted lower down, the reduced feed-line length and losses are a great benefit.

Linearly polarized antennas are “horizontal” or “vertical” in terms of the antenna’s position relative to the surface of the Earth, a reference that loses its meaning in space. The need to use circularly polarized (CP) antennas for space communications is well established, as in space there is no “horizontal” or “vertical,” but there is right-hand and left-hand circular polarization, CP. With CP the wavefront describes a rotational path about its central axis, either clockwise (right-hand or RHCP) or counter clockwise (left-hand or LHCP). If spacecraft antennas used linear polarization, ground stations would not be able to maintain polarization alignment with the spacecraft because of changing orientation. Ground stations using CP antennas are not (generally) sensitive to the polarization motions of the spacecraft antenna, and therefore will maintain a better communications link.

UPLINK ANTENNAS

Experience with AO-40 has clearly shown the advantages of using RHCP antennas for both the uplink and downlink communications. The antennas shown in Fig 23.21 are a single-boom RHCP Yagi antenna for U band, a pair of closely spaced Yagi antennas phased for RHCP for L band, and a helix-fed dish antenna for S band. The antenna gain requirements

for U band can easily be met with a 30-element “crossed Yagi,” two 15 element Yagi antennas mounted on a single boom with one placed a $\frac{1}{4}$ wavelength forward of the other. This arrangement allows for an uncomplicated phasing harness to couple the two antennas together to a single feedpoint. Antennas of this size have boom lengths of 4 to $4\frac{1}{2}$ wavelengths. The enterprising constructor can build a Yagi antenna from one of several references, such as *The ARRL Antenna Book*, or he might construct a 16 to 20 turn helix antenna for this service. Most of us might prefer, however, to purchase such a well-tested antenna from such commercial sources as M² or HyGain. In the past, KLM (now out of business) had offered a 40 element CP Yagi for U band satellite service, and many of these are still in satisfactory use today.

L-band uplink antennas become even more manageable, as their size for a given gain is only one-third of those for U band. Alternatively, higher gains can be obtained for the same boom lengths. With this band there is a narrower difference between using a dish antenna and a Yagi or helix, as a 21 dBic dish antenna would have a 1.2-m (4 foot) diameter. Some of us cannot afford such “real estate” on our elevation rotators and seek the lower wind-loading solutions offered by Yagi antennas. Long-boom rod-element Yagi, or loop-Yagi antennas, are commercially offered by M² and DEM, although this band is about the highest for practical Yagi antennas. The example shown in Fig 23.21 is a pair of rod-element Yagi antennas from M² in a robust arrangement. These antennas provide an overall gain of about 21.5 dBi. If greater L-band power is available than the 40 W shown in the illustrated station, the constructor may want to consider the helix antenna that follows.

L-BAND HELIX ANTENNA CONSTRUCTION

Fig 23.43 shows an easy-to-build antenna and support structure provided by K9EK. Fiberglass tubing was used for this structure as it has better outdoor longevity. Mounting of a helix of this nature requires that it be placed out “in front” of the elevation boom, so that there are no unwanted structures in the RF field of the antenna. This places a need for the counter weighting of the antenna to remove the unbalanced loading and strain on the elevation rotator. The constructor should take these provisions, and should consider the possible placement of the output amplifier as part of that counterweight, thus also making for a very short, low-loss feed line to the antenna.

Probably the easiest way to construct a helix antenna is to mark the wire, then close wind the spiral on a form, then stretch the winding out to match the required diameter and turns spacing. First, lay out the required length of #6 AWG bare copper wire (available as ground wire wherever house wiring is sold.) To straighten it, clamp one end in a vise, then squeeze the wire between two wood blocks and pull the blocks along the wire. Once the wire is straight and even, clearly mark the wire at each “cumulative wire length” dimension as shown in **Fig 23.44**. These marks show identical length per turn and they should line up along the completed helix. Allow 1-2 feet to remain on either end of the wire for handling, which will be cut off after construction. Cumulative length is used to prevent the compounding of measurement errors.

Then close wind the wire smoothly and tightly around a piece of $2\frac{1}{2}$ -inch pipe (measures $\phi 2.875$ inch), with the length marks outward. The wire will spring back some after winding, so using two people to help pull to keep the winding tight gener-

Fig 23.44—Construction details of L-band helix antenna.

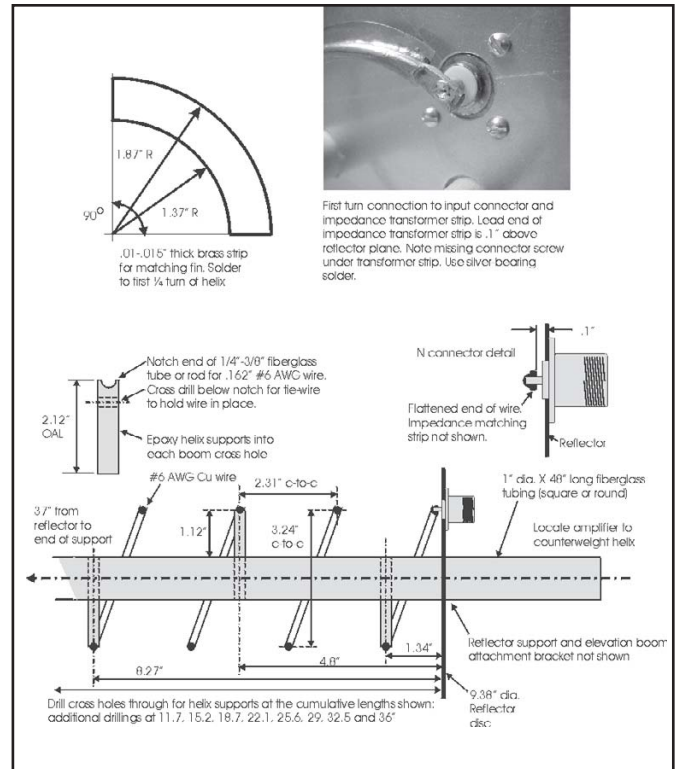

Fig 23.45—More construction details of L-band helix antenna.

ally works better. You must wind the helical element in a right-hand direction (clockwise); look at a standard machine screw or bolt and have the turns proceed in the same direction. Then hang the wire coil over a horizontal tube or form (the same PVC pipe used for winding will do well) that has been marked every 2.31 inches. Do this cumulatively to prevent errors. Holding the end turns (which will eventually be cut off) of the wire coil, gently stretch the helical element to the appropriate turn-to-turn spacing. Ensure that the turn-marks on the wire remain lined up; you may have to gently wind or unwind the helical element as you go. You can make a 2.15-inch (less your wire size) spacer to drop between turns to aid in getting the spacing correct.

Finally, cut off the excess wire on the input end of the helical element. Leave the opposite end uncut so if you goof on the input end, you can simply cut the error off and try again. After the antenna is completed, go back and cut off the excess from the far end. To connect the input end of the wire to the input connector, flatten the last 1/4-inch of the input end of the wire with locking grip pliers or a hammer and steel block. Once it is flat and even, drill a hole in the end of the wire to slip over the center pin on an N connector.

The theoretical impedance of a helix antenna fed from the periphery is 140 Ω .

A clever method of changing this to 50 Ω is by the addition of a $\lambda/4$ impedance transformer to the first quarter turn of the helical element wire itself. It has been found empirically that a 0.50-inch-wide strip of 0.010-inch-thick sheet brass makes a satisfactory impedance matching device. Cut the brass strip as shown in the figure. The strip is soldered to the first quarter turn of the helical element wire, starting 0.25 inch from the connector drilling. The underside of the strip must be flat relative to the reflector disc. Silver-bearing, lead-free plumbing solder is better than standard lead-tin solder and is highly recommended.

The method of helix antenna construction involves a single central length of 1.0 inch diameter fiberglass tubing with the helical element supported on 0.375-inch diameter fiberglass standoff rods or tubes. Fig 23.45 shows the dimensions and construction for this helix antenna. Carefully attach the helix support rods to the central boom as shown. Mount a 7 inch to 9 1/4-inch diameter (0.75 λ to 1 λ) reflector plate to the frame with homemade angle brackets. The helical element is slipped over the boom and stretched onto the support rods and held to the rods with wire ties. A homemade clamp plate and U-bolts are used to connect central rod to the antenna elevation boom.

After attaching the helical element onto

the support frame, solder the hole in the end of the first turn to the input connector, an N connector mounted from the back of the reflector plate. Position the impedance matching strip at 0.10-inch (2.5mm) spacing from the reflector plate and solder it in place. Then secure the helical element in place. On two samples of the antenna shown, the input return loss was measured in excess of -16 dB (SWR=1.38:1). If proper equipment is available, lower return loss and SWR values can be achieved with this tuning system.

A practical shortcoming of the axial mode helix antenna is not obvious. The entire helical element itself is a single, long piece of copper wire, connected to the input connector. Since this wire is physically isolated from dc ground, atmospheric static electricity may build up on the element until it damages the attached solid-state device. So, some method is needed to dc ground the helical element itself, without seriously interfering with the RF characteristics of the antenna. One method of preventing static buildup is to add a shorted $\lambda/4$ stub to the antenna feed. A shorted quarter-wave stub presents extremely high RF impedance at its non-shortened end, making it virtually invisible to RF energy at its design frequency. At the same time, it provides a dc short to ground for the helical element itself, effectively draining off static electricity

before it can build up. This shorted stub can be made from a T connector and coaxial cable. The length of the stub (measured from the center of the main cable to the short itself) must be calculated and must include the VF (velocity factor) of the cable being used. Note that an actual $\lambda/4$ stub is too short to be physically realizable; and a $\lambda/2$ must be added to the cable to create a $3\lambda/4$ stub. With RG-213 cable (VF = 0.66), the total length of the $3\lambda/4$ stub is 4.60 inches. This stub has been shown to have almost no effect on antenna performance at the design frequency.

PARABOLIC REFLECTOR ANTENNAS FOR S BAND

The satellite S-band downlinks have become very popular for a variety of reasons. Among the reasons are: good performance can be realized with a physically small downlink antenna and good quality down-converters and preamps are available at reasonable prices, as previously discussed. Increased operation on S band has long been advocated by a number of people including Bill McCaa, KØRZ, who led the team that designed and built the AO-13 S-band transponder² and James Miller, G3RUH, who operated one of the AO-40 command stations.³ Ed Krome, K9EK, and James Miller have published many articles detailing the construction of preamps, down-converters, and antennas for S band.^{4,5,6,7,8}

WØLMD notes that like a bulb in a flashlight, the parabolic reflector, or dish antenna must have a feed source looking into the surface of the dish. Some dishes are designed so that the feed source is mounted directly in front of the dish. This is referred to as a center-fed dish. Other dishes are designed so that the feed source is off to one side, referred to as an off-center fed dish, or just offset-fed dish. The offset-fed dish may be considered a section of a center-fed dish. The center-fed dish experiences some signal degradation due to blockage of the feed system, but this is usually an insignificantly small amount. The offset-fed dish is initially more difficult to aim, as the direction of reception is not the center axis like the center-fed dishes. The attitude of the offset dish is more likely to be vertical, making it less susceptible to loss from snow accumulation. Offset-fed dishes may have difficulty pointing horizontally for terrestrial communications. One enterprising ham, W4WSR, mounted his offset-fed PrimeStar dish upside down, which matched terrestrial pointing better. Older dishes tend to be center fed; newer dishes are offset fed.

The dish's parabola can be designed so

the focus point is closer to the surface of the dish, referred to as a "short focal length" dish, or further away from the dish's surface, referred to as a "long focal length" dish. To get the exact focal length, measure the diameter of the dish and the depth of the dish. The diameter squared divided by 16 times the depth is the focal length. The focal length divided by the diameter of the dish gives the *focal ratio*, commonly shown as *f/D*. Center-fed dishes are usually short focal ratios in 0.3 to 0.35 ranges. Offset-fed dishes are usually longer focal length such as 0.45 to 0.8. If you attach a couple of small mirrors (a couple of the YF's eye shadow mirrors when she isn't looking) to the outer front surface of a dish and then point the dish at the Sun, you will easily find the focus point of the dish. Put the reflector of the patch or helix just beyond this point of focus.

An alternate method for finding a dish's focal length is suggested by W1GHZ, and he provides that calculation on his Web site at: www.w1ghz.cx/10g/10g_home.htm. This method literally measures a solid-surface dish by the dimensions of the bowl of water that it will form when properly positioned.

While many of us enjoy building our own antennas, some of these microwave antennas are so small that they don't require a truck to transport them. Surplus market availability of these small dish antennas makes their construction unproductive. Many hams use the practices of AO-13 operators in using a surplus MMDS linear screen parabolic reflector antenna, **Fig 23.46**. These grid-dish antennas are often called "barbecue dishes". K5OE, **Fig 23.47**, and K5GNA, **Fig 23.48**, have been showing us how to greatly improve these linearly polarized reflectors by adapting them for the CP service. See the K5OE site: members.aol.com/k5oe/. The work shown us by these operators illustrate that simple methods can be used to "circularize" a linear dish and to

Fig 23.46—Another commercially available solution for S-band reception uses this TVRO antenna.

Fig 23.47—K5OE's mesh modification of a MMDS dish antenna with helix CP feed and DEM preamp.

Fig 23.48—K5GNA's "circularized" mesh modification of an MMDS dish antenna with helix CP feed and DEM preamp.

Fig 23.49—G3RUH’s 60-cm spun aluminum dish with CP patch feed, available as a kit.

Fig 23.50—PrimeStar offset-fed dish with WD4FAB’s helix-feed antenna. N0NSV was so pleased with the modification that he renamed the dish “FABStar,” and made a new label!

further add to its gain by using simple methods to increase the dish area and feed efficiency.

Some smaller dishes are constructed from solid aluminum or steel. **Fig 23.49** shows one such 60-cm spun aluminum dish that was designed by G3RUH and ON6UG. This kit, complete with a CP patch feed is available from SSB-USA and has a gain of 21 dBic and provides a 2.5-dB Sun noise signal. Sometimes fiberglass construction is used with a conductive coating, as shown in **Fig 23.50**. Some operators are using their large, 10-foot TVRO dishes for Amateur satellite service, although these types of antennas cannot easily be mounted on a tower to clear the nearby trees. These larger dishes are generally made from perforated steel or aluminum. Dishes with perforations slightly reduce the wind loading. If the perforations are made smaller than $\lambda/10$, the

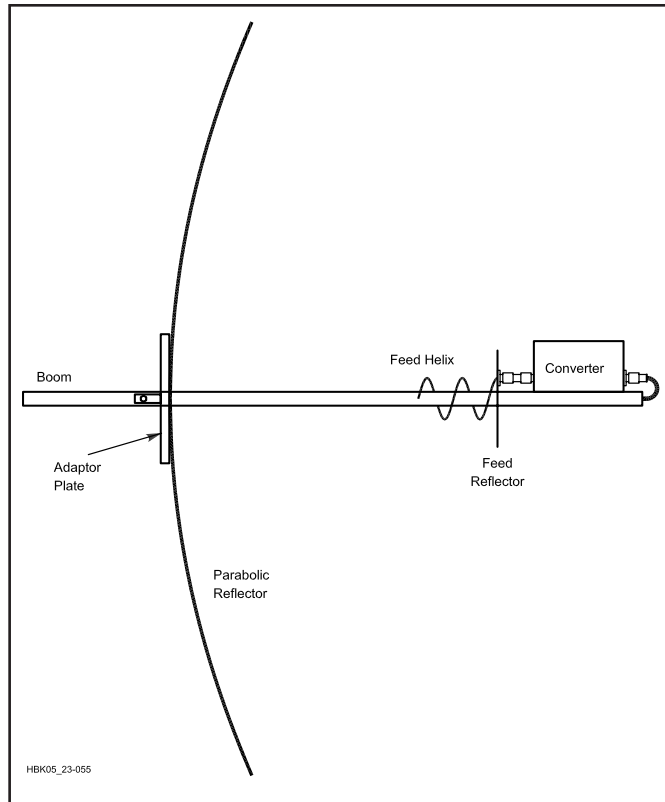

Fig 23.51—Detail of 60-cm S-band dish antenna with feed.

dish is equivalent to solid in terms of signal reflection. At 2401 MHz ($\lambda = 125$ mm), this is about 0.50 inch, making standard 0.25-inch fence mesh a good option for a dish surface with low wind loading.

In the USA, there are large numbers of dishes that can be obtained either free or at low cost. But in some parts of the world dishes are not so plentiful, so hams make their own. G3RUH shows us his example of creating a dish antenna, see **Fig 23.51**. There are three parts to the dish antenna—the parabolic reflector, the boom, and the feed. There are as many ways to accomplish the construction, as there are constructors. It is not necessary to slavishly replicate every nuance of the design. The only critical dimensions occur in the feed system. When the construction is complete, you will have a 60-cm diameter S-band dish antenna with a gain of about 20 dBi with RHCP and a 3-dB beamwidth of 18° . Coupled with the proper down-converter, performance will be more than adequate for S-band downlink.

DISH FEEDS

On www.ultimatecharger.com/, W0LMD describes that the feeding of a dish has two major factors that determine the efficiency. Like a flashlight bulb, the dish feed source should evenly illuminate the entire dish, and none of the feed energy

should spillover outside the dish’s reflecting surface. No feed system is perfect in illuminating a dish. Losses affect the gain from either under-illuminating or over-illuminating the dish (spillover losses). Typical dish efficiency is 50 percent. That’s 3 dB of lost gain. A great feed system for one dish can be a real lemon on another dish. A patch feed system is very wide angle, but a helix feed system is narrow angle. A short focal ratio center-fed dish requires a wide angle feed system to fully illuminate the dish, making the CP patch the preferred feed system. When used with an offset-fed dish, a patch-type feed system will result in a considerable spillover, or over-illumination loss, with an increased sensitivity to off-axis QRM, due to the higher f/D of this dish. Offset-fed dishes do much better when fed with a longer helix antenna.

A helix feed is simplicity personified. Mount a type N connector on a flat reflector plate and solder a couple of turns wire to the inner terminal. Designs are anywhere from two to six turns. The two-turn helices are used for very short focal length dishes in the $f/D = 0.3$ region, and the six-turn helices are used with longer focal length ($f/D \sim 0.6$) dishes, typically the offset-fed dishes. Since AO-40 is right circular and the dish reflection will reverse the polarity, the helix should be wound left circular, looking forward from the connector. Helix feeds

work poorly on the short focal length dishes but really perform well on the longer focal length offset-fed dishes.

A patch feed is almost as simple. It is typically a type N connector on a flat reflector plate with a tuned flat metal plate soldered to the inner terminal. Sometimes the flat plate is square; sometimes it is rectangular, sometimes round. It could have two feed points, 90° out of phase for circular polarization, as was used in the construction of the AO-40 U-band antennas. Some patches are made rectangular with clipped corners to add circularity. On 2401 MHz, the plate is about 2¼-inches square and spaced from ⅛ inch to ¼-inch away from the reflector. The point of attachment is about halfway between the

Fig 23.52—Details of CP patch feed for short f/D dish antennas by G3RUH and ON6UG.

center and the edge. A round patch for 2401 MHz is $\phi 2\frac{3}{8}$ inches. Patches work poorly on the longer focal length offset dishes, but do very well on the shorter focal length center-fed MMDS and TVRO dishes. A well studied CP patch feed for

these short f/D dishes is shown to us by G3RUH in Fig 23.53 and **Fig 23.52**.

For additional information on constructing antennas for use at microwave frequencies, see *The ARRL UHF/Microwave Experimenter's Manual*.

PARABOLIC DISH ANTENNA CONSTRUCTION

The following is a condensation of several articles written by G3RUH describing a dish antenna that can be easily built and used for reception of an S-band downlink. The dish itself was previously described, and the article continues:

The parabolic reflector used for the original antenna was intended to be a lampshade. Several of these aluminum reflectors were located in department store surplus. The dish is 585 mm in diameter and 110 mm deep corresponding to an f/D ratio of $585/110/16 = 0.33$ and a focal length of $0.33 \times 585 = 194$ mm. The f/D of 0.33 is a bit too concave for a simple feed to give optimal performance but the price was right, and the under-illumination keeps ground noise pickup to a minimum. The reflector already had a 40-mm hole in the center with three 4-mm holes around it in a 25-mm radius circle.

The boom passes through the center of the reflector and is made from 12.7-mm square aluminum tube. The boom must be long enough to provide for mounting to the rotator boom on the backside of the dish. The part of the boom extending through to the front of the dish must be long enough to mount the feed at the focus. If you choose to mount the down-converter or a preamp near the feed, some additional length will be necessary. Carefully check the requirements for your particular equipment.

A 3-mm thick piece of aluminum, 65 mm in diameter is used to support the boom at the center of the reflector. Once the center mounting plate is installed, the center boom is attached using four small angle brackets — two on each side of the reflector. See Fig 23.51 for details of reflector and boom assembly.

A small helix is used for the S-band antenna feed. The reflector for the helix is made from a 125-mm square piece of 1.6-mm thick aluminum. The center of the reflector has a 13-mm hole to accommodate the square center boom described above. The type N connector is mounted to the reflector about 21.25 mm from the middle. This distance from the middle is, of course, the radius of a helical antenna for S band. Mount the N connector with spacers so that the back of the connector is flush with the reflector surface. The helix feed assembly is shown in **Fig 23.53**.

Fig 23.53—Details of helix feed for S-band dish antennas. The Type N connector is fixed with three screws and is mounted on a 1.6-mm spacer to bring the PTFE molding flush with the reflector. An easier mounting can be using a smaller TNC connector. Reflectors should be 95-100 mm, circular. Dimensions are in mm, 1 inch = 25.4 mm.

Copper wire about 3.2 mm in diameter is used to wind the helix. Wind four turns around a 40-mm diameter form. The turns are wound counterclockwise. This is because the polarization sense is reversed from RHCP when reflected from the dish surface. The wire helix will spring out slightly when winding is complete.

Once the helix is wound, carefully stretch it so that the turns are spaced 28 mm (± 1 mm). Make sure the finished spacing of the turns is nice and even. Cut off the first half turn. Carefully bend the first quarter turn about 10° so it will be parallel to the reflector surface once the helix is attached to the N connector. This quarter turn will form part of the matching section.

Cut a strip of brass 0.2-mm thick and 6-mm wide matching the curvature of the first quarter turn of the helix by using a paper pattern. Be careful to get this pattern and subsequent brass cutting done exactly right. Using a large soldering iron and working on a heatproof surface, solder the brass strip to the first ¼ turn of the helix. Unless you are experienced at this type of soldering, getting the strip attached just right will require some practice. If it doesn't turn out right, just dismantle, wipe clean and try again.

After tack soldering the end of the helix to the type N connector, the first ¼ turn, with its brass strip in place, should be 1.2 mm above the reflector at its start (at the N connector) and 3.0 mm at its end. Be sure to line up the helix so its axis is perpendicular to the reflector. Cut off any extra turns to make the finished helix have 2¼ turns total. Once you are satisfied, apply a generous amount of solder at the

point the helix attaches to the N connector. Remember this is all that supports the helix.

Once the feed assembly is completed, pass the boom through the middle hole and complete the mounting by any suitable method. The middle of the helix should be

at the geometric focus of the dish. In the figures shown here, the feed is connected directly to the down-converter and then the down-converter is attached to the boom. You may require a slightly different configuration depending on whether you are attaching a down-converter,

preamp, or just a cable with connector. Angle brackets may be used to secure the feed to the boom in a manner similar to the boom-to-reflector mounting. Be sure to use some method of waterproofing if needed for your preamp and/or down-converter.

HELIX FEED FOR AN OFFSET DISH ANTENNA

The surplus PrimeStar offset fed dish antenna with its seven-turn helix feed antenna, Fig 23.50, is described in this section. When the feed antenna is directly coupled with a preamp/down-converter system, this antenna provides superb reception of S-band signals with the satellite transponder noise floor often being the noise-limiting factor in the downlink. This performance is as had been predicted by the W3PM spreadsheet analysis, Fig 23.54, and actual operating experience. Operating experience also demonstrates that this antenna can receive the Sun noise 5 dB above the sky noise. Don't try to receive the Sun noise with the antenna looking near the horizon, as terrestrial noise will be greater than 5 dB, at least in a big-city environment. The operator, N0NSV, who provided this dish was rewarded for his effort with a second feed antenna, and he in turn provided new labels for the dish, titling it "FABStar".

The reflector of this dish is a bit out of the ordinary, with a horizontal ellipse shape. It is still a single paraboloid that

was illuminated with an unusual feedhorn. At 2401 MHz we must be satisfied with a more conventional feed arrangement. A choice must be made to under-illuminate the sides of the dish while properly feeding the central section, or over-illuminating the center while properly feeding the sides. For the application shown here, the former choice was made. The W1GHZ water-bowl measurements showed this to be a dish with a focal point of $f = 500.6$ mm and requiring a feed for an $f/D = 0.79$. The total illumination angle of the feed is 69.8° in the vertical direction and a feedhorn with a 3-dB beamwidth of 40.3° . At 50 percent efficiency this antenna was calculated to provide a gain of 21.9 dBi. A seven-turn helix feed antenna was estimated to provide the needed characteristics for this dish and is shown in Fig 23.55.

The helix is basically constructed as described for the G3RUH parabolic dish, noted above. A matching section for the first $\lambda/4$ turn of the helix is spaced from the reflector at 2 mm at the start and 8 mm at the end of that fractional turn. Modifi-

cations of the design include the use of a cup reflector. For the reflector, a 2-mm thick circular plate is cut for a $\phi 94$ mm (0.75λ) with a thin aluminum sheet metal cup, formed with a depth of 47 mm. Employment of the cup enhances the performance of the reflector for a dish feed.

The important information for this seven-turn helix antenna is: Boom, 12.7 mm square tube or "C" channel; Element, $\phi 1/8$ -inch copper wire or tubing; Close wind element on a $\phi 1.50$ -inch tube or rod; Finished winding is $\phi 40$ mm spaced to a helical angle of 12.3° , or 28-mm spacing. These dimensions work out to have the element centerline to be of a cylindrical circumference of 1.0λ .

When WD4FAB tackled this antenna, he felt that the small amount of helical element support that James Miller used was inadequate, in view of the real life

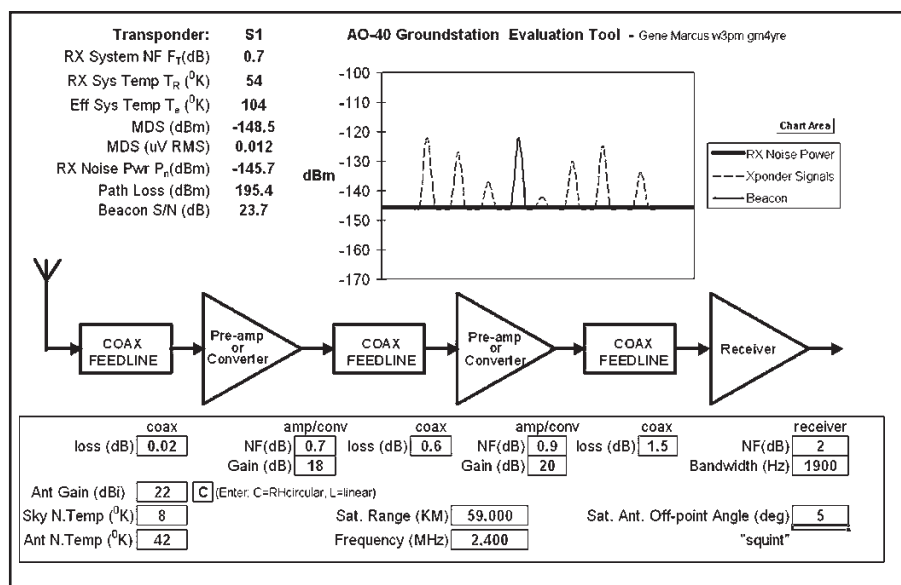

Fig 23.54—Screen display of W3PM's spreadsheet evaluation of ground station operation with AO-40.

Fig 23.55—Seven-turn LHCP helix dish feed antenna with DEM preamp.

Fig 23.56—Mounting details of seven-turn helix and preamp.

bird traffic on the antennas at his QTH. He chose to use PTFE (Teflon) support posts at every $\frac{1}{2}$ turn. This closer spacing of posts also permitted a careful control of the helix winding diameter and spacing making this antenna *very* robust. A fixture was set up on the drill press to uniformly predrill the holes for the element spacers and boom. Attachment of the reflector is through three very small aluminum angle brackets on the element side of the boom.

Mounting of the helix to the dish requires modification of the dish's receiver mounting boom. **Fig 23.56** shows these modifications using a machined mount. NM2A has constructed one of these antennas and shown that a machine shop is not needed for this construction. He has made a "Z" shaped mount from aluminum angle plate and then used a spacer from a block of acrylic sheet. The key here is to get the dish focal point at the 1.5-turn point of the feed antenna, which is also at about the lip of the reflector cup.

Fig 23.57—Rain cover for preamp using a two-liter soft-drink bottle with aluminum foil tape for protection from sun damage.

Fig 23.58—Welded pipe fitting mount bracket for FABStar dish antenna.

The W1GHZ data for this focal point is 500.6 mm from the bottom edge of the dish and 744.4 mm from the top edge. A two-string measurement of this point can confirm the focal point, all as shown by Wade in his writings. When mounting this feed antenna the constructor must be cautious to aim the feed at the *beam-center* of the dish, and not the geometric center, as the original microwave horn antenna were constructed. Taking the illumination angle information noted above, the helix feed antenna should be aimed 5.5° down from the geometric center of the dish.

As illustrated in Fig 23.56, a DEM preamp was directly mounted to the feed helix, using TNC connector that had been chosen for this case, as an N connector is quite large for the S-band helix. A male chassis mount connector should be mounted on either the preamp or the antenna so that the preamp can be directly connected to the antenna without any adaptors. This photo also illustrates how the reflector cup walls were riveted to the reflector plate. Exposed connectors must

be protected from rainwater. Commonly, materials such as messy Vinyl Mastic Pads (3M 2200) or Hand Moldable Plastic (Coax Seal) are used. Since this is a tight location for such mastic applications, a rain cover was made instead from a two-liter soft-drink bottle as shown in **Fig 23.57**. Properly cutting off the top of the bottle allows it to be slid over the helix reflector cup and secured with a large hose clamp. Sun-damage protection of the plastic bottle must be provided and that was done with a wrapping of aluminum foil pressure-sensitive-adhesive tape.

There are many methods for mounting this dish antenna to your elevation boom. Constructors must give consideration to the placement of the dish to reduce the wind loading and off-balance to the rotator system by this mounting. In the illustrated installation, the off-balance issue was not a major factor, but the dish was placed near the center of the elevation boom, between the pillow block bearing supports. As there is already sizeable aluminum plate for these bearings, the dish was located to "cover" part of that plate, so as to not add measurably to the existing wind-loading area of the overall assembly. A mounting bracket provided with the stock dish clamps to the end of a standard 2-inch pipe (actual measure: $\phi 2.38$ inch) stanchion. This bracket was turned around on the dish and clamped to the leg of a welded pipe Tee assembly, see **Fig 23.58**. Pipe reducing fittings were machined and fitted in the Tee top bar, which was cut in half for clamping over the $1\frac{1}{2}$ -inch pipe used for the elevation boom. Bolts were installed through drilled hole and used to clamp this assembly.

AN INTEGRATED DUAL-BAND ANTENNA SYSTEM

An effective system can be built starting with off-the-shelf components—the Teksharp 1.2-meter dish and AIDC-3731AA downconverter. These systems include not only antennas, but also high quality receiving converters, both of which are covered here.

Operators are finding an increased availability of components for their stations, providing them with a broad selection of the needed equipment.⁹ The products described here allow a single dish antenna to provide for the required dual-band operation, with an S-band (2.3 GHz) downlink and L-band (1.2 GHz) uplink.

A new company has surfaced on the amateur equipment horizon, Teksharp. Teksharp is providing kits for both 1.2- and 1.8-meter-diameter parabolic dish antennas. Additionally, S-band receiving converters are available from a number of different suppliers, including Teksharp. Here, Dick Jansson, WD4FAB, selected a well-proven converter, the modified AIDC-3731AA, from Bob Seydler, K5GNA. Bob takes commercial converters and modifies them for S-band amateur service, including an upgrade of the front-end band-pass filtering. This down-converter was selected for its superior and proven passband filtering, allowing an L-band transmitting uplink on the same antenna as the S-band downlink.

The antenna system described here includes the dish antenna, its dual-band feed system and the receiving converter. These three elements are critical for high quality communications. This antenna system was combined with a proven 40-W, tower mounted L-band amplifier, also described in this chapter, resulting in a fully functioning station.

THE TEKSHARP 1.2 METER DISH

The assembly methods are expected to be the same for the 1.8-meter dish. That larger antenna provides additional performance and flexibility, if desired. The gains for the 1.2-meter dish are 21.0 dBi at L-band, and 26.6 dBi at S-band.

For this project, the antenna arrived in a compact, 36×12×4 inch box of parts. **Fig 23.59** shows these parts laid out for assembly. A set of well machined and formed aluminum ribs is the key to any parabolic dish design and these are well executed. WD4FAB measured the dimensions of these ribs to understand the basic dimensional features of the dish. These figures are 1204 mm, 245 mm and 370 mm for diameter, depth and focus, respectively. Therefore, the resulting focus to diameter ratio (F/D) is 0.307.

Fig 23.59—The antenna parts as received from Teksharp.

Fig 23.60—A modified antenna base plate assembly. See the text for a description.

Separate plastic packages include the antenna assembly screws and the antenna mounting bolts. Teksharp also sent some well illustrated assembly instructions and a plastic template for the petals (or gores) for the hardware cloth covering the dish.

The included hex-head screws and nuts for the antenna assembly were high quality stainless steel. The U bolts and mast-mounting clamp hardware provided were also high quality, but the bolts and clamps were conventionally plated. It is useful to note that parts fabricated and finished in these materials can quickly corrode and become unusable in a humid climate. The machined parts for these antennas were very well made and finished, and they were a pleasure to work with.

Teksharp provides a well-suited bracket plate that supports the feed boom while also providing for the mounting of the dish to

the elevation boom. In the installation shown in **Fig 23.60** at WD4FAB, a modified mounting from a previous dish described elsewhere in this chapter was used. If your arrangement is more conventional, you may be able to make use of the Teksharp mounting hardware without modification.

Before starting the assembly, a copy of a rib shape was made in order to develop some cardboard templates representing the dish surface. A 602-mm circular radius template was also fabricated to aid the author in shaping the perimeter bands to dimension rather than by guess. The dish-surface template was used to check and maintain the parabolic shape of the dish surface as the mesh cloth petals were assembled to the ribs. These petals do not always follow the rib shape in the space between the ribs and the use of the template helped correct those surface inaccuracies while still under construction. The **Antennas** chapter of this *Handbook* and the *ARRL Antenna Book*¹⁰ provide excellent information on dish antenna construction methods.

Following the well-written Teksharp instructions, the ribs were assembled to the circular hub plate and the structure then closed with the formed perimeter bands. In the author's shop, he fashioned the ability to hold the framework in a shop vise, making the assembly task much easier. On one of the rib ends at the top of the dish, a nut was replaced with a riveted-in-place blind anchor nut to allow the coax cables to be clamped to the dish rim without having to simultaneously handle too much loose hardware while performing that step.

It is now time to create a parabolic dish

Fig 23.61—Dish antenna during assembly.

out of this strong and lightweight framework. The constructor must provide his own fabric cloth for this part of the assembly. The kit recommendations are to use ¼-inch galvanized cloth, a low cost item available at most hardware stores. The author had some eight-wires-per-inch aluminum cloth left over from a previous attempt to build a dish antenna. This was ideal, as galvanized material has a habit of eventually rusting away in a humid climate. Fig 23.61 shows the partially assembled dish in the author's shop.

ANTENNA FEED

Early dish antennas for these ranges used helical antennas as feeds. The experiences of other operators in the testing of AO-40 antennas has shown that low F/D parabolic antennas, such as this one, are most effectively fed using patch rather than helical antennas. (See the several articles by Jerry Brown, K5OE, at members.aol.com/k5oe/. Also see articles by Robert Suding, WØLMD, at www.ultimatecharger.com/dish.html.)

WØLMD provides some useful multi-band patch antennas that can be purchased for this service, as does Teksharp. The author decided to follow K5OE's guidance as recently published (see Fig 23.62).¹¹ The sharp-eyed reader may observe that WD4FAB made some modifications to the original patch design, through the addition of some nylon screws on the L-band patch. Please be advised to build this antenna exactly as in the original article unless you have some quality laboratory test equipment! Fortunately, WD4FAB had the use of a good network analyzer at the AMSAT Laboratory.

Fig 23.62—Details of the dual-band patch-feed system.

Fig 23.63—This photo shows the downconverter assembled to the rear of the feed assembly.

AIDC-3731AA S BAND DOWNCONVERTER

The next element of this system is the AIDC-3731AA downconverter from K5GNA. This converter offers one of the lower-cost approaches to receiving AO-40's 2401 MHz downlink signal. Fig 23.63 shows the converter mounted directly to the male Type N connector on the S-band patch antenna. The output port provides a 2-meter IF output through the F connector on the side.

This converter is now available with a low overhead internal voltage regulator, allowing it to be powered by a 13.8 V dc supply source and still obtain proper regulation of the 12 V dc needed for the internal circuits. There is a considerable advantage in using this regulation scheme as it keeps the total power dissipation low, thus holding down the temperature rise from the 2.5 W of power dissipation. There is interest in keeping this power dissipation low to minimize frequency shift due to temperature rise. Converters exposed to the sun will have noticeable frequency shifts with clouds shading the sun. This 13.8 V dc power is supplied to the converter through a bias T in the shack and RG-6 coaxial cable to the IF connector of the converter.

FEED ASSEMBLY

Following the directions in K5OE's article for the dual-band patch antenna, WD4FAB provided a mounting angle on the patch assembly using a piece of steel strapping angle. The author also machined an aluminum sleeve adapter for mounting between the J-shaped feed boom and this steel angle, as can be seen in Fig 23.63.

Glossary of Satellite Terminology

AMSAT—A registered trademark of the Radio Amateur Satellite Corporation, a nonprofit scientific/educational organization located in Washington, DC. It builds and operates Amateur Radio satellites and has sponsored the OSCAR program since the launch of OSCAR 5. (AMSAT, PO Box 27, Washington, DC 20044.)

Anomalistic period—The elapsed time between two successive perigees of a satellite.

AO-#—The designator used for AMSAT OSCAR spacecraft in flight, by sequence number.

AOS—Acquisition of signal. The time at which radio signals are first heard from a satellite, usually just after it rises above the horizon.

Apogee—The point in a satellite's orbit where it is farthest from Earth.

Area coordinators—An AMSAT corps of volunteers who organize and coordinate amateur satellite user activity in their particular state, municipality, region or country. This is the AMSAT grassroots organization set up to assist all current and prospective OSCAR users.

Argument of perigee—The polar angle that locates the perigee point of a satellite in the orbital plane; drawn between the ascending node, geocenter, and perigee; and measured from the ascending node in the direction of satellite motion.

Ascending node—The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Southern Hemisphere into the Northern Hemisphere.

Az-el mount—An antenna mount that allows antenna positioning in both the azimuth and elevation planes.

Azimuth—Direction (side-to-side in the horizontal plane) from a given point on Earth, usually expressed in degrees. North = 0° or 360°; East = 90°; South = 180°; West = 270°.

Circular polarization (CP)—A special case radio energy emission where the electric and magnetic field vectors rotate about the central axis of radiation. As viewed along the radiation path, the rotation directions are considered to be right-hand (RHCP) if the rotation is clockwise, and left-hand (LHCP) if the rotation is counterclockwise.

Descending node—The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Northern Hemisphere into the Southern Hemisphere.

Desense—A problem characteristic of many radio receivers in which a strong RF signal overloads the receiver, reducing sensitivity.

Doppler effect—An apparent shift in frequency caused by satellite movement toward or away from your location.

Downlink—The frequency on which radio signals originate from a satellite for reception by stations on Earth.

Earth station—A radio station, on or near the surface of the Earth, designed to transmit or receive to/from a spacecraft.

Eccentricity—The orbital parameter used to describe the

geometric shape of an elliptical orbit; eccentricity values vary from $e = 0$ to $e = 1$, where $e = 0$ describes a circle and $e = 1$ describes a straight line.

EIRP—Effective isotropic radiated power. Same as ERP except the antenna reference is an isotropic radiator.

Elliptical orbit—Those orbits in which the satellite path describes an ellipse with the Earth at one focus.

Elevation—Angle above the local horizontal plane, usually specified in degrees. (0° = plane of the Earth's surface at your location; 90° = straight up, perpendicular to the plane of the Earth).

Epoch—The reference time at which a particular set of parameters describing satellite motion (**Keplerian elements**) are defined.

EQX—The reference equator crossing of the ascending node of a satellite orbit, usually specified in UTC and degrees of longitude of the crossing.

ERP—Effective radiated power. System power output after transmission-line losses and antenna gain (referred to a dipole) are considered.

ESA—European Space Agency. A consortium of European governmental groups pooling resources for space exploration and development.

FO-#—The designator used for Japanese amateur satellites, by sequence number. Fuji-OSCAR 12 and Fuji-OSCAR 20 were the first two such spacecraft.

Geocenter—The center of the Earth.

Geostationary orbit—A satellite orbit at such an altitude (approximately 22,300 miles) over the equator that the satellite appears to be fixed above a given point.

Groundtrack—The imaginary line traced on the surface of the Earth by the subsatellite point (SSP).

Inclination—The angle between the orbital plane of a satellite and the equatorial plane of the Earth.

Increment—The change in longitude of ascending node between two successive passes of a specified satellite, measured in degrees West per orbit.

Iskra—Soviet low-orbit satellites launched manually by cosmonauts aboard Salyut missions. Iskra means "spark" in Russian.

JAMSAT—Japan AMSAT organization.

Keplerian Elements—The classical set of six orbital element numbers used to define and compute satellite orbital motions. The set is comprised of inclination, Right Ascension of Ascending Node (RAAN), eccentricity, argument of perigee, mean anomaly and mean motion, all specified at a particular epoch or reference year, day and time. Additionally, a decay rate or drag factor is usually included to refine the computation.

LEO—Low Earth Orbit satellite such as the Phase 1 and Phase 2 OSCARs.

LHCP—Left-hand circular polarization.

LOS—Loss of signal—The time when a satellite passes out of range and signals from it can no longer

This angle also provided an added support for the AIDC-3731AA converter, shown strapped down with a plastic cable tie. As assembled, this is a robust feed assembly.

Mounting of the patch assembly was done with the patches aligned parallel to the plane of the dish and on the dish center line. Place the S-band reflector at the focal

distance, 370 mm (14.57 inches), from the dish surface at the center. This adjustment is made by moving the feed boom along its mounting clamps until the proper measurement is achieved. That is all you have to do. You can play with mirrors, as in the instructions, to focus the sun on the patches, but doing this adjustment by mea-

surement is easier and it is all that really needs to be done.

K5OE cautions that rain, bird droppings and bugs can mess up the tuning and operation of the patch feed antennas. He advises the use of some kind of protection for antennas. In addition, the author has an aversion to having water in hard-to-reach

be heard. This usually occurs just after the satellite goes below the horizon.

Mean anomaly (MA) — An angle that increases uniformly with time, starting at perigee, used to indicate where a satellite is located along its orbit. MA is usually specified at the reference epoch time where the Keplerian elements are defined. For AO-10 the orbital time is divided into 256 parts, rather than degrees of a circle, and MA (sometimes called phase) is specified from 0 to 255.

Perigee is therefore at MA = 0 with apogee at MA = 128.

Mean motion — The Keplerian element to indicate the complete number of orbits a satellite makes in a day.

Microsat — Collective name given to a series of small amateur satellites having store-and-forward capability (OSCARs 14-19, for example).

Molniya — Type of elliptical orbit, first used in the Russian Molniya series, that features a ground track that more or less repeats on a daily basis.

NASA — National Aeronautics and Space Administration, the US space agency.

Nodal period — The amount of time between two successive ascending nodes of satellite orbit.

Orbital elements — See *Keplerian Elements*.

Orbital plane — An imaginary plane, extending throughout space, that contains the satellite orbit.

OSCAR — Orbiting Satellite Carrying Amateur Radio.

PACSAT — Packet radio satellite (see *Microsat* and *UoSAT-OSCAR*).

Pass — An orbit of a satellite.

Passband — The range of frequencies handled by a satellite translator or transponder.

Perigee — The point in a satellite's orbit where it is closest to Earth.

Period — The time required for a satellite to make one complete revolution about the Earth. See *Anomalistic period* and *Nodal period*.

Phase 1 — The term given to the earliest, short-lived, low Earth orbit (LEO) OSCAR satellites that were not equipped with solar cells. When their batteries were depleted, they ceased operating.

Phase 2 — LEO OSCAR satellites. Equipped with solar panels that powered the spacecraft systems and recharged their batteries, these satellites have been shown to be capable of lasting up to five years (OSCARs 6, 7 and 8, for example).

Phase 3 — Extended-range, high-elliptical-orbit OSCAR satellites with very long-lived solar power systems (OSCARs 10 and 40, for example).

Phase 4 — Proposed OSCAR satellites in geostationary orbits.

Polar Orbit — A low, circular orbit inclined so that it passes over the Earth's poles.

Precession — An effect that is characteristic of AO-10 and AO-40 orbits. The satellite apogee SSP will gradually change over time.

Project OSCAR — The California-based group, among the first to recognize the potential of space for Amateur Radio; responsible for OSCARs I through IV.

QRP days — Special orbits set aside for very low power uplink operating through the satellites.

RAAN — Right Ascension of Ascending Node. The Keplerian element specifying the angular distance, measured eastward along the celestial equator, between the vernal equinox and the hour circle of the ascending node of a spacecraft. This can be simplified to mean roughly the longitude of the ascending node.

Radio Sputnik — Russian Amateur Radio satellites (see *RS #*).

Reference orbit — The orbit of Phase II satellites beginning with the first ascending node during that UTC day.

RHCP — Right-hand circular polarization.

RS # — The designator used for most Russian Amateur Radio satellites (RS-1 through RS-15, for example).

Satellite pass — Segment of orbit during which the satellite "passes" nearby and in range of a particular ground station.

Sidereal day — The amount of time required for the Earth to rotate exactly 360° about its axis with respect to the "fixed" stars. The sidereal day contains 1436.07 minutes (see *Solar day*).

Solar day — The solar day, by definition, contains exactly 24 hours (1440 minutes). During the solar day the Earth rotates slightly more than 360° about its axis with respect to "fixed" stars (see *Sidereal day*).

Spin modulation — Periodic amplitude fade-and-peak resulting from the rotation of a satellite's antennas about its spin axis, rotating the antenna peaks and nulls.

SSP — Subsatellite point. Point on the surface of the Earth directly between the satellite and the geocenter.

Telemetry — Radio signals, originating at a satellite, that convey information on the performance or status of onboard subsystems. Also refers to the information itself.

Transponder — A device onboard a satellite that receives radio signals in one segment of the spectrum, amplifies them, translates (shifts) their frequency to another segment of the spectrum and retransmits them. Also called linear translator.

UoSAT-OSCAR (UO #) — Amateur Radio satellites built under the coordination of radio amateurs and educators at the University of Surrey, England.

Uplink — The frequency at which signals are transmitted from ground stations to a satellite.

Visibility Circle — The range of area on the Earth that are "seen" by a satellite. This is also called the "footprint" for that satellite.

Window — Overlap region between acquisition circles of two ground stations referenced to a specific satellite. Communication between two stations is possible when the subsatellite point is within the window.

coaxial connectors. Water in these connectors does not ensure a good satellite signal! To solve both of these problems, WD4FAB went shopping for an antenna cover at his favorite "antenna parts store," K-Mart. He found help from Martha Stewart, no less, in the form of a nice, clear styrene plastic "3.3 quart airtight canister."

One of these canisters was modified to fit over the patch assembly and the feed boom. This canister was also shortened to allow it to fit into the cover lip of an unmodified canister mounted on the "rear" of the feed. The modified canister was mounted to the patch reflector with three small angle brackets, as seen in Fig 23.63.

Some of the cutoff plastic cylinder should be saved. This can then be glued to the end of the cutoff container, to shim that OD to fit into the inside diameter of the cover lip of the rear canister. The author also epoxy-bonded a set of blind nuts to the inside of the canister so that the screws through the cover lip of the rear-mounted canister will

Fig 23.64—The 3.3-quart plastic canister converted for use as a radome at the feedpoint.

keep it together. That arrangement is shown in **Fig 23.64**. The slot in the front canister that passes the feed boom has space for the coaxial cables for L and S band. A further protection measure was to cover the exposed plastic with aluminum foil tape, as seen in **Fig 23.64**. This was not done to area in front of the patch antennas. This tape is there to protect the plastic from sun damage, although this type of clear plastic has a good record in avoiding UV harm.

INSTALLATION

With all preparations made, completion of the installation of the dish antenna and converter was a breeze. **Fig 23.65** shows the dish assembly bolted to the author's old PrimeStar antenna mount. Just remember to use the built-in screw adjustment provided in the PrimeStar mount to aim the dish centerline along the centerline of your antenna pointing system. The beamwidths of L- and S-band operations in this assembly are fairly narrow, so your pointing precision will need to be pretty good. Many of the details of the WD4FAB elevation boom system are shown in **Fig 23.65** as well.

Before finally closing the protective plastic containers over the feed antennas, be sure that all of the coaxial cable connections are tight and the cables are dressed properly. This final closure will need to be done at this step in the assembly. Be sure to arrange the coaxial cables so that they don't drag on the feed boom. The cable clamps at the top of the dish are there to dress the cables and support the feed boom. This is shown in **Fig 23.66**.

Fig 23.66 also shows the dish system in operating position along with the U-band (70 cm) cross-polarized (CP) Yagi antenna on the far left, and the two smaller M2 23CM22EZA antennas

that were tested previously. The author has kept these two L-band antennas in service for use on 1296 MHz. He placed a ground-commanded relay to switch between the two antenna systems in the amplifier box on the top of the tower. This is also convenient to use to compare the two L-band antenna systems.

ON THE AIR

This configuration was tested with the AO-40 satellite (which is no longer operational at the time of this writing). Tests showed that AO-40 downlink signals on S band, 2401 MHz, were really solid with this system. The pointing requirements were narrow, and had to be good to within 3° to 4°, based on the specified beam width at these frequencies. The noise floor of AO-40 was clearly detectable, about 2 dB above cold sky noise.

For the uplink, WD4FAB had a usable return signal with 40 W of RF on L band when the satellite "squint" was 20° or lower, as reported in note 10. When the squint is low, good downlink signals were realized with only about 5-10 W PEP of L-band power. When the author compared the Teksharp antenna on L band to the M2 23CM22EZA stacked antennas, as shown in **Fig 23.66**, he saw better than an S-unit (>3-4 dB on his Kenwood TS-2000 transceiver) improvement in downlink signal. This improved performance was seen in the wider ranges of squint angles that can be used with the Teksharp antenna on the L-band uplink. When the AO-40 squint angles were greater than 20°, he still had to use his U-band uplink transmitter with the CP Yagi antenna.

Measurements of Sun noise have been attempted with this antenna system. These have been disappointing, with values of around 2 dB seen. This is compared to the

solid 5 dB of Sun noise measured with the WD4FAB previous PrimeStar dish. One of the probable reasons for the lowered performance can be attributed to the front-end band-pass filtering provided in the receive converter. The operating experience with this system has been absolutely solid, however.

IN SUMMARY

It is important to consider all of the interrelated characteristics of an antenna system. It is insufficient to just whip up "any" antenna, marry "any" receive converter to that antenna and then use "any" transmitting scheme to operate with full-duplex signals from high-performance satellites. We've had the ability to employ computer analysis, as shown to us by Gene Marcus, W3PM, with his spreadsheet analysis: www.amsat.org/amsat/ftp/software/spreadsheet/w3pm-ao40-v2.1.zip.

Manufacturers: Antenna: Teksharp (Rick Fletcher, KG6IAL), www.teksharp.com, 5770 McKellar Dr, San Jose, CA 95129; inquiries@teksharp.com; Price: 1.2 meter dish, \$165; feed boom, \$40; dual-band (S/L) patch feed, \$200. Downconverter Bob Seydler, K5GNA, members.aol.com/k5gna/myhomepage/, 8522 Rebawood, Humble, TX 77346-1789; 281-852-0252, bob@k5gna.com. Price: \$100, setup for 12 V operation add \$20.

JUST THE BEGINNING

This section barely nicks the surface of satellite operating. There is much more to learn and enjoy. It is suggested that you spend some time at the AMSAT Web site. You'll pick up a wealth of information there. Speaking of "picking up," grab a copy of the *ARRL Radio Amateur's Satellite Handbook* and the *ARRL Antenna Book* (see your favorite dealer, or buy it on *ARRLWeb*). Between these two resources you'll be able to tap just about all the amateur satellite knowledge you're likely to need.

In the meantime, see you in orbit!

Earth-Moon-Earth (EME)

EME communication, also known as "moonbounce," has become a popular form of space communication. The concept is simple: The moon is used as a passive reflector for VHF and UHF signals. With a total path length of nearly 500,000 miles, EME is the ultimate DX. EME is a natural and passive propagation phenomenon, and EME QSOs count toward the WAS, DXCC and VUCC awards. EME opens up the VHF and UHF bands to a new universe of worldwide DX.

The first demonstration of EME capability was done by the US Army Signal Corps just after WW II. In the 1950s, using 400 MW of effective radiated power, the US Navy established a moon relay link between Washington, DC, and Hawaii that

could handle four multiplexed Teletype (RTTY) channels. The first successful amateur reception of EME signals occurred in 1953 by W4AO and W3GKP.

It took until 1960 for two-way amateur communications to take place. Using surplus parabolic dish antennas and high-power klystron amplifiers, the Eimac Radio Club, W6HB, and the Rhododendron Swamp VHF Society, W1BU, accomplished this milestone in July 1960 on 1296 MHz. In the 1960s, the first wave of amateur EME enthusiasts established amateur-to-amateur contacts on 144 MHz and 432 MHz. In April 1964, W6DNG and OH1NL made the first 144-MHz EME QSO. 432-MHz EME experimentation was delayed by the 50-W power limit (removed January 2, 1963). Only one

month after the first 144-MHz QSO was made, the 1000-ft-diameter dish at Arecibo, Puerto Rico, was used to demonstrate the viability of 432-MHz EME, when a contact was made between KP4BPZ and W1BU. The first amateur-to-amateur 432-MHz EME QSO occurred in July 1964 between W1BU and KH6UK.

The widespread availability of reliable low-noise semiconductor devices along with significant improvements in Yagi arrays ushered in the second wave of amateur activity in the 1970s. Contacts between stations entirely built by amateurs became the norm instead of the exception. In 1970, the first 220- and 2304-MHz EME QSOs were made, followed by the first 50-MHz EME QSO in 1972.

Fig 23.67—Tommy Henderson, WD5AGO, pursues 144-MHz EME from his Tulsa, Oklahoma, QTH with this array. Local electronics students helped with construction.

Fig 23.68—Variations in EME path loss can be determined from this graph. SD refers to semi-diameter of the moon, which is indicated for each day of the year in *The Nautical Almanac*.

1970s activity was still concentrated on 144 and 432 MHz, although 1296-MHz activity grew.

As the 1980s approached, another quantum leap in receive performance occurred with the use of GaAsFET preamplifiers. This, and improvements in Yagi performance (led by DL6WU's log-taper design work), and the new US amateur power output limit of 1500 W have put EME in the grasp of most serious VHF and UHF operators. The 1980s saw 144- and 432-MHz WAS and WAC become a reality for a great number of operators. The 1980s also witnessed the first EME QSOs on 3456 MHz and 5760 MHz (1987),

followed by EME QSOs on 902 MHz and 10 GHz (1988).

EME is still primarily a CW mode. As stations have improved, SSB is now more popular. Regardless of the transmission mode, successful EME operating requires:

- 1) As close to the legal power output as possible.
- 2) A fairly large array (compared to OSCAR antennas).
- 3) Accurate azimuth and elevation rotation.
- 4) Minimal transmission-line losses.
- 5) A low system noise figure, preferably with the preamplifier mounted at the array.

CHOOSING AN EME BAND

Making EME QSOs is a natural progression for many weak-signal terrestrial operators. Looking at EME path loss vs frequency (**Fig 23.68**), it may seem as if the lowest frequency is best, because of reduced path loss. This is not entirely true. The path-loss graph does not account for the effects of cosmic and man-made noise, nor does it relate the effects of ionospheric scattering and absorption. Both short- and long-term fading effects also must be overcome.

50-MHz EME is quite a challenge, as the required arrays are very large. In addition, sky noise limits receiver sensitivity at this frequency. Because of power and licensing restrictions, it is not likely that many foreign countries will be able to get on 50-MHz EME.

144 MHz is probably the easiest EME band to start on. It supports the largest number of EME operators. Commercial equipment is widely available; a 144-MHz EME station can almost be completely assembled from off-the-shelf equipment. 222 MHz is a good frequency for EME, but there are only a handful of active stations, and 222 MHz is available only in ITU Region 2.

432 MHz is the most active EME band after 144 MHz. Libration fading is more of a problem than at 144 MHz, but sky noise is more than an order of magnitude less than on 144 MHz. The improved receive signal-to-noise ratio may more than make up for the more rapid fading. However, 432-MHz activity is most concentrated into the one or two weekends a month when conditions are expected to be best.

902 MHz and above should be considered if you primarily enjoy experimenting and building equipment. If you plan to operate at these frequencies, an unobstructed moon window is a must. The antenna used is almost certain to be a dish. 902 MHz has the same problem that 222 MHz has — it's not an international band. Equipment and activity are expected to be limited for many years.

1296 MHz currently has a good amount of activity from all over the world. Recent equipment improvements indicate 1296 MHz should experience a significant growth in activity over the next few years. 2300 MHz has received renewed interest. It suffers from nonaligned international band assignments and restrictions in different parts of the world.

ANTENNA REQUIREMENTS

The tremendous path loss incurred over the EME circuit requires a high-power transmitter, a low-noise receiver and a high-performance antenna array. Al-

though single-Yagi QSOs are possible, most new EME operators will rapidly become frustrated unless they are able to work many different stations on a regular basis. Because of libration fading and the nature of weak signals, a 1- or 2-dB increase in array gain will often be perceived as being much greater. An important antenna parameter in EME communications is the antenna noise temperature. This refers to the amount of noise received by the array. The noise comes from cosmic noise (noise generated by stars other than the sun), Earth noise (thermal noise radiated by the Earth), and noise generated by man-made sources such as power-line leaks and other broadband RF sources.

Yagi antennas are almost universally used on 144 MHz. Although dish antennas as small as 24 ft in diameter have been successfully used, they offer poor gain-to size trade-offs at 144 MHz. The minimum array gain for reliable operation is about 18 dBd (20.1 dBi). The minimum array gain should also allow a station to hear its own echoes on a regular basis. This is possible by using four 2.2- λ Yagis. The 12-element 2.5- λ Yagi described in the **Antennas** chapter is an excellent choice. When considering a Yagi design, you should avoid old-technology Yagis, that is, designs that use either constant-width spacings, constant-length directors or a combination of both. These old-design Yagis will have significantly poorer side lobes, a narrower gain bandwidth and a sharper SWR bandwidth than modern log-taper designs. Modern wideband designs will behave much more predictably when stacked in arrays, and, unlike many of the older designs, will deliver close to 3 dB of stacking gain.

222-MHz requirements are similar to those of 144 MHz. Although dish antennas are somewhat more practical, Yagis still predominate. The 16-element 3.8- λ Yagi described in the **Antennas** chapter is a good building block for 222-MHz EME. Four of these Yagis are adequate for a minimal 222-MHz EME station, but six or eight will provide a much more substantial signal.

At 432 MHz, parabolic-dish antennas become viable. The minimum gain for reliable 432-MHz EME operation is 24 dBi.

Yagis are also used on 432 MHz. The 22-element Yagi described in the **Antennas** chapter is an ideal 432-MHz design. Four of the 22-element Yagis meet the 24-dBi-gain criteria, and have been used successfully on EME. If you are going to use a fixed polarization Yagi array, you should plan on building an array with substantially more than 24-dBi gain if you

desire reliable contacts with small stations. This extra gain is needed to overcome polarization misalignment.

At 902 MHz and above, the only antenna worthy of consideration is a parabolic dish. While it has been proven that Yagi antennas are capable of making EME QSOs at 1296 MHz, Yagi antennas, whether they use rod or loop elements, are simply not practical.

EME QSOs have been made at 1296 MHz with dishes as small as 6 ft in diameter. For reliable EME operation with similarly equipped stations, a 12-ft diameter dish (31 dBi gain at 1296 MHz) is a practical minimum. TVRO dishes, which are designed to operate at 3 GHz make excellent antennas, provided they have an accurate surface area. The one drawback of TVRO dishes is that they usually have an undesirable F/d ratio. More information on dish construction and feeds can be found in *The ARRL Antenna Book* and *The ARRL UHF/Microwave Experimenter's Manual*.

POLARIZATION EFFECTS

All of the close attention paid to operating at the best time, such as nighttime perigee, with high moon declination and low sky temperatures is of little use if signals are not aligned in polarization between the two stations attempting to make contact. There are two basic polarization effects. The first is called spatial polarization. Simply stated, two stations (using az-el mounts and fixed linear polarization) that are located far apart, will usually not have their arrays aligned in polarization as seen by the moon. Spatial polarization can easily be predicted, given the location of both stations and the position of the moon.

The second effect is Faraday rotation. This is an actual rotation of the radio waves in space, and is caused by the charge level of the Earth's ionosphere. At 1296 MHz and above, Faraday rotation is virtually nonexistent. At 432 MHz, it is believed that up to a 360° rotation is common. At 144 MHz, it is believed that the wavefront can actually rotate seven or more complete 360° revolutions. When Faraday rotation is combined with spatial polarization, there are four possible results:

- 1) Both stations hear each other and can QSO.
- 2) Station A hears station B, station B does not hear station A.
- 3) Station B hears station A, station A does not hear station B.
- 4) Neither station A nor station B hear each other.

At 144 MHz, there are so many revolutions of the signal, and the amount of Faraday rotation changes so fast that,

generally, hour-long schedules are arranged. At 432 MHz, Faraday rotation can take hours to change. Because of this, half-hour schedules are used. During the daytime, you can count on 90 to 180° of rotation. If both stations are operating during hours of darkness, there will be little Faraday rotation, and the amount of spatial polarization determines if a schedule should be attempted.

At 1296 MHz and above, circular polarization is standard. The predominant array is a parabolic reflector, which makes circular polarization easy to obtain. Although the use of circular polarization would make one expect signals to be constant, except for the effect of the moon's distance, long-term fading of 6 to 9 dB is frequently observed.

With improved long-Yagi designs, for years the solution to overcoming polarization misalignment has been to make the array larger. Making your station's system gain 5 or 6 dB greater than required for minimal EME QSOs will allow you to work more stations, simply by moving you farther down the polarization loss curve. After about 60° of misalignment, however, making your station large enough to overcome the added losses quickly becomes a lifetime project! See **Fig 23.69**.

At 432 MHz and lower, Yagis are widely used, making the linear polarization standard. Although circular polarization may seem like a simple solution to polarization problems, when signals are reflected off the moon, the polarization sense of circularly polarized radio wave is reversed, requiring two arrays of opposite polarization sense be used. Initially, crossed Yagis with switchable polarization may also look attractive. Unfortunately, 432-MHz Yagis are physically small enough that the extra feed lines and switching devices become complicated, and usually adversely affect array performance. Keep in mind that even at 144 MHz, Yagis cannot tolerate metal mounting masts and frames in line with the Yagi elements.

When starting out on EME, keep in mind that it is best to use a simple system. You will still be able to work many of the larger fixed-polarization stations and those who have polarization adjustment (only one station needs to have polarization control). Once you gain understanding and confidence in your simple array, a more complex array such as one with polarization rotation can be attempted.

RECEIVER REQUIREMENTS

A low-noise receiving setup is essential for successful EME work. Many EME signals are barely, but not always, out of the

noise. To determine actual receiver performance, any phasing line and feed line losses, along with the noise generated in the receiver, must be added to the array noise reception. When all losses are considered, a system noise figure of 0.5 dB (35 K) will deliver about all the performance that can be used at 144 MHz, even when low-loss phasing lines and a quiet array are used.

The sky noise at 432 MHz and above is low enough (cold sky is <15 K (kelvins) at 432 MHz, and 5 K at 1296 MHz) so the lowest possible noise figure is desired. Current high-performance arrays will have array temperatures near 30 K when unwanted noise pickup is added in. Phasing line losses must also be included, along with any relay losses. Even at 432 MHz, it is impossible to make receiver noise insignificant without the use of a liquid-cooled preamplifier. Current technology gives a minimum obtainable GaAsFET preamplifier noise figure, at room temperature, of about 0.35 dB (24 K).

GaAsFET preamps have also been standard on 1296 MHz and above for several years. Noise figures range from about 0.4 dB at 1296 MHz (30 K) to about 2 dB (170 K at 10 GHz). HEMT devices are now available to amateurs, but are of little use below 902 MHz because of 1/f noise. At higher frequencies, HEMT devices have already shown impressively low noise figures. Current HEMT devices are capable of noise figures close to 1.2 dB at 10 GHz (93 K) without liquid cooling.

At 1296 MHz, a new noise-limiting factor appears. The physical temperature of the moon is 210 K. This means that just like the Earth, it is a black-body radiator. The additional noise source is the reflec-

tion of sun noise off the moon. Just as a full moon reflects sunlight to Earth, the rest of the electromagnetic spectrum is also reflected. On 144 and 432 MHz, the beamwidth of a typical array is wide enough (15° is typical for 144 MHz, 7° for 432 MHz) that the moon, which subtends a 0.5° area is small enough to be insignificant in the array's pattern. At 1296 MHz, beamwidths approach 2°, and moon-noise figures of up to 5 dB are typical at full moon. Stations operating at 2300 MHz and above have such narrow array patterns that many operators actually use moon noise to assure that their arrays are pointed at the moon!

A new weak-signal operator is encouraged to experiment with receivers and filters. A radio with passband tuning or IF-shift capability is desired. These features are used to center the passband and the pitch of the CW signal to the frequency at which the operator's ears perform best. Some operators also use audio filtering. Audio filtering is effective in eliminating high-frequency noise generated in the radio's audio or IF stages. This noise can be very fatiguing during extended weak signal operation. The switched-capacitor audio filter has become popular with many operators.

TRANSMITTER REQUIREMENTS

Although the maximum legal power

Table 23.4

Transmitter Power Required for EME Success

Power at the array

50 MHz	1500 W
144 MHz	1000 W
222 MHz	750 W
432 MHz	500 W
902 MHz	200 W
1296 MHz	200 W
2300 MHz and above	100 W

(1500 W out) is desirable, the actual power required can be considerably less, depending on the frequency of operation and size of the array. Given the minimum array gain requirements previously discussed, the power levels recommended for reasonable success are shown in **Table 23.4**

The amplifier and power supply should be constructed with adequate cooling and safety margins to allow extended slow-speed CW operation without failure. The transmitter must also be free from drift and chirp. The CW note must be pure and properly shaped. Signals that drift and chirp are harder to copy. They are especially annoying to operators who use narrow CW filters. A stable, clean signal will improve your EME success rate.

Fig 23.69—The graph shows how quickly loss because of polarization misalignment increases after 45°. The curve repeats through 360°, showing no loss at 0° and maximum loss at 90° and 270°.

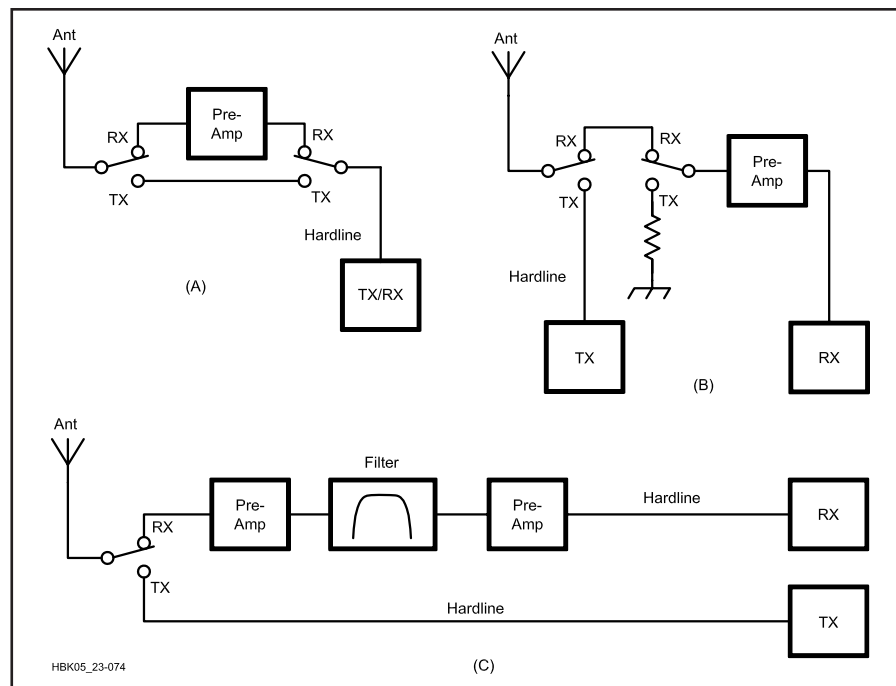

Fig 23.70—Two systems for switching a preamplifier in and out of the receive line. At A, a single length of cable is used for both the transmit and receive line. At B is a slightly more sophisticated system that uses two separate transmission lines. At C, a high-isolation relay is used for TR switching. The energized position is normally used on receive.

CALCULATING EME CAPABILITIES

Once all station parameters are known, the expected strength of the moon echoes can be calculated given the path loss for the band in use (see Fig 23.72). The formula for the received signal-to-noise ratio is:

$$S / N = P_o - L_t + G_t - P_l + G_r - P_n \quad (1)$$

where

- P_o = transmitter output power (dBW)
- L_t = transmitter feed-line loss (dB)
- G_t = transmitting antenna gain (dBi)
- P_l = total path loss (dB)
- G_r = receiving antenna gain (dBi)
- P_n = receiver noise power (dBW).

Receiver noise power, P_n , is determined by the following:

$$P_n = 10 \log_{10} KBT_s \quad (2)$$

where

- $K = 1.38 \times 10^{-23}$ (Boltzmann's constant)
- B = bandwidth (Hz)
- T_s = receiving system noise temperature (K).

Receiving system noise temperature, T_s , can be found from:

$$T_s = T_a + (L_r - 1) T_l + L_r T_r \quad (3)$$

where

- T_a = antenna temperature (K)
- L_r = receiving feed-line loss (ratio)
- T_l = physical temperature of feed line (normally 290 K)
- T_r = receiver noise temperature (K).

An example calculation for a typical 432-MHz EME link is:

- $P_o = +30$ dBW (1000 W)
- $L_t = 1.0$ dB
- $G_t = 26.4$ dBi ($8 \times 6.1\text{-}\lambda$ 22-el Yagis)
- $P_l = 262$ dB
- $G_r = 23.5$ dBi (15 ft parabolic)
- $T_a = 60$ K
- $L_r = 1.02$ (0.1-dB preamp at antenna)
- $T_l = 290$ K
- $T_r = 35.4$ K (NT = 0.5 dB)
- $T_s = 101.9$ K
- $P_n = -188.5$ dB
- $S/N = + 5.4$ dB

It is obvious that EME is no place for a compromise station. Even relatively sophisticated equipment provides less-than-optimum results.

Fig 23.71 gives parabolic dish gain for a perfect dish. The best Yagi antennas will not exceed the gain curve shown in the

Antennas chapter. If you are using modern, log-taper Yagis, properly spaced, figure about 2.8 to 2.9 dB of stacking gain. For old-technology Yagis, 2.5 dB may be closer to reality. Any phasing line and power divider losses must also be subtracted from the array gain.

LOCATING THE MOON

The moon orbits the Earth once in approximately 28 days, a lunar month. Because the plane of the moon's orbit is tilted from the Earth's equatorial plane by approximately 23.5° , the moon swings in a sine-wave pattern both north and south of the equator. The angle of departure of the moon's position at a given time from the equatorial plane is termed declination (abbreviated decl). Declination angles of the moon, which are continually changing (a few degrees a day), indicate the latitude on the Earth's surface where the moon will be at zenith. For this presentation, positive declination angles are used when the moon is north of the equator, and negative angles when south.

The longitude on the Earth's surface where the moon will be at zenith is related to the moon's Greenwich Hour Angle, abbreviated G.H.A. or GHA. "Hour angle" is defined as the angle in degrees to the west of the meridian. If the GHA of the moon were 0° , it would be directly over the Greenwich meridian. If the moon's GHA were 15° , the moon would be directly over the meridian designated as 15° W longitude on a globe. As one can readily understand, the GHA of the moon is continually changing, too, because of both the orbital velocity of the moon and the Earth's rotation inside the moon's orbit. The moon's GHA changes at the rate of approximately 347° per day.

GHA and declination are terms that may be applied to any celestial body. *The Astronomical Almanac* (available from the Superintendent of Documents, US Government Printing Office) and other publications list the GHA and decl of the sun and moon (as well as for other celestial bodies that may be used for navigation) for every hour of the year. This information may be used to point an antenna when the moon is not visible. *Almanac* tables for the sun may be useful for calibrating remote-readout systems.

Using the Almanac

The Astronomical Almanac and other almanacs show the GHA and declination of the sun or moon at hourly intervals for every day of the period covered by the book. Instructions are included in such books for interpolating the positions of the sun or moon for any time on a given date.

The orbital velocity of the moon is not constant, and therefore precise interpolations are not linear.

Fortunately, linear interpolations from one hour to the next, or even from one day to the next, will result in data that is entirely adequate for Amateur Radio purposes. If linear interpolations are made from 0000 UTC on one day to 0000 UTC on the next, worse-case conditions exist when apogee or perigee occurs near midday on the next date in question. Under such conditions, the total angular error in the position of the moon may be as much as a sixth of a degree. Because it takes a full year for the Earth to orbit the sun, the similar error for determining the position of the sun will be no more than a few hundredths of a degree.

If a polar mount (a system having one axis parallel to the Earth's axis) is used, information from the *Almanac* may be used directly to point the antenna array. The local hour angle (LHA) is simply the GHA plus or minus the observer's longitude (plus if east longitude, minus if west). The LHA is the angle west of the observer's meridian at which the celestial body is located. LHA and declination information may be translated to an EME window by taking local obstructions and any other constraints into account.

Azimuth and Elevation

An antenna system that is positioned in azimuth (compass direction) and elevation (angle above the horizon) is called an *az-el* system. For such a system, some additional work will be necessary to convert the almanac data into useful information. The GHA and decl information may be converted into azimuth and elevation angles with the mathematical equations that follow. A calculator or computer that treats trigonometric functions may be used. **CAUTION:** Most almanacs list data in degrees, minutes, and either decimal minutes or seconds. Generally, computer programs have typically required this information in degrees and decimal fractions, so a conversion may be necessary before the almanac data is entered.

Determining az-el data from equations follows a procedure similar to calculating great-circle bearings and distances for two points on the Earth's surface. There is one additional factor, however. Visualize two observers on opposite sides of the Earth who are pointing their antennas at the moon. Imaginary lines representing the boresights of the two antennas will converge at the moon at an angle of approximately 2° . Now assume both observers aim their antennas at some distant star. The boresight lines now may be consid-

ered to be parallel, each observer having raised his antenna in elevation by approximately 1° . The reason for the necessary change in elevation is that the Earth's diameter in comparison to its distance from the moon is significant. The same is not true for distant stars, or for the sun.

Equations for az-el calculations are:

$$\sin E = \sin L \sin D + \cos L \cos D \cos \text{LHA} \quad (4)$$

$$\tan F = \frac{\sin E - K}{\cos E} \quad (5)$$

$$\cos C = \frac{\sin D - \sin E \sin L}{\cos E \cos L} \quad (6)$$

where

E = elevation angle for the sun

L = your latitude (negative if south)

D = declination of the celestial body

LHA = local hour angle = GHA plus or minus your longitude (plus if east longitude, minus if west longitude)

F = elevation angle for the moon

K = 0.01657, a constant (see text that follows)

C = true azimuth from north if $\sin \text{LHA}$ is negative; if $\sin \text{LHA}$ is positive, then the azimuth = $360 - C$.

Assume our location is 50° N latitude, 100° W longitude. Further assume that the GHA of the moon is 140° and its declination is 10° . To determine the az-el information we first find the LHA, which is 140 minus 100 or 40° . Then we solve equation 4:

$$\begin{aligned} \sin E &= \sin 50 \sin 10 + \cos 50 \cos 10 \cos 40 \\ \sin E &= 0.61795 \text{ and } E = 38.2^\circ \end{aligned}$$

Solving equation 5 for F, we proceed. (The value for $\sin E$ has already been determined in equation 4.)

$$\begin{aligned} \tan F &= \frac{0.61795 - 0.06175}{\cos 38.2} \\ &= 0.76489 \end{aligned}$$

From this, F, the moon's elevation angle, is 37.4° .

We continue by solving equation 6 for C. (The value of $\sin E$ has already been determined.)

$$\cos C = \frac{\sin 10 - 0.61795 \sin 50}{\cos 38.2 \cos 50}$$

C therefore equals 126.4° . To determine if C is the actual azimuth, we find the polarity for $\sin \text{LHA}$, which is $\sin 40^\circ$ and

Fig 23.71—Parabolic-antenna gain vs size, frequency and surface errors. All curves assumed 60% aperture efficiency and 10-dB power taper. Reference: J. Ruze, British IEEE.

has a positive value. The actual azimuth then is $360 - C = 233.6^\circ$.

If az-el data is being determined for the sun, omit equation 5; equation 5 takes into account the nearness of the moon. The solar elevation angle may be determined from equation 4 alone. In the above example, this angle is 38.2° .

The mathematical procedure is the same for any location on the Earth's surface. Remember to use negative values for southerly latitudes. If solving equation 4 or 5 yields a negative value for E or F, this indicates the celestial body below the horizon.

These equations may also be used to determine az-el data for man-made satellites, but a different value for the constant, K, must be used. K is defined as the ratio of the Earth's radius to the distance from the Earth's center to the satellite.

The value for K as given above, 0.01657 is based on an average Earth-moon distance of 239,000 miles. The actual Earth-moon distance varies from approximately 225,000 to 253,000 mi. When this change in distance is taken into account, it yields a change in elevation angle of approximately 0.1° when the moon is near the horizon. For greater precision in determining the correct elevation angle for the moon, the moon's distance from the Earth may be taken as:

$$D = -15,074.5 \times SD + 474,332$$

where

D = moon's distance in miles

SD = moon's semi-diameter, from the almanac.

Computer Programs

Digital modes are also used for EME communications. The *WSJT* software for *Windows* includes a mode known as JT44. This software enables moonbounce contacts using sound-card-equipped PCs, single Yagi antennas and under 200 watts of RF—an accomplishment that seemed virtually impossible in previous years. It now appears possible that this mode, and other digital modes that may appear in the future, will place EME communication within reach of hams with both modest antenna space and budgets. Complete details and operating instructions can be viewed by downloading the *WSJT User Guide* at pulsar.princeton.edu/~joel/K1JT/WSJT300.PDF.

As has been mentioned, a computer may be used in solving the equations for azimuth and elevation. For EME work, it is convenient to calculate az-el data at 30-minute intervals or so, and to keep the results of all calculations handy during the EME window. Necessary antenna-position corrections can then be made periodically.

RealTrak prints out antenna azimuth and elevation headings for nearly any celestial object. It can be used with the Kansas City Tracker program described in the satellite section to track celestial objects automatically. *VHF PAK* provides real-time moon and celestial object position information. Two other real-time tracking programs are *EME Tracker* and the *VK3UM EME Planner*.

Libration Fading of EME Signals

One of the most troublesome aspects of

receiving a moonbounce signal, besides the enormous path loss and Faraday rotation fading, is libration fading. This section will deal with libration (pronounced *lie-brayshun*) fading, its cause and effects, and possible measures to minimize it.

Libration fading of an EME signal is characterized in general as fluttery, rapid, irregular fading not unlike that observed in tropospheric scatter propagation. Fading can be very deep, 20 dB or more, and the maximum fading will depend on the operating frequency. At 1296 MHz the maximum fading rate is about 10 Hz, and scales directly with frequency.

On a weak CW EME signal, libration fading gives the impression of a randomly keyed signal. In fact on very slow CW telegraphy the effect is as though the keying is being done at a much faster speed. On very weak signals only the peaks of libration fading are heard in the form of occasional short bursts or “pings.”

Fig 23.72 shows samples of a typical EME echo signal at 1296 MHz. These recordings, made at W2NFA, show the wild fading characteristics with sufficient S/N ratio to record the deep fades. Circular polarization was used to eliminate Faraday fading; thus these recordings are of libration fading only. The recording bandwidth was limited to about 40 Hz to minimize the higher sideband-frequency components of libration fading that exist but are much smaller in amplitude. For those who would like a better statistical description, libration fading is Rayleigh distributed. In the recordings shown in Fig 23.72, the average signal-return level computed from path loss and mean reflection coefficient of the moon is at about the +15 dB S/N level.

It is clear that enhancement of echoes far in excess of this average level is ob-

served. This point should be kept clearly in mind when attempting to obtain echoes or receive EME signals with marginal equipment. The probability of hearing an occasional peak is quite good since random enhancement as much as 10 dB is possible. Under these conditions, however, the amount of useful information that can be copied will be near zero. Enthusiastic newcomers to EME communications will be stymied by this effect since they know they can hear the signal strong enough on peaks to copy but can't make any sense out of what they try to copy.

What causes libration fading? Very simply, multipath scattering of the radio waves from the very large (2000-mile diameter) and rough moon surface combined with the relative motion between Earth and moon called librations. To understand these effects, assume first that the Earth and moon are stationary (no libration) and that a plane wave front arrives at the moon from your Earthbound station as shown in Fig 23.73A.

The reflected wave shown in Fig 23.73B consists of many scattered contributions from the rough moon surface. It is perhaps easier to visualize the process as if the scattering were from many small individual flat mirrors on the moon that reflect small portions (amplitudes) of the incident wave energy in different directions (paths) and with different path lengths (phase). Those paths directed toward the moon arrive at your antenna as a collection of small wave fronts (field vectors) of various amplitudes and phases. The vector summation of all these coherent (same frequency) returned waves (and there is a near-infinite array of them) takes place at the feed point of your antenna (the collecting point in your antenna system). The level of the final summation as mea-

sured by a receiver can, of course, have any value from zero to some maximum. Remember that we assumed the Earth and moon were stationary, which means that the final summation of these multipath signal returns from the moon will be one fixed value. The condition of zero relative motion between Earth and moon is a rare event that will be discussed later in this section.

Consider now that the Earth and moon are moving relative to each other (as they are in nature), so the incident radio wave “sees” a slightly different surface of the moon from moment to moment. Since the lunar surface is very irregular, the reflected wave will be equally irregular, changing in amplitude and phase from moment to moment. The resultant continuous summation of the varying multipath signals at your antenna feed-point produces the effect called libration fading of the moon-reflected signal.

The term *libration* is used to describe small perturbations in the movement of celestial bodies. Each libration consists mainly of its diurnal rotation; moon libration consists mainly of its 28-day rotation which appears as a very slight rocking motion with respect to an observer on Earth. This rocking motion can be visualized as follows: Place a marker on the surface of the moon at the center of the moon disc, which is the point closest to the observer, as shown in Fig 23.74. Over time, we will observe that this marker wanders around within a small area. This means the surface of the moon as seen from the Earth is not quite fixed but changes slightly as different areas of the periphery are exposed because of this rocking motion. Moon libration is very slow (on the order of 10^{-7} radians per second) and can be determined with some difficulty from pub-

Fig 23.72—Chart recording of moon echoes received at W2NFA on July 26, 1973, at 1630 UTC. Antenna gain 44 dBi, transmitting power 400 W and system temperature 400 K.

lished moon ephemeris tables.

Although the libration motions are very small and slow, the larger surface area of the moon has nearly an infinite number of scattering points (small area). This means that even slight geometric movements can alter the total summation of the returned multipath echo by a significant amount. Since the librations of the Earth and moon are calculable, it is only logical to ask if there ever occurs a time when the total libration is zero or near zero. The answer is yes, and it has been observed and verified experimentally on radar echoes that minimum fading rate (not depth of fade) is coincident with minimum total libration. Calculation of minimum total libration is at best tedious and can only be done successfully by means of a computer. It is a problem in extrapolation of rates of change in coordinate motion and in small differences of large numbers.

EME OPERATING TECHNIQUES

Many EME signals are near the threshold of readability, a condition caused by a combination of path loss, Faraday rotation and libration fading. This weakness and unpredictability of the signals has led to the development of techniques for the exchange of EME information that differ from those used for normal terrestrial work. The fading of EME signals chops dashes into pieces and renders strings of dots incomplete. This led to the use of the "T M O R" reporting system. Different, but similar, systems are used on the low bands (50 and 144 MHz) and the high bands (432 MHz and above). **Tables 23.5** and **23.6** summarize the differences between the two systems.

As equipment and techniques have improved, the use of normal RST signal reports has become more common. It is now quite common for two stations working for the first time to go straight to RST reports if signals are strong enough. These normal reports let stations compare signals from one night to the next. EME QSOs are often made during the ARRL VHF contests. These contacts require the exchange of 4-digit grid locators. On 432 MHz and above, the sending of GGGG has come to mean "Please send me your grid square," or conversely, "I am now going to send my grid square."

The length of transmit and receive periods is also different between the bands. On 50 and 144 MHz, 2-minute sequences are used. That is, stations transmit for two full minutes, and then receive for two full minutes. One-hour schedules are used, with the eastern-most station (referenced to the international date line) transmitting first. **Table 23.7** gives the 2-minute sequence

Table 23.5

Signal Reports Used on 144-MHz EME

T — Signal just detectable
M — Portions of call copied
O — Complete call set has been received
R — Both "O" report and call sets have been received
SK — End of contact

Table 23.6

Signal Reports Used on 432-MHz EME

T — Portions of call copied
M — Complete calls copied
O — Good signal—solid copy (possibly enough for SSB work)
R — Calls and reports copied
SK — End of contact

procedure. On 222 MHz, both the 144 and 432-MHz systems are used.

On 432 MHz and above, 2¹/₂-minute sequences are standard.

The longer period is used to let stations with variable polarization have adequate time to peak the signal. The last 30 seconds is reserved for signal reports only. **Table 23.8** provides more information on the 432-MHz EME QSO sequence. The western-most station usually transmits first. However, if one of the stations has variable polarization, it may elect to transmit second, to take the opportunity to use the first sequence to peak the signal. If both stations have variable polarization, the station that transmits first should leave its polarization fixed on transmit, to avoid "polarization chasing."

CW sending speed is usually in the 10 to 13-wpm range. It is often best to use greater-than-normal spacing between individual dits and dahs, as well as between complete letters. This helps to overcome libration fading effects. The libration fading rate will be different from one band to another. This makes the optimum CW speed for one band different from another. Keep in mind that characters sent too slowly will be chopped up by typical EME fading. Morse code sent too fast will simply be jumbled. Pay attention to the sending practices of the more successful stations, and try to emulate them.

Doppler shift must also be understood. As the moon rises or sets it is moving toward or away from objects on Earth. This leads to a frequency shift in the moon echoes. The amount of Doppler shift is directly proportional to frequency. At 144

Fig 23.73— How the rough surface of the moon reflects a plane wave as one having many field vectors.

Fig 23.74— The moon appears to "wander" in its orbit about the Earth. Thus a fixed marker on the moon's surface will appear to move about in a circular area.

MHz, about 500 Hz is the maximum shift. On 432 MHz, the maximum shift is 1.5 kHz. The shift is upward on moonrise and downward on moonset. When the moon is due south, your own echoes will have no Doppler shift, but stations located far away will still be affected. For scheduling, the accepted practice is to transmit zero beat on the schedule frequency, and tune to compensate for the Doppler shift. Be careful—most transmitters and transceivers have a built-in CW offset. Some radios read this offset when transmitting, and others don't. Find out how your transmitter operates and compensate as required.

Random operation has become popular in recent years. In the ARRL EME contest, many of the big guns will not even accept schedules during the contest periods, because they can slow down the pace of their contest contacts.

EME Operating Times

Obviously, the first requirement for EME operation is to have the moon visible by both EME stations. This requirement not only consists of times when the moon is above the horizon, but when it is actually clear of obstructions such as trees and buildings. It helps to know your exact EME operating window, specified in the form of beginning and ending GHAs (Greenwich

Table 23.7

144-MHz Procedure — 2-Minute Sequence

6	R R R R R	DE VE7BBG SK

Hour Angle) for different moon declinations. This information allows two different stations to quickly determine if they can simultaneously see the moon.

Once your moon window is determined, the next step is to decide on the best times during that window to schedule or operate. Operating at perigee is preferable because of the reduced path loss. Fig 23.68 shows that not all perigees are equal. There is about a 0.6-dB difference between the closest and farthest perigee points. The next concern is operating when the moon is in a quiet spot of the sky. Usually, northern declinations are preferred, as the sky is quietest at high declinations. If the moon is too close to the sun, your array will pick up sun noise and reduce the sensitivity of your receiver. Finally, choosing days with minimal libration fading is also desirable.

Perigee and apogee days can be determined from the *Astronomical Almanac* by inspecting the tables headed “S.D.” (semi-diameter of the moon in minutes of arc). These semi-diameter numbers can be compared to Fig 23.68 to obtain the approximate moon distance. Many computer programs for locating the moon now give the moon’s distance. The expected best weekends to operate on 432 MHz and the higher bands are normally printed well in advance in various EME newsletters.

When the moon passes through the galactic plane, sky temperature is at its maximum. Even on the higher bands this is one of the least desirable times to operate. The areas of the sky to avoid are the con-

stellations of Orion and Gemini (during northern declinations), and Sagittarius and Scorpius (during southern declinations). The position of the moon relative to these constellations can be checked with information supplied in the *Astronomical Almanac* or *Sky and Telescope* magazine.

Frequencies and Scheduling

According to the ARRL-sponsored band plan, the lower edge of most bands is reserved for EME operation. On 144 MHz, EME frequencies are primarily between 144.000 and 144.080 MHz for CW, and 144.100 and 144.120 MHz for SSB. Random CW activity is usually between 144.000 and 144.020 MHz. In the US, 144.000 to 144.100 MHz is a CW sub-band, so SSB QSOs often take place by QSYing up 100 kHz after a CW contact has been established. Because of the large number of active 144-MHz stations, coordinating schedules in the small EME window is not simple. The more active stations usually have assigned frequencies for their schedules.

On 432 MHz, the international EME CW calling frequency is 432.010 MHz. Random SSB calling is done on 432.015 MHz. Random activity primarily takes place between 432.000 and 432.020 MHz. The greater Doppler shift on 432 MHz requires greater separation between schedule frequencies than on 144 MHz. Normally 432.000 MHz, 432.020 MHz and each 5-kHz increment up to 432.070 MHz are used for schedules.

Activity on 1296 MHz is centered be-

tween 1296.000 and 1296.040 MHz. The random calling frequency is 1296.010 MHz. Operation on the other bands requires more specific coordination. Activity on 33 cm is split between 902 and 903 MHz. Activity on 2300 MHz has to accommodate split-band procedures because of the different band assignments around the world.

EME Net Information

An EME net meets on 14.345 MHz on weekends for the purpose of arranging schedules and exchanging EME information. The net meets at 1600 UTC. OSCAR satellites are becoming more popular for EME information exchange. When Mode B is available, a downlink frequency of 145.950 MHz is where the EME group gathers. On Mode L and Mode JL, the downlink frequency is 435.975 MHz.

Other Modes

Most EME contacts are still made on CW, although SSB has gained in popularity and it is now common to hear SSB QSOs on any activity weekend. The ability to work SSB can easily be calculated from Eq 1. The proper receiver bandwidth (2.3 kHz) is substituted. SSB usually requires a +3-dB signal-to-noise ratio, whereas slow-speed CW contacts can be made with a 0-dB signal-to-noise ratio. Slow-scan television and packet communication has been attempted between some of the larger stations. Success has been limited because of the greater signal-to-noise ratios required for these modes, and severe signal distortion from libration fading.

Chapter 24

Web, Wi-Fi, Wireless and PC Technology

With the Internet and the Personal Computer (PC) more commonplace in homes and ham shacks around the world, some fear it may actually destroy Amateur Radio! Their reasoning is that increasingly powerful PCs, coupled with access to the Internet or world-wide web (www), will primarily divert youth from the lure, mystique and magic of radio. Could an advancement in technology with the corresponding economies-of-scale actually deprive Amateur Radio of an influx of fresh, young operators and enthusiasts?

The PC and its Internet link to the world around us have surely changed many

lifestyles — young and old and those in between. But far from destroying Amateur Radio as we know it, these technologies have greatly enhanced and improved the ham radio experience of countless operators! Many hams with an interest or passion in homebrewing, DXing, contesting, and the wide variety of other related areas of interest now take for granted nearly instantaneous access to information and interest-related Web sites. Computers and modems are sometimes used for the operation of various modes, and can also be a primary part of the actual

ham radio equipment (e.g., a *transceiver* or *receiver*).

In this chapter, in addition to covering many of these exciting areas described above, we will also review the personal/commercial *wireless* world around us that is extraneous to ham frequencies, equipment or operation. This chapter was written by Donald R. Greenbaum, N1DG, and Dana G. Reed, W1LC. It also includes contributions from John J. Champa, K8OCL, Reed E. Fisher, W2CQH, Howard S. Huntington, K9KM, and Ronnie P. Milione, KB2UAN.

The World Wide Web (www) — The Internet

SEARCH ENGINES

The Internet encompasses millions and millions of pages of information. There is simply too much information on the subject of ham radio to find without properly using search engines. There are many related ham sites, but the most popular are listed in the sidebar *A Ham's Guide to Useful Internet Sites*. In any event, the most popular search engines are *Google*, *Yahoo*, *Ask Jeeves*, *Alta Vista*, *Dogpile*, *Look Smart*, *Overture*, *Teoma* and *Find What*.

The secret to a successful search is to be specific by limiting the results or *hits*. Simply typing "ham radio" as the topic of interest to you is not sufficient. A query on *ham* yielded links to Web sites mentioning ham radio, ham (the food) and other hits totaling over 7 million pages! A more specific search of *ham radio* reduced the page count to 1.7 million pages, still too numerous to be helpful. Narrowing and refining your search is as simple as adding

Search Engines — Electronic Parts and Cross Referencing

A QRP list member was trying to search, or cross reference, a semiconductor in Google, but without success. He had probably only entered the exact part number. The part was described as possibly of one family of semiconductor, but apparently in Google he used the part number "IRF331A" which indeed comes up blank.

However, a knowledge of manufacturing prefixes or numbering systems used for semiconductors or other components can be very valuable. Originally, IRF was the prefix for International Semiconductor Parts. Entering that in Google.com, I came up with a Web page: www.irf.com. From there, I came to a search engine on the page that eventually led to their cross reference guide — and the fact that the IRF331A can possibly be replaced (depending on the application) by the IRF330. However, an upgraded part is the IRF440, or the 2N6760.

Knowing a general supplier of replacement semiconductors, my next stop — had this not worked out — would have been www.NTE.com. The main point here is to study distributors catalogs, for knowledge of part-numbering conventions for whatever electronics you might need. Get to know company logos that are applied to parts as these will shorten your searches if the company still exists, using that logo. For the totally unfamiliar part, a logo can be very helpful to focus your search.—*Stuart Rohre, K5KVH*

A HAM'S GUIDE TO USEFUL INTERNET SITES

Since website URLs change so often, any attempt to present a comprehensive list here would be out of date by the time of publication. Accordingly, we have instead listed general ham-related sites that contain current links to many of the specific radio sites on the Web:

ARRL: www.arrl.org Where else would you go for ham radio news?

AC6V: www.ac6v.com/ Rod has links to over 6,000 other radio related sites covering all topics imaginable.

AA1V: www.goldtel.net/aa1v/ Don has the usual DX links plus some pretty good NASA links not found on other sites.

DX Zone: www.dxzone.com/ A good commercially-run site that is well laid out providing 4500 links to other commercial and private ham run sites.

425 DX News: www.425dxn.org/ Good Italian non-commercial site for DX News and links to DX-related sites.

K4UTE: www.nfdxa.com/K4UTE/K4UTE.HTML One of the best sources of QSL routes and links to other DX-related activities.

NG3K: www.ng3k.com/Misc/adxo.html Want to know who's going where and the link to their Web site? Since 1996, Bill has been keeping track of these things on this Web site and has everything archived for searching.

QSL.NET: www.qsl.net/master.htm Al, K3TKJ, provides free hosting to thousands of hams for radio-related Web pages.

K1BV Awards Directory: www.dxawards.com/ Are you into wallpaper? Ted has one of the best sites for award information and links to those offering them.

MODS: www.mods.dk/ Modifying your radio? Find hundreds of links compiled over the last eight years by Erik, OZ2AEP.

Linux Ham Radio Software Directory: radio.linux.org.au/ Do you prefer Linux to Windows? This site lists Perl scripts ranging from modeling antennas to European Microwave Beacon propagation forecasting.

Satellite Tracking Software: www.david-taylor.pwp.blueyonder.co.uk/software/wxtrack.htm

QSL Museum: www.hamgallery.com/ In addition to one of the most complete online QSL collections, Tom (K8PX) has one of the more complete ham radio link sites on the web.

VOICE OVER INTERNET PROTOCOL — VoIP

Like our airwaves, the Internet can carry our transmissions over great distances. Unlike ham radio, the Internet is only digital. If we use voice or video over that medium those modes must be converted into that digital format before sending and converted back to analog upon receipt. Two software packages have emerged to allow hams to converse over the Internet in what is known as Voice over Internet Protocol, or VoIP. ARRL offers a new publication titled *VoIP: Internet Linking for Radio Amateurs*. The book discusses in great detail the brief outline of the topic that follows.¹

Echolink

Recognizing the growing use of the Internet by hams, K1RFD wrote a software program called Echolink. Now even antenna-restricted hams can enjoy the fun with a computer, a microphone and an Internet connection. You can connect via Echolink to other licensed hams on computers, mobiles transmitting through repeaters linked to the Internet via connected VHF repeaters and even nodes connected via HF. There are more than 120,000 registered users in 147 countries worldwide. There are also conference nodes, some specific to other hobbies such as aviation. It is the ultimate party line encompassing computers, radio and the Internet. Like radio, it is non-duplex; both stations cannot talk at once. The software is free (you must be licensed) and is downloadable from www.echolink.org. The software is very user friendly, and all control features are click-of-a-mouse enabled. The only requirement of your PC is a sound card and microphone.

IRLP

Unlike Echolink, which allows two hams to communicate without having a radio, IRLP takes a different approach to VoIP. David Cameron, VE7LTD, designed the Internet Radio Linking Project (IRLP). As he says on his Web site, he designed the software to provide a simple and easy system to link radio systems together using the Internet as the communications backbone.

IRLP users do not need to own computers. They simply access the network nodes using VHF or UHF FM transceivers.

The IRLP network is Linux based and requires a Linux-based Pentium PC at each node running *Speak Freely* software, an interface card (purchased inexpensively from VE7LTD), your radio and a sound card. The sound card takes the analog audio from the radio, converts it to compressed digital packets and sends short streams over the

more words. This is called using keywords, and choosing them wisely will reduce the page count to manageable levels. *Ham radio software* reduces our search to 427,000 pages while *ham radio dsp software* reduces it to 18,600 pages; you can keep refining your search by adding keywords, and there is no need to include the word *and* between the words.

Another way to reduce hits on your search is to exclude categories. For instance, if you want to search for ham you can exclude the food ham by *ham -food*. If you want to search for an item but only want to search for it on a specific Web site, you can do that too. For instance, to look on the ARRLWeb you can do *license*

renewal site: www.arrl.org.

Searching for specific part numbers for your do-it-yourself projects is similarly easy. In the *PC Technology* section of this chapter we discuss isolation transformers. A search for *273-1374* brings you right into the RadioShack catalog, as well as pages on how to build other projects with it. There is a fine line for being too specific in searches. Sometimes the part number can be too exact, and adding either a manufacturer or looking up the description of *isolation transformers* are a broader alternative that will help if the specific part search comes up negative. See also the sidebar *Search Engines — Electronic Parts and Cross Referencing*.

Fig 24.1 — NOAA North Pole map image of recent, real-time auroral activity.

Fig 24.2 — Solar Terrestrial Dispatch graphic depicting frequency usability in real time.

Internet to the connected nodes via the interface card. The control software controls the packets along with continuous tone coded sub audible squelch signals (CTCSS) to start

and stop the streams. CTCSS is also used by the transmitting user to pass commands to the nodes for the information as to which node a user wants to connect to, start and stop the connection and a host of other settlable parameters to control the process. Streams can be sent to one or many nodes.

The software, interface cards and all manuals are available from the IRLP website at www.irlp.net

PROPAGATION FORECASTING

One of the most valuable pieces of information available on the Web is the various real time propagation statistics and tools. Current gray-line paths are vital to the LF operator. MUF values are helpful to HF operators. Current observed sunspot activity, solar storm indexes, etc. are all posted on various ham and government Web sites giving the Internet-connected ham useful tools to know where the best paths to the DX are. Current solar flux numbers are published by the Canadian Space Agency as monitored at its Penticton Observatory: www.drao-ofr.hia-ihh.nrc-cnrc.gc.ca/icarus/www/current_flux.shtml

Since Auroral activity is harmful to HF transmissions over the globe, NOAA provides both North and South Pole real time auroral maps: sec.noaa.gov/pmap/gif/pmapN.gif. A recent North Pole image is shown in **Fig 24.1**.

Knowing which frequencies are usable in real time is also as handy a propagation

tool as a ham could want. As shown in **Fig 24.2**, a real-time graphic can be found at the Solar Terrestrial Dispatch Web site: www.spacew.com/www/realtime.html.

VIRUS PROTECTION AND FIREWALLS

Lastly, no Internet user should be connecting to the Web without up-to-date virus protection. Norton Antivirus and McAfee are the two most popular commercial products. There are also some shareware products available. However, virus protection alone does not offer full protection from intruders. Hams increase the risk of being infected by opening ports to allow IRLP, Telnet, Instant Messenger, VoIP, or FTP applications. The solution is installing one of two types of firewalls. The first is an inexpensive software-based firewall from Norton or McAfee for under \$50. They detect both internal and external attempts to compromise your personal computer (PC). The more expensive but more capable solution is a hardware-based device commonly known as a Firewall Appliance. In addition to the simple intruder detection found in firewall software, they contain an intruder *prevention* system, the ability to connect multiple PCs (as a router or switch), monitor ability on all traffic in and out of the network, open secure ports (VPN) and automatically obtain updates to firmware.

Notes

Wi-Fi Glossary

Access Point (AP) — A wireless bridging device that connects 802.11 stations to shared resources and a wired network such as the Internet.

Ad Hoc — In wireless LAN (WLAN) networks this is a direct wireless connection between two laptop computers without the use of an AP.

AP — Access point.

Carrier Sense Multiple Access / Collision Avoidance (CSMA/CA) — The wireless method that tries to avoid simultaneous access or collisions by not transmitting, if another signal is detected on the same frequency channel.

Direct-Sequence Spread Spectrum

(DSSS) — The type of modulation used in 802.11b that is capable of maximum half-duplex data speeds of 11 Mbps.

Frequency Hopping Spread Spectrum (FHSS) — A type of modulation used in early 802.11 devices that uses a time-varied narrow signal to spread the signal over a wide band. Maximum half-duplex data rate is 2 Mbps.

Institute of Electrical and Electronics Engineers (IEEE) — The professional standards setting organization for data networking devices.

Orthogonal Frequency Division Multiplexing (OFDM) — A type of modulation that splits a wide frequency band into

many narrow frequency bands. Both 802.11a and 802.11g use OFDM.

Service Set Identity (SSID) — The identification for an AP. It is transmitted continuously in the form of a beacon.

Wired Equivalent Privacy (WEP) — A standard for providing minimal privacy of wireless LAN communication by encrypting individual data frames.

Wireless Fidelity (Wi-Fi) — The Wireless Ethernet Compatibility Alliance certification program to ensure that equipment claiming to be in compliance with 802.11 standards is truly interoperable. The term Wi-Fi5 is sometimes applied to 802.11a equipment that operates on the 5-GHz band.

Wireless Fidelity (Wi-Fi)

COMPUTER CONNECTIONS BY RADIO

Wireless local area networks (WLAN) using spread spectrum transmit in the 902-MHz range (802.11), in the 2.4-GHz

frequency range (802.11b and 802.11g), and in the 5-GHz frequency range (802.11a). Combining spread spectrum transmission's characteristics with a low power output (30 to 100-mW range) means

it is highly unlikely that one spread spectrum network user will interfere with another. Spread spectrum transmissions distribute or "spread" a radio signal over a broad frequency range. There are vari-

ous techniques for doing this spreading.

The older WLAN systems operate in the 902-MHz range based on the IEEE 802.11 standard and use frequency hopping spread spectrum modulation, or FHSS. This modulation technique uses what is called a predetermined pseudo-random sequence to transmit data. This pseudo-random sequence is actually a predetermined digital signal pattern that places data on a combination of frequencies across the entire spread spectrum channel. The receiving station must know the specific signal pattern used by the transmitting station to decode the data. These early 802.11 systems generally operated with slightly higher power (250 mW) but at much slower data rates of typically 2 Mbps.

New-generation WLAN

The first of the new generation of WLAN systems is based on the IEEE 802.11b standard and use a modulation technique known as direct-sequence spread spectrum, or DSSS. This modulation technique achieves higher data rates by using a different pseudo-random code known as a Complimentary Sequence. The 8-bit Complimentary Sequence can encode 2 bits of data for the 5.5 Mbps data rate or 6 bits of data for the 11 Mbps data rate. This is known as Complimentary Code Keying (CCK).

The latest generation of WLAN devices

are based the same type of modulation, Orthogonal Frequency Division Multiplexing (OFDM) but operate on different frequency bands. OFDM provides its spreading function by transmitting the data simultaneously on multiple carriers. 802.11g operating in the 2.4-GHz range and 802.11a operating in the 5-GHz range both specify 20-MHz wide channels with 52 carriers spaced every 312.5 kHz. OFDM radios can be used to transmit data rates of 6, 9, 12, 18, 24, 36, 48 and 54 Mbps.

The WLAN Advantage

The main advantage of WLAN systems is that the laptop PC users are not tied to an RJ-45 type of wall outlet. At home they can roam between the home office and the patio. At work, they can move with ease between an office and a conference room, for example. There is a significant economic advantage for businesses re-locating office areas. With the use of WLAN technology, it is not necessary to spend the time and money to rewire an entire floor or building. These small radio devices with their small antennas and low power can readily transmit through several layers of drywall. If more than one access point, or AP, is required to cover the business area, several AP devices can all be linked together by putting them in the same virtual LAN in the wired network. Consequently, rather than having to

wire each individual office and conference room, only the various AP nodes need to be wired together. This can produce a huge savings in time and expense.

WLAN Security

Although the majority of WLAN operate in the open mode allowing anyone in the area convenient access the network, often a minimum level of information security is desirable. This can be provided by using a WLAN encryption protocol built into the equipment called Wired Equivalent Privacy, or WEP. For those situations requiring a higher level of security, most commercial firms simply re-employ their virtual private network (VPN) or tunneling strategy commonly used to allow secure network remote access for mobile workers and teleworkers. However, in the case of WLAN use, extra steps need to be taken to ensure that the VPN user ID and password are not being wirelessly transmitted in the clear without some form of encryption. A new WLAN security standard called IEEE 802.1x attempts to address this need but is currently plagued with interoperability issues.

Wi-Fi systems being used in Amateur Radio applications are typically referred to as High Speed Multimedia (HSMM), and these techniques are discussed in detail in the HSMM section of the **Modes and Modulation Sources** chapter of this *Handbook*.

Wireless Technology Glossary

AMPS (Advanced Mobile Phone Service) — First standardized cellular service in the world, released in 1983. Uses the 800-900 MHz frequency band.

Analog — A signal that can vary continuously between a maximum and minimum value. For example, the voice voltage waveform from the output of a microphone is analog. RF voltage waveforms (as those from AM, FM and SSB transmitters) are also analog.

Cap Code — A specific address encoded into both a data transmission and the intended receiving equipment so the receiving equipment can discriminate against unintended or unwanted messages.

CDMA (Code Division Multiple Access) — A digital radio system that separates users by digital codes.

Cellular — Characteristic of or pertaining to a system of wireless communication made up of many individual cell units. The term itself is derived from the typical geographic honeycomb shape of the areas

into which a coverage region is divided.

CELP (Codebook Excited Linear Predictive coding) — A type of low-bit-rate voice coder that emulates a single human voice tract. Details can be found in Ref. 3 at the end of this chapter.

CSMA/CD (Carrier Sense Multiple Access / Collision Detection) — A set of rules that determine how network devices respond when two devices attempt to use a data channel simultaneously (called a *collision*). After detecting a collision, a device waits a random delay time and then attempts to re-transmit the message. If the device detects a collision again, it now waits twice as long to try to re-transmit the message.

DHCP (Dynamic Host Configuration Protocol) — An external assignment mechanism that provides a “care-of address” to a mobile client (see also *Foreign Agent*).

Digital — A signal that has only discrete values, usually two (logic 1 and logic 0), that changes at predetermined intervals. The

value (e.g., voltage) present in a single time period is called a bit. The number of bits transferred per second is called the bit rate that has units of bits per second (bit/s), or kilobits per second (kbit/s), etc.

E-mail — Electronic mail sent and received via computers with modems. Transmission media can be existing telephone or other communication lines, wireless, or not uncommonly—both.

Encode — The process whereby a transmission contains additional data or code added to facilitate proper routing of the transmission to the desired point or points.

Encryption — Technology used to form a secure channel between a wireless client and the server to support user authentication, data integrity, and data privacy.

ESN (Electronic Serial Number) — A manufacturer-assigned identity contained in a data transmission from a call placed to verify that the hardware used belongs to a

valid cellular account.

Ethernet — A local-area network (LAN) protocol. Ethernet uses a bus or star topology and supports data transfer rates of 10 Mbit/s, 100 Mbit/s, 1 Gbit/s and 10 Gbit/s. Ethernet uses the CSMA/CD access method to handle simultaneous demands, and is one of the most widely implemented LAN standards.

FDMA (Frequency Division Multiple Access) — A radio system that separates user channels by frequency. Amateur Radio equipment presently uses FDMA.

Footprint — The coverage area of an individual cell.

Foreign Agent — A special “node” which is present on a foreign network and provides mobility services to visiting mobile nodes.

GPS (Global Positioning System) — A Dept. of Defense-developed, worldwide, satellite-based radio navigation system.

Handoff — Process whereby a mobile telephone network automatically transfers a call from cell to cell—possibly to another channel—as a mobile crosses adjacent cells.

Home Agent — A host on a mobile’s home network responsible for trapping its packets, and forwarding them to the mobile’s present location.

LAN (Local Area Network) — A computer network that spans a relatively small area. Most LANs are confined to a single building or group of buildings. However, one LAN can be connected to other LANs over any distance via telephone lines and radio waves. A system of LANs connected in this way is called a *wide-area network* (WAN). Most LANs connect workstations and personal computers. Each *node* (individual computer) in a LAN has its own central processing unit (CPU) with which it executes programs, but it is also able to access data and devices anywhere on the LAN. This means that many users can share expensive devices, such as laser printers, as well as data. Users can also use the LAN to communicate with each other, by sending e-mail or engaging in chat sessions.

Mobile Host — Also known as a “mobile node,” this addressed entity in the Mobile IP protocol roams between its home network and foreign networks.

Mobile IP — This mobile industry standard enhances the IP protocol to remedy problems associated with using the standard TCP/IP with a mobile entity. It allows for transparent routing of IP datagrams to mobile hosts (nodes) on the Internet.

Modem — A hardware device, either internally or externally connected to a computer that provides a connection from the computer and some of its programs to a landline (phone or communications line).

Network Independence — The ability to roam among networks (e.g., BellSouth Wireless Data Network, CDPD, Wireless LAN, Ethernet), although traditionally accomplished using the same access media such as SLIP, PPP, etc.

Node — A unique host on a network such as a printer, computer device, handheld Personal Digital Assistant (PDA), or a mainframe.

PCMCIA (Personal Computer Memory Card International Association) — An organization consisting of some 500 companies that has developed a standard for small, credit card-sized devices called *PC Cards*, originally designed for adding memory to portable computers.

PDA (Personal Digital Assistant) — A handheld device that functions as a personal organizer. Many PDAs began as pen-based, i.e., using a writing stylus rather than a keyboard for input, thus utilizing handwriting recognition features. Some PDAs feature voice recognition technologies. At present, most PDAs offer either a stylus or keyboard version.

POS (Point of Service) — A generation of narrowband digital, two-way, low-powered wireless services in the 800-900 MHz bands that will support confirmed delivery of message, full two-way data transfer, voice messaging and connectivity via the Internet.

PPP (Point-to-Point Protocol) — A method of connecting a computer to the Internet. PPP is more stable than the older SLIP protocol and provides error-checking features.

Remote Presence — The ability to establish remote network connections and still appear to be connected to the home network.

Security — The ability to create secure channels for user authentication, data integrity, and data privacy.

SLIP (Serial Line Internet Protocol) — An older method of connecting a computer to the Internet. A more commonly used method is PPP. SLIP is an older and simpler protocol, but from a practical perspective, there’s not much difference between connecting to the Internet via SLIP or PPP. In general, service providers only offer one protocol, although some support both protocols.

TCP/IP (Transmission Control Pro-

ocol/Internet Protocol) — The suite of communications protocols used to connect hosts on the Internet. TCP/IP uses several protocols, the two main ones being TCP and IP. TCP/IP is built into the UNIX operating system and is used by the Internet, making it the *de facto* standard for transmitting data over networks. Even network operating systems that have their own protocols, such as *Netware*, also support TCP/IP.

TDMA (Time Division Multiple Access) — A digital radio system that separates users by time.

Third Party Mobile IP — An Internet technology solution that provides both wireless and wireline IP network and media roaming/communications to both Intranet and Internet services.

Throughput — The amount of data processed, or transferred from one place to another in a specified amount of time. Data transfer rates for disk drives and networks are measured in terms of throughput. Typically, throughput is measured in kbit/s, Mbit/s, and Gbit/s.

TIA (Telecommunications Industry Association) — Telecommunications Industry Association, 2500 Wilson Blvd, Arlington, VA 22001. On the web: www.tiaonline.org.

TIP1 — The wireless group in Committee T1. Alliance for Telecommunications Industry Solutions, 122 G St. NW, Suite 500, Washington, DC 20005. On the web: www.atiss.org.

Virtual Private Network — Network created when a mobile user connects a data terminal to a foreign network and establishes a presence equivalent to a direct connection to the home network.

WAN (Wide Area Network) — A computer network that spans a relatively large geographical area. Typically, a WAN consists of two or more local-area networks (LANs). Computers connected to a wide-area network are often connected through public networks such as the telephone system. They can also be connected through leased lines or satellites. The largest WAN in existence is the Internet.

Windows OS — Microsoft *Windows* Operating System.

Wireless Data — Information or “intelligence,” sent or received by wireless transmission/reception without the direct aid of a landline.

WLAN (Wireless Local Area Network) — A local-area network that uses high frequency radio waves rather than wires to communicate between nodes.

Wireless Technology

Most hams have an interest in gadgets. In recent years, the public's use of radio waves to communicate on the telephone and via mobile computer networks has increased tremendously. This section of the chapter is written by Ron Milione, KB2UAN, and explains how these wireless systems work. Reed E. Fisher, W2CQH, also contributed to the cellular subsection.

Radio communications have been with us for a long time, with analog voice as the principal application. Today, tens of millions of people in the United States are using two-way radio for point-to-point or point-to-multipoint voice communications.

The past 25 years have seen an explosion in wireless communications and computer technology. The past eight years have seen the explosion of the Internet. Standing at the center of this convergence is wireless data technology.

Wireless data gives you the freedom to work from almost anywhere and gives you access to personal information when you are on the go. Whether the wireless system is accessing e-mail from an airport or receiving dispatch instructions in a taxi, maintaining a data connection with a remote network from almost anywhere can be realized.

Wire or fiber-based data communications span a wide range of *throughput* and distances—56 kbps over a modem connection; 10/100 Mbps over an *Ethernet* segment; and gigabit speeds over fiber. Similarly, wireless connections span a wide range. The world of wireless data includes fixed microwave links, wireless Local Area Networks (LANs), data over cellular networks, wireless Wide Area Networks (WANs), satellite links, digital dispatch networks, one-way and two-way paging networks, diffuse infrared, laser-based communications, keyless car entry, the Global Positioning System (GPS) and more.

The benefits of wireless include communications when and where no other communication links are possible, connections at lower cost in many scenarios, faster connections, backups to landlines, networks that are much faster to install and data connections for mobile users.

FUNDAMENTAL CONCEPTS IN CELLULAR TECHNOLOGY

In a cellular radiotelephone system the desired radio coverage area is divided up into a number of smaller geographical areas called cells. **Fig 24.3** shows a typical seven-cell ($n = 7$) cluster. Each cell has a radius r , which may be up to eight miles in

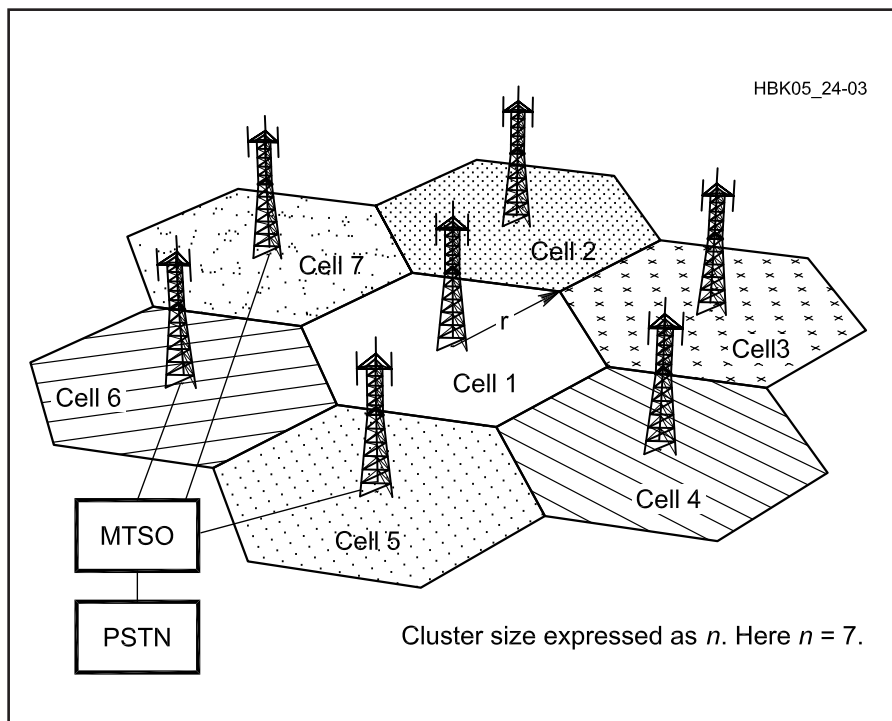

Fig 24.3 — A seven-cell cluster.

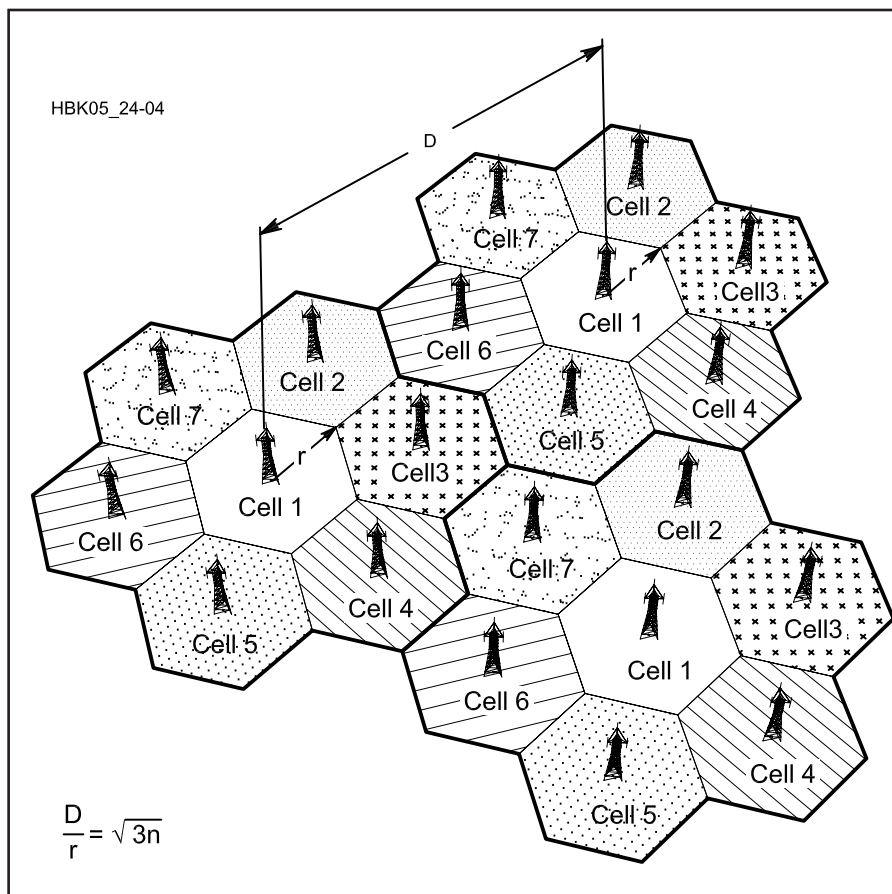

Fig 24.4 — Frequency reuse over an area to conserve spectrum.

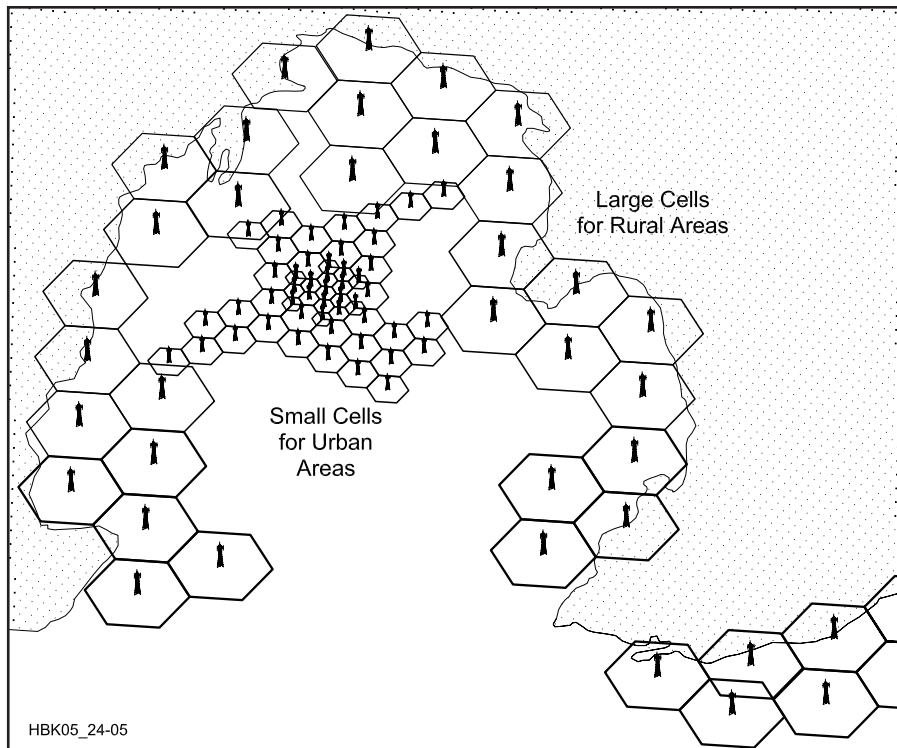

Fig 24.5 — Cell size corresponding to density of population and use.

a startup system. Each cell uses a unique group of radio channels (channel set) that is different from the others. Thus, there is no interference between radio users within a cell cluster. At the center of each cell is located a base station (cell-site) with associated radio tower and antenna system. Mobile stations, located within the cell, communicate with the base station via two-way UHF radio links. The base stations are linked to an MTSO (Mobile Telephone Switching Office) by landline (usually wireline) transmission lines. The MTSO is connected to the PSTN (Public Switched Telephone Network) by additional links. Thus, radio mobile station users can communicate with wireline PSTN users.

Mobile station users can also communicate with other mobile station users, but only through the MTSO and PSTN. The MTSO has other important functions including location and handoff (handover). When a larger serving area is required, cell clusters are placed together as shown in Fig 24.4. In this configuration, all cells with the same number use the same channel set. This condition is called frequency reuse, a prime feature of cellular systems. Co-channel interference now becomes important, for a mobile station in cell #1 may interfere with other mobile stations in the surrounding #1 cells. In Fig 24.4, the distance between same-numbered cells is called D . The co-channel interference ratio is a function of D/r . In a hexagonal grid $D/r = \sqrt{3n}$. For $n =$

7 , $D/r = \sqrt{21} = 4.58$. For ground-to-ground UHF radio propagation, the received carrier power (C) falls off with distance raised to the 4th power. The worst case C/I (carrier-to-interference ratio) is: $C/I = 40 \log (D/r)$. For $n = 7$, $C/I = 40 \log 4.58 = 26.4 \text{ dB}$. A properly designed AMPS cellular system requires $C/I > 18 \text{ dB}$ in 95% of the coverage area and this value provides satisfactory voice transmission.

As the mobile station moves away from its serving base station, the mobile station's received carrier power (C) becomes smaller and eventually approaches the system noise floor (N). The cell radius r must be kept small enough to provide a satisfactory carrier-to-noise ratio (C/N). An AMPS system with $r = 8$ miles, serving mobile stations with roof-mounted antennas, is designed to provide $C/N > 18 \text{ dB}$ in 95% of the coverage area.

Fig 24.5 shows the concept of cell splitting, which is another feature of cellular systems. For example, in densely populated regions such as the center of a city, the cell radius can be reduced from eight miles to four miles. Since the C/I is a function of D/r , it is not reduced when D and r are both made small.

Cellular and PCS Frequency Bands

The 850 MHz cellular frequency band was allocated by the FCC in 1974. Cellular radios operate in the FDD (Frequency Division Duplex) mode that means that

both transmitter and receiver are active at the same time. The transmitter of the base station transmits on a forward (downlink) channel, while at the same time the transmitter of the mobile station transmits on a reverse (uplink) channel 45 MHz lower. The cellular uplink band is 824-849 MHz and the downlink band is 869-894 MHz. The bands are divided into two blocks for the two cellular service providers licensed in each coverage area. In 1995, the FCC allocated a new band for a new all-digital, cellular-like service called PCS (Personal Communications Service). The PCS uplink band is 1850-1910 MHz, and the downlink band is 1930-1990 MHz. PCS also uses FDD and the duplex frequency spacing is 80 MHz. The bands are divided into six blocks for the six PCS service providers licensed in each coverage area. There are currently more than 100 million cellular and PCS subscribers in the United States (US).

Cellular Air Interfaces

Air interfaces are the protocol standards used by phone companies to provide cellular voice and data service. The base station, mobile station and MTSO hardware and software are usually implemented with proprietary equipment procured from manufacturers chosen by the cellular/PCS service providers. In contrast, the cellular air interfaces are documented in open (public) standards complying with FCC regulations.

Cellular/PCS standards in the US are generated by the TIA and T1P1, then finally approved by the American National Standards Institute (ANSI). Four standards provide most of the cellular service in the US. Three of the four standards operate in the 850-MHz cellular band. Three different standards operate in the 1.9-GHz PCS band. An obvious disadvantage of multiple air interface standards, and two frequency bands, is the difficulty encountered by "roaming" mobile stations when they enter non-home systems. This problem has necessitated the design of higher cost "dual-band, multi-mode" mobile stations. The four standards are:

- **AMPS (Advanced Mobile Phone Service)** — AMPS was the first cellular system in the US. Service commenced in October 1983 in Chicago. AMPS was standardized by the TIA as IS-553. AMPS is an FDMA (Frequency Division Multiple Access) system that means that user channels are separated by frequency. (Amateur Radio currently uses FDMA.) The channel spacing is 30 kHz, which allows 832 FDD channels in each 25-MHz band near 850 MHz. AMPS, is an analog/digital system. Voice uses analog PM (Phase Modu-

lation) with a peak frequency deviation of ± 12 kHz. Digital system control, e.g. call setup and handoff, uses 10 kbit/s binary FM (Frequency Modulation) with a peak frequency deviation of ± 7 kHz. There is no digital service provided to the users. A user-provided modem must be attached to the mobile station. At this time, most US cellular customers still use AMPS. (See Ref. 1 at the end of this chapter for a description of a typical AMPS base station.) By 1986, there was already worry that AMPS service might soon become saturated in city centers. There was a competitive effort to design new cellular air interfaces with increased spectral efficiency — more user channels per MHz. It was decided that all future cellular systems must be digital.

There are many advantages to digital transmission above the obvious benefit to users requiring data transmission services. Unfortunately, there are a few disadvantages. Digital has a sharp threshold, so there are no “fringe” coverage areas. The received signal is either excellent, or absent. Digital requires the use of low-bit-rate voice coders and their associated artifacts. Wireline digital transmission systems encode voice using 64 kbit/s PCM (Pulse Code Modulation) waveform coders that provide nearly distortion-free coding. Since 64 kbit/s PCM cannot fit into the narrowband radio channels, a number of low rate, e.g. 8 kbit/s, coders have been devised. Most use the CELP principle that emulates a single human voice tract. Strange sounds may appear at the receiver when the CELP coder is driven by multiple voices, music or background noises. See Ref. 3 at the end of this chapter for a description of CELP and other voice coders.

- **TDMA (Time Division Multiple Access)** — TDMA was the first all-digital US cellular system. TDMA service started in the late 1980s. It was standardized by the TIA as IS-54 and provided three times the traffic capacity of an AMPS system. It was designed to gradually replace AMPS. The channel spacing was kept at 30 kHz so that TDMA channels could be mixed with AMPS channels. Within each 30 kHz frequency channel are placed three time-divided digital channels. Thus, “TDMA” is actually a hybrid TDMA/FDMA system. QPSK (Quadrature Phase Shift Keying) modulation is used which provides a “raw” channel bit rate of 48.6 kbit/s. The raw user bit rate is $48.6/3 = 16.1$ kbit/s. After bit error control techniques are applied, each user is provided an almost error free 8 kbit/s data service or 8 kbit/s VSELP (a version of CELP) voice coder service. An upbanded version of TDMA, with en-

hanced features, operates in the 1.9 GHz PCS band. It is standardized as IS-136.

- **CDMA (Code Division Multiple Access)** — By 1986, some in the cellular industry believed that CDMA techniques would provide more capacity than TDMA. In the US, CDMA was standardized by the TIA as IS-95. CDMA uses the same up and down bands as AMPS and TDMA, but channel spacing is 1.25 MHz. CDMA separates the user bit streams by digital codes.

More than 40 users can occupy the same 1.25 MHz frequency channel at the same time. The “raw” bit rate provided to each user is 28.8 kbit/s. After bit error control, each user is given a 9.6 kbit/s data channel or 13 kbit/s QCELP (a version of CELP) voice service. In this direct-sequence type of CDMA transmitter, the incoming user-generated bit stream (either digital voice or data) is multiplied (exclusive-OR) with a 1.2288 Mbit/s pseudo-random digital spreading code. Each user is given a unique code. The 1.2288 Mbit/s multiplier output bit stream enters a QPSK modulator, and is then amplified and transmitted with a spreaded RF bandwidth near 1.25 MHz.

In the CDMA receiver, the incoming mixed signal — received from all of the active users—is multiplied by the desired user’s unique code that is synchronized with the transmitter code (a challenging task). Only the desired user’s de-spreaded 28.8 kbit/s bit stream will emerge from the multiplier. The other codes emerge as wideband noise that is eliminated by a low-pass filter.

Tight mobile-station, transmit-power control must be used for the CDMA system uplink to achieve its expected capacity. All mobile station transmissions received at the base station should be within a few dB of each other. To achieve this severe requirement, mobile station power output is updated 800 times per second by a base station-generated 800 bit/s power control data stream interspersed into the downlink 28.8 kbit/s data stream.

It is difficult to calculate the user capacity of a CDMA system. The per-channel spectral efficiency of CDMA (40 bit streams in 1.25 MHz) is comparable with AMPS (40 channels in 1.20 MHz). However, CDMA is so resistant to co-channel interference that all CDMA radio channels can be used in all cells ($n = 1$). Therefore, there is a traffic capacity increase of at least seven times that of a standard AMPS system. An upbanded version of CDMA, with enhanced features, operates in the 1.9-GHz PCS band. It is standardized as IS-95A.

- **GSM/PCS-1900** — GSM (Global System for Mobile Communications) was imported from Europe in the mid 1990s. In the

US it operates only in the 1.9 GHz US PCS band. It was standardized by the T1P1 as J-STD-007. It is a TDMA/FDMA system. Frequency channel spacing is 200 kHz and the channel bit rate is 270 kbit/s. GMSK (Gaussian Mean Shift Keying), a type of narrowband binary FM, is the modulation method. There are eight time slots in each RF channel, so the user raw bit rate is $270/8 = 33.75$ kbit/s. After bit error control, each user is provided a 9.6 kbit/s data channel or a 13 kbit/s RPE-LTP (Regular Pulse Excited-Long Term Prediction) voice coder for voice. The spectral efficiency of GSM (8 bit streams in 200 kHz) is only slightly better than AMPS (8 channels in 240 kHz). This weakness is mitigated by using $n = 4$, a layout tolerated by the more interference-resistant GSM digital transmission. Thus, GSM can handle about twice as much traffic capacity as AMPS.

Radio Link Operating Protocols

The AMPS system uses three protocols for system communication between the base station and the mobile station:

- **PAGING** — At least one channel in each cell is used for paging mobiles with incoming calls from the MTSO. A downlink paging bit stream, the same in each cell, is continuously monitored by power-ON, non-active mobile stations. When a mobile station recognizes its user number, it responds on the uplink-paging channel. The paging stream then hands off the mobile station to a setup channel. Conversely, the mobile station originates a call by sending its request on the uplink-paging channel.

- **SETUP** — At least three channels are used in each cell for setup; the mobile station-base station link sets up and tears down calls. After the two-way setup procedure is finished, the mobile station is commanded to tune to its assigned voice channel. Mobile authentication is performed during setup. Each mobile station has a NAM (Numeric Address Module) and an ESN (Electronic Serial Number). The NAM contains the user’s telephone number. The manufacturer-assigned ESN is unique. At setup, the MTSO verifies that the NAM and ESN numbers are valid.

- **LOCATION AND HANDOFF** — While an active mobile station is linked to its serving base station, its radio signal strength is also being periodically monitored by the six surrounding base stations. When the averaged signal strength at a neighboring base station exceeds that measured at the serving station, the MTSO commands a handoff to the neighbor. This handoff procedure allows un-interrupted trans-mission as the mobile station moves through the cell cluster. Handoff is accomplished by a “blank-and-burst” procedure. The down-link voice

channel is interrupted, and a brief 10 kbit/s digital message commands the mobile to move to its newly assigned frequency channel. The mobile station acknowledges, via blank-and-burst on the uplink voice channel, then tunes to the newly assigned channel. If handoff fails, the call is terminated.

The TDMA, CDMA and GSM digital systems use similar procedures. DSP (digital signal processing) techniques provide better authentication and user privacy. Details are found in Ref. 2 at the end of this section.

Virtual Private Network

A Virtual Private Network is created when a mobile user connects a data terminal to a foreign network, either via dial-in or public networks, and establishes a presence equivalent to a direct connection to the home network.

The Wireless Mobile IP solution is intended to enable the creation of Virtual Private Networks by using the Internet as the communications backbone to connect mobile users. The following features characterize Virtual Private Networks:

Remote presence — the ability to establish remote network connections and still appear to be connected to the home network.

Network independence — the ability to roam among networks (e.g., BellSouth Wireless Data Network, CDPD, Wireless LAN, Ethernet). Traditionally, IP network independence (roaming) is done over the same media access (e.g., SLIP, PPP, Ethernet). Virtual Private Network implementation offers the ability to roam across not only single media IP networks, but across multiple wireless and wireline media *without user intervention*.

Security — the ability to help create secure channels for authentication, data integrity, and data privacy.

Third Party Mobile IP — this solution is unique in that it provides wireless and wireline IP network and media roaming/communications to both Intranet and Internet services.

The ability for mobile users to roam seamlessly and without intervention among radio frequency (RF) networks and wireline networks allows the system to operate at maximum system efficiency.

MOBILE COMPUTING

With the rapid growth and availability of wireless data networks, wireless communications tools and Internet standards, mobile workers are finding new ways to do business in today's competitive environment. The need for the mobile worker to access mission-critical information requires access to corporate databases and Internet/Intranet

applications. In addition, convenient and reliable file transfer, integrated messaging, and personalized information delivery allow the mobile employee to work at peak productivity levels.

Successful communications between mobile workers and their corporate environment requires the right combination of technologies. From a business standpoint, these technologies must be cost-effective and easy to use. For long-term viability, they should be based on open system architectures and industry standard interfaces.

Virtual Private Networks have emerged to provide networking solutions to a growing mobile workforce. These networks allow businesses to provide their mobile employees with access to corporate information and applications by connecting them to the enterprise via the Internet. A Virtual Private Network provides a low cost extension to the enterprise while offering secure access to an open networking environment.

Mobile IP Security

Mobile IP is an Internet industry standard that enhances the IP protocol to remedy these existing problems and allow the transparent routing of IP datagrams to mobile nodes on the Internet. Security is an integral part of building a Virtual Private Network solution. The Wireless Mobile IP Network Configuration utilizes Mobile IP encryption to form a secure channel between the Wireless client and server to support user authentication, data integrity, and data privacy in mobile environments.

Using the Wireless Mobile IP encryption, a secure channel is formed which allows various foreign networks to become extensions of the home network.

Mobile IP Benefits

The Wireless Mobile IP solution is intended to enable enterprises to create their own Virtual Private Networks, thus providing:

- (1) Low initial costs
- (2) Low operating costs
- (3) Solution flexibility
- (4) Significant productivity gains

By providing seamless network roaming and communications capabilities, Mobile IP provides a networking solution to bring enterprises into the 21st century.

Many of the spread spectrum devices on the market today are listed as FCC Part 15 devices. There are three frequency bands allocated to this service:

- 902-928 MHz (26-MHz bandwidth)
- 2400-2483.5 MHz (83.5-MHz bandwidth)
- 5725-5850 MHz (125-MHz bandwidth)

Regulations

In 1999, the FCC greatly liberalized amateur spread spectrum rules, allowing spreading techniques not previously permitted. Amateurs are no longer limited to frequency hopping and direct sequence; any documented spreading code may now be utilized. Amateurs may now freely use SS devices designed under Part 15 of the Commission's rules for amateur applications as well, keeping in mind the identification requirements of the Amateur Service. The maximum power allowed for an amateur SS emission is now 100 watts, up from the previous limit of a single watt! However, stations that transmit more than one watt must utilize automatic power control to limit power output to the minimum necessary to communicate. For information on the rules change, see *ARRLWeb* at: www.arrl.org/news/stories/1999/09/08/2/. For the text of the rules, see Section 97.311 in *The ARRL FCC Rule Book*.

KEEPING CURRENT WITH WIRELESS

Changes to the wireless communications industry have been dramatic since the first mobile phone systems were introduced. The high-tech, expanding nature of this fascinating area will continue to drive new wireless communication developments. The following are some related Web sites where interested readers can keep up-to-date on this fast-paced technology:

PC Technology (Personal Computers in the Shack)

The Personal Computer debuted in 1980 with offerings by Commodore (PET), Tandy (TRS-80) and Apple (Apple II). Almost immediately, hams found them to be useful additions to the shack. These first computers were little more than a 4-MHz processor with a little RAM (4kB) an audio tape drive and an imbedded *BASIC* operating system. One of the first applications available for hams was an RTTY decoder. The age of digital modes for hams was about to expand exponentially.

As the photo in **Fig 24.6** indicates, today the PC is an important part of any radio station. In most cases, it is the control center of the various pieces of equipment we use. In an extreme example, you can use it to download from the web the test questions to take your exam, learn the code, design your antennas, and even search ebay or QRZ.com to buy a radio. It can control the radio, provide various digital modes through the use of the sound card, connect to the Internet for solar flux numbers to compute which bands have propagation, use TELNET for packet spots to help find a DX station, provide software to log the QSO and keep track of award progress, and finally assist the operator in finding the QSL route to complete the process (or in the case of the new Logbook of The World (LoTW) upload the QSO to the ARRL site and perhaps have that confirmation in hours). What could be a more important tool to the operator?

ERGONOMICS

Since the computer will connect to most of your equipment, it is usually found in the center of the operating arena. A tower unit on the floor will give it some distance from the RF generators and keep the desktop free for equipment that you need to handle. A

well-designed station will have the keyboard, mouse and keyer (assuming you are a CW op!) all within a 45-degree arc on either side of your operating chair. Use of an LCD monitor will preserve more space on your desk as well as produce less RF in the shack.

HARDWARE

The computer itself should have a minimum of 256 MB of memory (more is better), hard drive with 40 GB minimum space, a rewritable CD, two serial ports, and a sound card. Serial ports are becoming a thing of the past; newer PCs have replaced them with USB ports. However, there are now many commercial USB-to-Serial Converter devices that allow you to still connect older DB9-serial devices to the newer PCs. If you are connecting your station to the Internet (recommended), you also need to consider a modem or Ethernet port depending on your Internet service provider. To save space on the operating table, locate your PC on the floor if possible (tower) and use an LCD display to preserve maximum desk space — and be less of a heat source.

One of the first things to consider is interference from the radio to the PC or from the PC to the radio. If your radio is properly grounded, your antennas at a proper distance from the shack, and you use well-shielded cables, the chance of RF getting into your PC is remote. It is also good practice to try to keep your radios and computer equipment on separate power circuits.

Receiving computer-generated RF in your radios is often the result of poorly designed monitors or leakage from the monitor cables. Whenever adding new

computer equipment into the shack it is good to immediately scan the bands to find any new birdies or new noise. Should there be any, shutting off the monitor and then the computer will isolate which of the two pieces of equipment are at fault. In many cases, the installation of toroids on the monitor cable and all cables (power, speaker, CAT, Keyboard or Microphone) that are a source of radiating will eliminate the problem.

Most modern radios have a CAT (Computer Access Terminal) port that is a serial 9 pin (MINIDIN9). Some older radios required a computer interface device that was usually RS232 based. Yet other radios use DIN6 or CI-V interface devices. Complicating the interface issue is the trend to USB ports instead of serial ports. Fortunately, the commercial ham market has kept up with the lack of standards with a host of good USB to Radio Port products. MicroHam is one such source (www.microham.com) covering just about all the USB wiring possibilities. The basic commands to control your radio are available from the radio manufacturer's Web sites. Third-party software applications all support these functions and are discussed in detail below.

Your computer sound card can act as a digital modem enabling you to operate FSK, PSK, SSTV, FAX and other digital modes. However, you also will find the need for a direct-controlled interface to key the transmitter in response to signals over the serial port's RTS or DTR pins. The interface should also include an attenuator to simplify the connection between the computer sound card and the transceiver microphone jack. This type of interface may also be used to connect your

Fig 24.6 — Don, N1DG, and his computer-enriched operating station.

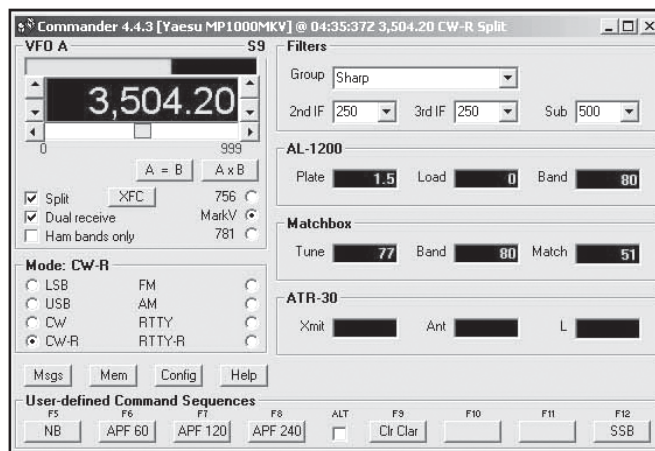

Fig 24.7 — The DXLAB Commander Control Panel.

computer to your radio for Echolink or IRLP operation. The RIGblaster from West Mountain Radio is one of several commercial products for this.

Lastly, most logging and contest software generates Morse code. Connecting the output of the radio to the input of the sound card is simple enough with a stereo cable. However, be sure to isolate the two devices with an isolation transformer in the cable (such as a RadioShack 273-1374) to prevent 60-Hz hum from arriving with the signal. The output from the PC to the radio can come either from a parallel or serial port. There are several commercial products available, the best for parallel ports being from Jack Shuster, W1WEF. Two suppliers of interfaces are N3JT (n3jt@arri.net) and W1WEF (w1wef@arri.net).

The recent introduction of *Windows XP* further complicates the software output to serial or parallel ports. *WinXP* no longer allows programs direct access to them. However, there are two shareware programs — *Directio* and *Userport* — that will install drivers on your operating system to allow most ham logging and modem software to reach the ports. Both are free downloads at www.embeddedtronics.com/design&ideas.html.

SOFTWARE

Radio Control Software

One of the most popular free programs is *Commander*, (www.qsl.net/civ_commander/) by DXLab Software. It is one of many shareware modules by DXLabs and this specific program interfaces with the recent radios from Ten-Tec, ICOM, Kenwood and Yaesu.

Through its graphical interface shown in **Fig 24.7**, a click of the mouse allows you to set filters, frequency ranges pursuant to your license class, memories for favorite frequencies and customization for the way you want your radio setups. All the logging programs listed below have rig control as part of their logging features. However, most of the general logging programs do not have the ability to set filters and menu items as *Commander* does (see **Fig 24.7**). They are designed for other things.

Logging Software

In 1986, two logging programs appeared for *MS-DOS*-based PCs that would inaugurate an easier way of keeping track of operating awards and contest scoring. The first, the *WB2DND Log Database*, was built around *DBASE III* and became popular among DXers and DXpeditioners. At the same time, K1EA

introduced *CT*. Computerized logging enabled faster contacts, more accurate recording of those contacts, easy scoring and simple QSL management. Today's logging software not only logs, but it controls the radios, uses the sound card to send and decode digital mode transmissions, and even interfaces to packet-spotting networks via VHF packet or Internet nodes.

In 1996, the CEØZ and VKØHI expeditions took computer logging to the next level by posting their logs on their Web sites during the DXpeditions so hams could check their progress while the DXpeditions were still in progress. In order to standardize the format among the many logging programs that appeared over the last 15 years, two standards emerged to allow for the easy use of the information being collected. General logging programs now allow you to export your data in a format known as ADIF (Amateur Data Interface Format), which allows you to use multiple programs and move data among them and share log data with friends or QSL Managers. You never need to worry about obsolescence of your data. If your publisher goes out of business, or no longer supports new platforms, you can choose from a large selection of other programs that will load your logs without retyping everything.

The second format has been written and is used by contesters to submit their scores to the various organizations sponsoring the contests. This format is known as Cabrillo and is available on all contest software today. By submitting all contest logs in a standard format, adjudicators can link the logs with a common database and quickly see errors for scoring adjustments.

It is worth noting that both current general logging programs and contest software also handle both of these standards to make transferring the contest logs into the general logging programs for award tracking.

LoTW

No discussion of general logging and the award tracking can be complete without a discussion of the latest development in this area. In 2003, the ARRL launched a web-based depository of QSO data called the *Logbook of The World (LoTW)*. The purpose is to electronically verify QSLs and provide those certified QSLs for its award programs (and eventually other ham-organization award programs). *LoTW* has its own website (www.arri.org/lotw/default) that is password protected. Membership is free but digital certificates and passwords are issued only after licensing, and user details are

verified by mail to the address of the licensee. This assures that the data submitted is actually done so by the operator.

The free software to obtain your certificate (called *TQSL*), and instructions, are downloadable from www.arri.org/lotw/#download. Once receiving a digital certificate, the Cabrillo or ADIF logs can be *signed* and uploaded over the web to the database. The software automatically matches your data to the database and shows your QSLs in a variety of formats. In the first six months since the web site went live, 7,000 users have uploaded over 40 million QSO records resulting in QSL matches of over 1.2 million records.

Logging/Contesting Software

Some of today's popular logging/contesting software packages include:

CT (ConTest, by K1EA) Web site:

k1ea.com

Contest logger for DOS/Win85/98/2000 Freeware

Dxbase (by Scientific Solutions). Web

site: dxbase.com/proddxbw.htm

General logging software for Win95/98 and Windows/NT/2000 \$90

DX4WIN (by KK4HD). Web site:

dx4win.com/

General logging software for Win95/98/ME/XP/2000/NT \$99.

EasyLog (by Microware Software). Web

site: easylog.com/eng/index.htm

Windows full-featured logging software \$89.54.

HC Log (Buckmaster Publishing). Web

site: <http://hamcall.net>

Logging software integrated to work with *HamCall* CD-ROM.

Logic 7 (Personal Database Applica-

tions, Inc.). Web site: hosenose.com

Windows full-featured logging software \$129.

MiLOG (SA Engineering). Web site:

logwindow.com

Contesting software for Windows \$69.95.

NA (by K8CC). Web site:

datomonline.com

Contest logger for DOS \$60.

N1MM Logger (by N1MM, AB5K,

PA3CEF, G4UJS, N7ZFI, N2AMG).

Web site: <http://pages.ctime.net/n1mm/>

Contest logger for 95/98/ME/NT/2000/XP Freeware.

N3FJP Software. Web site: n3fjp.com

Windows-based logging/contesting software. Various prices by contest/version.

ProLog2K (by W5VP) Web site: prolog2k.com/
General logging software for Win95/98/ME/2000/NT/XP \$50.

SWISSLOG (by HB9BJS) Web site: informatix.li/english/Frame_EN.htm
General logging software for Win95/98/ME/NT4/2000/XP 70 Euros.

TR Log (by N6TR) Web site: qth.com/tr/
Contest logger for DOS \$75.

VHF log (by W3KM) Web site: <http://www.qsl.net/w3km/features.htm>
VHF contest logger With CW/PTT/DVK for Win98, ME, 2000 or XP. Freeware.

WinEQF (by N3EQF) Web site: eqf-software.com
General logging Program for Win95/98, ME, NT, XP, or Win2K \$59.95.

WriteLog (by W5XD) Web site: writelog.com/
Contest logging software for Win95/98, NT, Win2K \$75.

This list is by no means complete but it will give you a start to explore the products available based on your interests.

PACKETCLUSTER AND AR CLUSTER

During the late 1980s, Dick Newell, AK1A, developed PacketCluster software to link PCs together via VHF radios to DX-related information. Now 15 years later, the software is still in use, but is slowly being replaced by Internet-based Telnet software such as AR Cluster, DX Spider, CLX, DxNet, Clusse, and WinCluster.

These software servers enable users to announce and receive DX spots, general information announcements, and send personal talk messages and email. Almost all logging software today has Telnet software built in to interface to the Internet nodes and retrieve Cluster spots.

AR Cluster (developed by AB5K) allows the user to tailor the information he receives. Since it is an SQL Database, the

user can query that database in an almost unlimited way. SH/DX commands can be by call, band, mode, DX Country, State or Country of the spotter, the node the spot came from, DTS (Date/Time stamp), ITU or CQ Zone, or even from a comment associated with the spot. Further, the inquiry can be any one or all of the above parameters. Looking for the last 50 spots for a DXpedition is as simple as sh/dx/50 CALLSIGN. The user can also set specific filters for his use so that spots sent to him are set to the specific parameters he has set for his call. A VHF-only user does not need to see HF spots. Spots outside of licensed frequencies can be ignored, etc. The AR-Cluster user manual can be read at www.ab5k.net/ArcDocs/UserManual/ArcUserManual.htm.

One of the best sources of Telnet Ham radio sites is maintained by K6PBT on his website <http://telnet.dxcluster.info/>.

MODE-SPECIFIC SOFTWARE

The ability of using the sound card as a modem has enabled hams to operate many digital modes without addition equipment. Software has emerged that generate and decode these modes and in some cases even log the contacts made. While some of the logging software listed earlier includes mode decoding routines, the most feature-rich software is mode specific. Some popular programs in this software category:

Multi-Modes:

Test Procedures

This chapter, written by ARRL Technical Advisor Doug Millar, K6JEY, covers the test equipment and measurement techniques common to Amateur Radio. With the increasing complexity of amateur equipment and the availability of sophisticated test equipment, measurement and test procedures have also become more complex. There was a time when a simple bakelite cased volt-ohm meter (VOM) could solve most problems. With the advent of modern circuits that use advanced digital techniques, precise readouts and higher frequencies, test requirements and equipment have changed. In addition to the test procedures in this chapter, other test procedures appear in Chapters 10 and 11.

TEST AND MEASUREMENT BASICS

The process of testing requires a knowledge of what must be measured and what accuracy is required. If battery voltage is measured and the meter reads 1.52 V, what does this number mean? Does the meter always read accurately or do its readings change over time? What influences a meter reading? What accuracy do we need for a meaningful test of the battery voltage?

A Short History of Standards and Traceability

Since early times, people who measured things have worked to establish a system of consistency between measurements and measurers. Such consistency ensures that a measurement taken by one person could be duplicated by others — that measurements are reproducible. This allows discussion where everyone can be assured that their measurements of the same quantity would have the same result. In most cases, and until recently, consistent measurements involved an artifact: a physical

object. If a merchant or scientist wanted to know what his pound weighed, he sent it to a laboratory where it was compared to the official pound. This system worked well for a long time, until the handling of the standard pound removed enough molecules so that its weight changed and measurements that compared in the past no longer did so.

Of course, many such measurements depended on an accurate value for the force of gravity. This grew more difficult with time because the outside environment— such things as a truck going by in the street — could throw the whole procedure off. As a result, scientists switched to physical constants for the determination of values. As an example, a meter was defined as a stated fraction of the circumference of the Earth over the poles.

Generally, each country has an office that is in charge of maintaining the integrity of the standards of measurement and is responsible for helping to get those standards into the field. In the United States that office is the National Institute of Standards and Testing (NIST), formerly the

National Bureau of Standards. The NIST decides what the volt and other basic units should be and coordinates those units with other countries. For a modest fee, NIST will compare its volt against a submitted sample and report the accuracy of the sample. In fact, special batteries arrive there each day to be certified and returned so laboratories and industry can verify that their test equipment really does mean 1.527 V when it says so.

Basic Units: Frequency and Time

Frequency and time are the most basic units for many purposes and the ones known to the best accuracy. The formula for converting one to the other is to divide the known value into 1. Thus the time to complete a single cycle at 1 MHz = 0.000001 s.

The history of the accuracy of time keeping, of course, begins with the clock. Wooden clocks, water clocks and mechanical clocks were ancestors to our current standard: the electronic clock based on frequency. In the 1920s, quartz crystal controlled clocks were developed in the laboratory and used as a standard. With the

Table 25.1
Standard Frequency Stations

(Note: In recent years, frequent changes in these schedules have been common.)

<i>Call Sign</i>	<i>Location</i>	<i>Frequency (MHz)</i>
BSF	Taiwan	5, 15
CHU	Ottawa, Canada	3.330, 7.335, 14.670
FFH	France	2.500
IAM/IBF	Italy	5.000
JJY	Japan	2.5, 5, 8, 10, 15
LOL	Argentina	5, 10
RID	Irkutsk	5.004, 10.004, 15.004
RWM	Moscow	5, 4.996, 9.996, 14.996
WWV/WWVH	USA	2.5, 5, 10, 15, 20
VNG	Australia	2.5, 5
ZSC	South Africa	4.291, 8.461, 12.724 (part time)

advent of radio communication time intervals could be transmitted by radio, and a very fundamental standard of time and frequency could be used locally with little effort. Today transmitters in several countries broadcast time signals on standard calibrated frequencies. **Table 25.1** contains the locations and frequencies of some of these stations.

In the 1960s, Hewlett-Packard began selling self-contained time and frequency standards called cesium clocks. In a cesium clock a crystal frequency is generated and multiplied to microwave frequencies. That energy is passed through a chamber filled with cesium gas. The gas acts as a very narrow band-pass filter. The output signal is detected and the crystal oscillator frequency is adjusted automatically so that a maximum of energy is detected. The output of the crystal is thus linked to the stability of the cesium gas and is usually accurate to several parts in 10^{-12} . This is much superior to a crystal oscillator alone; but at close to \$40,000 each, cesium frequency standards are a bit extravagant for amateur use.

A rubidium frequency standard is an alternative to the cesium clock. They are not quite as accurate as the cesium, but they are much less expensive, relatively quick to warm up and can be quite small. Older models occasionally appear surplus. As with any precision instrument, it should be checked over and calibrated before use.

Most hams do not have access to cesium or rubidium standards—or need them. Instead we use crystal oscillators. Crystal oscillators provide three levels of stability. The least accurate is a single crystal mounted on a circuit board. The crystal frequency is affected by the temperature environment of the equipment, to the extent of a few parts per million (ppm) per degree Celsius. For example, the frequency of a 10-MHz crystal with temperature stability rated at 3 ppm might vary 60 Hz when temperature of the crystal changes by 2°C. If the crystal oscillator is followed by a frequency multiplier, any variation in the crystal frequency is also multiplied. Even so, the accuracy of a simple crystal oscillator is sufficient for most of our needs and most amateur equipment relies on this technique. For a discussion of crystal oscillators and temperature compensation, look in the

Oscillators and Synthesizers chapter of this *Handbook*.

The second level of accuracy is achieved when the temperature around the crystal is stabilized, either by an “oven” or other nearby components. Crystals are usually designed to stabilize at temperatures far above any reached in normal operating environments. These oscillators are commonly good to 0.1 ppm per day and are widely used in the commercial two-way radio industry.

The third accuracy level uses a double oven with proportional heating. The two ovens compensate for each other automatically and provide excellent temperature stability. The ovens must be left on continuously, however, and warm-up requires several days to two weeks.

Crystal *aging* also affects frequency stability. Some crystals change frequency over time (age) so the circuit containing the crystal must contain components to compensate for this change. Other crystals become more stable over time and become excellent frequency standards. Many commercial laboratories go to the expense of buying and testing several examples of the same oscillator and select the best one for use. As a result, many surplus oscillators are surplus for a reason. Nevertheless, a good stable crystal oscillator can be accurate to 1×10^{-9} per day and very appropriate for amateur applications.

Time and Frequency Calibration

Many hams have digital frequency counters, which range from surplus lab equipment to new highly integrated instruments with nearly everything on one chip. Almost all of these are very precise and display nine or more digits. Many are even quite stable. Nonetheless, a 10-MHz oscillator accurate to 1 ppm per month can vary ± 10 Hz in one month. This drift rate may be acceptable for many applications, but the question remains: How accurate is it?

This question can be answered by calibrating the oscillator. There are several ways to perform this calibration. The most accurate method compares the unit in question by leaving the oscillator operating, transporting it to an oscillator of known frequency and then making a comparison. A commonly used comparison

method connects the output of the calibrated oscillator into the horizontal input of a high frequency oscilloscope, and the oscillator to be measured to the vertical input. It helps, but they need not be on the same frequency. By noting how long it takes the sine wave to travel one division at a given sweep speed, one can calculate the resulting drift in parts per million per minute (ppm/min).

Another technique of oscillator calibration uses a VLF phase comparator. This is a special direct-conversion receiver that picks up the signal from WWVB on 60 kHz. Phase comparison is used to compare WWVB with the divided frequency of the oscillator being tested. Many commercial units have a small strip chart printer attached and switches to determine the receiver frequency. Since these 60-kHz VLF Comparator receivers have been largely replaced by units that use Loran signals or rubidium standards, they can be found at very reasonable prices. A very effective 60-kHz antenna can be made by attaching an audio transformer with the low-impedance winding connected to the receiver antenna terminals by way of a series dc blocking capacitor. The high-impedance winding is then connected between ground and a random length of wire. A typical VLF Comparator can track an oscillator well into a few parts in 10^{-10} . This technique directly compares the oscillator with an NIST standard and can even characterize oscillator drift characteristics in ppm per day or week.

Another fairly direct method compares an oscillator with one of the WWV HF signals. The received signal is not immensely accurate, but if the oscillator of a modern HF transceiver is carefully compared, it will be accurate enough for all but the most demanding work.

The last and least accurate way to calibrate an oscillator is to compare it with another oscillator or counter owned by you or another local ham. Unless the calibration of the other oscillator or counter is known, this comparison could be very misleading. True accuracy is not determined by the label of a famous company or impressive looks. Metrologists (people who calibrate and measure equipment) spend more time calibrating oscillators than any other piece of equipment.

DC Instruments and Circuits

This section discusses the basics of analog and digital dc meters. It covers the design of range extenders for current, voltage and resistance; construction of a simple meter; functions of a digital voltmeter (DVM) and procedures for accurate measurements.

Basic Meters

In measuring instruments and test equipment suitable for amateur purposes, the ultimate readout is generally based on a measurement of direct current. There are two basic styles of meters: analog meters that use a moving needle display, and digital meters that display the measured values in digital form. The analog meter for measuring dc current and voltage uses a magnet and a coil to move a pointer over a calibrated scale in proportion to the current flowing through the meter.

The most common dc analog meter is the D'Arsonval type, consisting of a coil of wire to which the pointer is attached so that the coil moves (rotates) between the poles of a permanent magnet. When current flows through the coil, it sets up a magnetic field that interacts with the field of the magnet to cause the coil to turn. The design of the

instrument normally makes the pointer move in direct proportion to the current.

Digital Multimeters

In recent years there has been a flood of inexpensive digital multimeters (DMMs) ranging from those built into probes to others housed in large enclosures. They are more commonly referred to as digital voltmeters (DVMs) even though they are multimeters; they usually measure voltage, current and resistance. After some years of refining circuits such as the "successive approximation" and "dual slope" methods, most meters now use the dual-slope method to convert analog voltages to a digital reading. DVMs have basically three main sections as shown in **Fig 25.1**.

The first section scales the voltage or current to be measured. It has four main circuits:

- a chain of multiplier resistors that reduce the input voltage to 0-1 V,
- a converter that changes 0-1 V ac to dc,
- an amplifier that raises signals in the 0-100 mV range to 0-1 V and
- a current driver that provides a constant current to the multiplier chain for resistance measurements.

The second section is an integrator. It is usually based on an operational amplifier that is switched by a timing signal. The timing signal initially shorts the input of the integrator to provide a zero reference. Next a reference voltage is connected to charge the capacitor for a determined amount of time. Finally the last part of the timing cycle allows the capacitor to discharge. The time it takes the capacitor to discharge is proportional to either the input voltage (V_{in} , after it was scaled into the range of 0 to 1 V) or $1 - V_{in}$, depending on the meter design. This discharge time is measured by the next section of the DVM, which is actually a frequency counter. Finally, the output of the frequency counter is scaled to the selected range of voltage or current and sent to the final section of the DVM — the digital display.

Since the timing is quite fast and the capacitor is not used long enough to drift much in value, the components that most determine accuracy are the reference voltage source and the range multiplier resistors. With the availability of integrated resistor networks that are deposited or diffused onto the same substrate, drift is

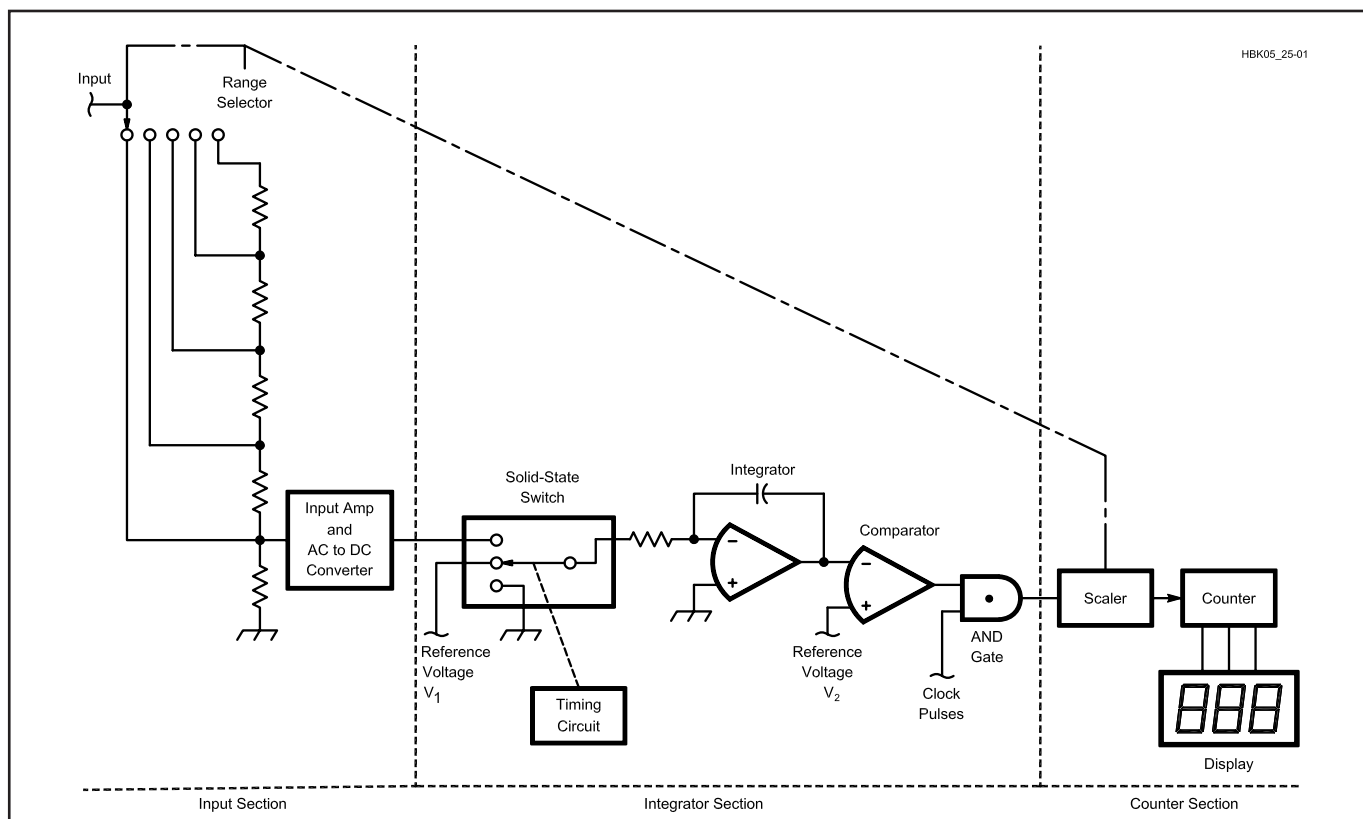

Fig 25.1 — A typical digital voltmeter consists of three parts: the input section for scaling, an integrator to convert voltage to pulse count, and a counter to display the pulse count representing the measured quantity.

automatically compensated because all branches of a divider drift in the same direction simultaneously. The voltage sources are generally Zener diodes on substrates with accompanying series resistors. Often the resistor and Zener have opposite temperature characteristics that cancel each other. In more complex DVMs, extensive digital circuitry can insert values to compensate for changes in the circuit and can even be automatically calibrated remotely in a few moments.

Liquid crystal displays (LCD) are commonly used for commercial DVMs. As a practical matter they draw little current and are best for portable and battery-operated use. The usual alternative, light emitting diode (LED) displays, draw much more current but are better in low-light environments. Some older surplus units use gas plasma displays (orange-colored digits). You may have seen plasma displays on gas-station pumps. They are not as bright as LEDs, but are easier to read. On the down side, plasma displays require high-voltage power supplies, draw considerable current and often fail after 10 years or so.

The advantages of DVMs are high input resistance (10 M Ω on most ranges), accurate and precise readings, portability, a wide variety of ranges and low price. There is one disadvantage, however: Digital displays update rather slowly, often only one to two times per second. This makes it very difficult to adjust a circuit for a peak (maximum) or null (minimum) response using only a digital display. The changing digits do not give any clue of the measurement trend and it is easy to tune through the peak or null between display updates. In answer, many new DVMs are built with an auxiliary bar-graph display that is updated constantly, thus providing instantaneous readings of relative value and direction of changes.

Current Ranges

The sensitivity of an analog meter is usually expressed in terms of the current required for full-scale deflection of the pointer. Although a very wide variety of ranges is available, the meters of interest in amateur work give maximum deflection with currents measured in microamperes or milliamperes. They are called microammeters and milliammeters, respectively.

Thanks to the relationships between current, voltage and resistance expressed by Ohm's Law, it is possible to use a single low-range instrument (for example, 1 mA or less for full-scale pointer deflection) for a variety of direct-current measurements. Through its ability to measure current, the instrument can also be used indirectly to

measure voltage. In the same way, a measurement of both current and voltage will obviously yield a value of resistance. These measurement functions are often combined in a single instrument: the volt-ohm-milliammeter or VOM, a multirange meter that is one of the most useful pieces of test equipment an amateur can possess.

Accuracy

The accuracy of a D'Arsonval-movement dc meter is specified by the manufacturer. A common specification is $\pm 2\%$ of full scale, meaning that a 0-100 μA meter, for example, will be correct to within 2 μA at any part of the scale. There are very few cases in amateur work where accuracy greater than this is needed. When the instrument is part of a more complex measuring circuit, however, the design and components can each cause error that accumulates to reduce the overall accuracy.

Extending Current Range

Because of the way current divides between two resistances in parallel, it is possible to increase the range (more specifically to decrease the sensitivity) of a dc current meter. The meter itself has an inherent resistance (its internal resistance) which determines the full-scale current passing through it when its rated voltage is applied. (This rated voltage is on the order of a few millivolts.) When an external resistance is connected in parallel with the meter, the current will divide between the two and the meter will respond only to that part of the current that flows through its movement. Thus, it reads only part of the total current; the effect makes more total current necessary for a full-scale meter reading. The added resistance is called a "shunt."

We must know the meter's internal resistance before we can calculate the value for a shunt resistor. Internal resistance may vary from a fraction of an ohm to a few thousand ohms, with greater resistance values associated with greater sensitivity. When this resistance is known, it can be used in the formula below to determine the required shunt for a given multiplication:

$$R = \frac{R_m}{n - 1} \quad (1)$$

where

- R = shunt resistance, ohms
- R_m = meter internal resistance, ohms
- n = the factor by which the original meter scale is to be multiplied.

Often the internal resistance of a particular meter is unknown (when the meter

Fig 25.2 — This test setup allows safe measurement of a meter's internal resistance. See text for the procedure and part values.

is purchased at a flea market or is taken from a commercial piece of equipment, for example). Unfortunately, the internal resistance of a meter cannot be measured directly with an ohmmeter without risk of damage to the meter movement.

Fig 25.2 shows a method to safely measure the internal resistance of a linearly calibrated meter. It requires a calibrated meter that can measure the same current as the unknown meter. The system works as follows: S1 is switched off and R2 is set for maximum resistance. A supply of constant voltage is connected to the supply terminals (a battery will work fine) and R2 is adjusted so that the unknown meter reads exactly full scale. Note the current shown on M2. Close S1 and alternately adjust R1 and R2 so that the unknown meter (M1) reads exactly half scale and the known meter (M2) reads the same value as in the step above. At this point, half of the current in the circuit flows through M1 and half through R1. To determine the internal resistance of the meter, simply open S1 and read the resistance of R1 with an ohm-meter.

The values of R1 and R2 will depend on the meter sensitivity and the supply voltage. The maximum resistance value for R1 should be approximately twice the expected internal resistance of the meter. For highly sensitive meters (10 μA and less), 1 k Ω should be adequate. For less sensitive meters, 100 Ω should suffice. Use no more supply voltage than necessary.

The value for minimum resistance at R2 can be calculated using Ohm's Law. For example, if the meter reads 0 to 1 mA and the supply is a 1.5-V battery, the minimum resistance required at R2 will be:

$$R2 = \frac{1.5}{0.001}$$

$$R2 \text{ (min)} = 1500 \Omega$$

In practice a 2- or 2.5-k Ω potentiometer would be used.

Making Shunts

Homemade shunts can be constructed from several kinds of resistance wire or from ordinary copper wire if no resistance wire is available. The copper wire table in the **Component Data and References** chapter of this *Handbook* gives the resistance per 1000 ft for various sizes of copper wire. After computing the resistance required, determine the smallest wire size that will carry the full-scale current, again from the wire table. Measure off enough wire to give the required resistance. A high-resistance 1- or 2-W carbon-composition resistor makes an excellent form on which to wind the wire, as the high resistance does not affect the value of the shunt. If the shunt gets too hot, go to a larger diameter wire of a greater length.

VOLTMETERS

If a large resistance is connected in series with a meter that measures current, as shown in **Fig 25.3**, the current multiplied by the resistance will be the voltage drop across the resistance. This is known as a multiplier. An instrument used in this way is calibrated in terms of the voltage drop across the multiplier resistor and is called a voltmeter.

Sensitivity

Voltmeter sensitivity is usually expressed in ohms per volt (Ω/V), meaning that the meter full-scale reading multiplied by the sensitivity will give the total resistance of the voltmeter. For example, the resistance of a 1 k Ω/V voltmeter is 1000 times the full-scale calibration voltage. Then by Ohm's Law the current required for full-scale deflection is 1 milliampere. A sensitivity of 20 k Ω/V , a commonly used value, means that the instrument is a 50- μA meter.

As voltmeter sensitivity (resistance) increases, so does accuracy. Greater meter

resistance means that less current is drawn from the circuit and thus the circuit under test is less affected by connection of the meter. Although a 1000- Ω/V meter can be used for some applications, most good meters are 20 k Ω/V or more. Vacuum-tube voltmeters (VTVMs) and their modern equivalent FET voltmeters (FETVOMs) are usually 10-100 M Ω/V and DVMs can go even higher.

Multipliers

The required multiplier resistance is found by dividing the desired full-scale voltage by the current, in amperes, required for full-scale deflection of the meter alone. To be mathematically correct, the internal resistance of the meter should be subtracted from the calculated value. This is seldom necessary (except perhaps for very low ranges) because the meter resistance is usually very low compared with the multiplier resistance. When the instrument is already a voltmeter with an internal multiplier, however, the meter resistance is significant. The resistance required to extend the range is then:

$$R = R_m (n - 1) \quad (2)$$

where

R_m = total resistance of the instrument
 n = factor by which the scale is to be multiplied

For example, if a 1-k Ω/V voltmeter having a calibrated range of 0 to 10 V is to be extended to 1000 V, R_m is $1000 \times 10 = 10$ k Ω , n is $1000/10 = 100$ and $R = 10,000 \times (100 - 1) = 990$ k Ω .

When extending the range of a voltmeter or converting a low-range meter into a voltmeter, the rated accuracy of the instrument is retained only when the multiplier resistance is precise. High-precision, hand-made and aged wire-wound resistors are used as multipliers of high-quality instruments. These are relatively expensive, but the home constructor can do well with 1% tolerance metal-film resistors. They should be derated when used for this purpose. That is, the actual power dissipated in the resistor should not be more than $1/10$ to $1/4$ the rated dissipation. Also, use care to avoid overheating the resistor body when soldering. These precautions will help prevent permanent change in the resistance of the unit.

Many DVMs use special resistor groups that have been etched on quartz or sapphire and laser trimmed to value. These resistors are very stable and often quite accurate. They can be bought new from various suppliers. It is also possible to "rescue" the divider/multiplier resistors from an older DVM that no longer functions and use them

as multipliers. Look for a series of four or five resistors that add up to 10 M Ω : 0.9, 9, 90, 900, 9,000, 90,000 and 900,000 Ω . There is usually another 1-M Ω resistor in series to isolate the meter from the circuit under test. A few of these high-accuracy resistors in "odd" values can help calibrate less-expensive instruments.

DC Voltage Standards

For a long time NIST has statistically compared a bank of special Weston Cell or cadmium sulfate batteries to arrive at the standard volt. By using a special tapped resistor, a 1.08-V battery can be compared to other voltages and instruments compared. However, these are very high-impedance batteries that deliver almost no current and are relatively temperature sensitive. They are made up of a solution of cadmium and mercury in opposite legs of an "H" shaped glass container. You can read much more about them in *Calibration—Philosophy and Practice*, published by the John Fluke Co of Mount Lake Terrace, Washington.

Hams often use an ordinary flashlight battery as a convenient voltage reference. A fresh *D cell* usually provides 1.56 V under no load, as would be measured by a DVM. The Heath Company, which supplied thousands of kits to the ham community for many years, used such batteries as the calibration references for many of their kits.

Recently, NIST has been able to use a microwave to voltage converter called a "Josephson Junction" to determine the value of the volt. The converter transfers the accuracy of a frequency standard to the accuracy of the voltage that comes out of it. The converter generates only 5 mV, however, which then must be scaled to the standard 1-V level. One problem with high-accuracy measurements is stray noise (low-level voltages) that creates a floor below which measurements are meaningless. For that reason, meters with five or more digits must be very quiet and any comparisons must be made at a voltage high enough to be above the noise.

DC MEASUREMENT CIRCUITS

Current Measurement with a Voltmeter

A current-measuring instrument should have very low resistance compared with the resistance of the circuit being measured; otherwise, inserting the instrument will alter the current from its value when the instrument is removed. The resistance of many circuits in radio equipment is high and the circuit operation is affected little, if at all, by adding as much as a few hun-

Fig 25.3 — A voltmeter is constructed by placing a current-indicating instrument in series with a high resistance, the "multiplier."

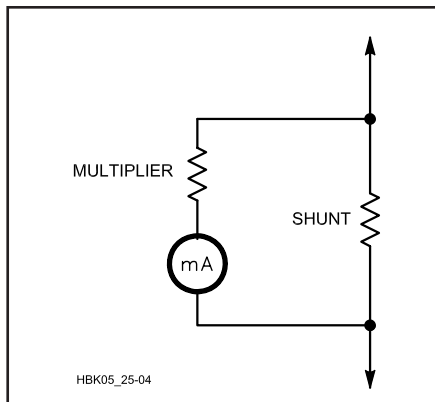

Fig 25.4 — A voltmeter can be used to measure current as shown. For reasonable accuracy, the shunt should be 5% of the circuit impedance or less, and the meter resistance should be 20 times the circuit impedance or more.

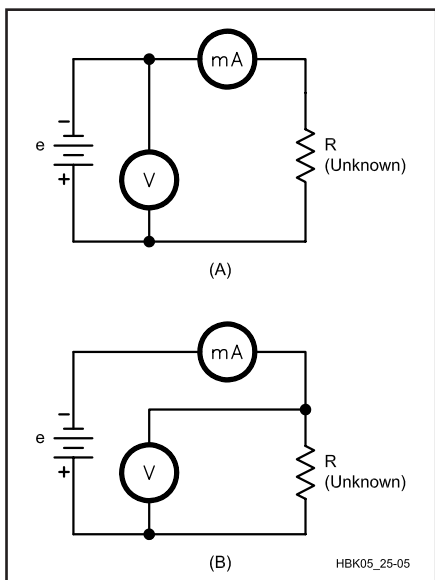

Fig 25.5 — Power or resistance can be calculated from voltage and current measurements. At A, error introduced by the ammeter is dominant. At B, error introduced by the voltmeter is dominant. The text gives an example.

dred ohms in series. [Even better, use a resistor that is part of the working circuit if one exists. Unsolder one end of the resistor, measure its resistance, reinstall it and then make the measurement.—Ed.] In such cases the voltmeter method of measuring current in place of an ammeter, shown in **Fig 25.4**, is frequently convenient. A voltmeter (or low-range milliammeter provided with a multiplier and operating as a voltmeter) having a full-scale voltage range of a few volts is used to measure the voltage drop across a suit-

able value of resistance acting as a shunt.

The value of shunt resistance must be calculated from the known or estimated maximum current expected in the circuit (allowing a safe margin) and the voltage required for full-scale movement of the meter with its multiplier. For example, to measure a current estimated at 15 A on the 2-V range of a DVM, we need to solve Ohm's Law for the value of R:

$$R_{\text{SHUNT}} = \frac{2 \text{ V}}{15 \text{ A}} = 0.133 \Omega$$

This resistor would dissipate $15^2 \times 0.133 = 29.92 \text{ W}$. For a short-duration measurement, 30 1.0- Ω , 1-W resistors could be parallel connected in two groups of 15 (0.067 Ω per group) that are series connected to yield 0.133 Ω . For long-duration measurements, 2- to 5-W resistors would be better.

Power

Power in direct-current circuits is usually determined by measuring the current and voltage. When these are known, the power can be calculated by multiplying voltage, in volts, by the current, in amperes. If the current is measured with a milliammeter, the reading of the instrument must be divided by 1000 to convert it to amperes.

The setup for measuring power is shown in **Fig 25.5A**, where R is any dc load, not necessarily an actual resistor. In this measurement it is always best to use the lowest voltmeter or ammeter scale that allows reading the measured quantity. This results in the percentage error being less than if the meter was reading in the very lowest part of the selected scale.

Resistance

If both voltage and current are measured in a circuit such as that in **Fig 25.5**, the value of resistance R (in case it is unknown) can be calculated from Ohm's Law. For reasonable results, two conditions should be met:

1. The internal resistance of the current meter should be less than 5% of the circuit resistance.
2. The input impedance of the voltmeter should be greater than 20 times the circuit resistance.

These conditions are important because both meters tend to load the circuit under test. The current meter resistance adds to the unknown resistance, while the voltmeter resistance decreases the unknown resistance as a result of their parallel connection.

Ohmmeters

Although **Fig 25.5B** suffices for occa-

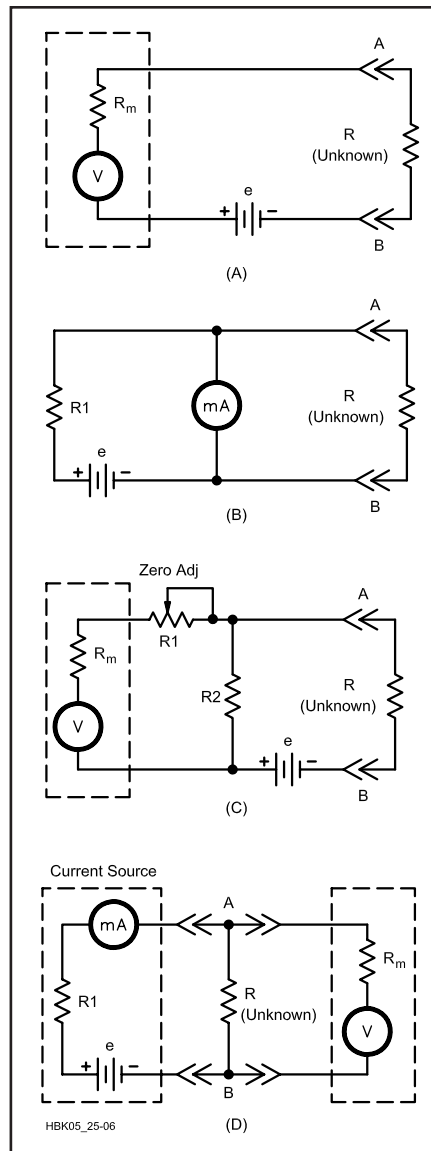

Fig 25.6 — Here are several kinds of ohmmeters. Each is explained in the text.

sional resistance measurements, it is inconvenient when we need to make frequent measurements over a wide range of resistance. The device generally used for this purpose is the ohmmeter. Its simplest form is a voltmeter (or milliammeter, depending on the circuit used) and a small battery. The meter is calibrated so that the value of an unknown resistance can be read directly from the scale. **Fig 25.6** shows some typical ohmmeter circuits. In the simplest circuit, **Fig 25.6A**, the meter and battery are connected in series with the unknown resistance. If a given movement of the meter's needle is obtained with terminals A-B shorted, inserting the resistance to be measured will cause the meter reading to decrease. When the resistance of the voltmeter is known, the following

formula can be applied.

$$R = \frac{eR_m}{E} - R_m \quad (3)$$

where

- R = unknown resistance, ohms
- e = voltage applied (A-B shorted)
- E = voltmeter reading with R connected
- R_m = resistance of the voltmeter.

The circuit of Fig 25.6A is not suited to measuring low values of resistance (less than 100 Ω or so) with a high-resistance voltmeter. For such measurements the circuit of Fig 25.6B is better. The unknown resistance is

$$R = \frac{I_2 R_m}{I_1 - I_2} \quad (4)$$

where

- R = unknown resistance, ohms
- R_m = the internal resistance of the milliammeter, ohms
- I₁ = current with R disconnected from terminals A-B, amps
- I₂ = current with R connected, amps.

This formula is based on the assumption that the current in the complete circuit will be essentially constant whether or not the unknown terminals are short circuited. This requires that R₁ be much greater than R_m. For example, 3000 Ω for a 1-mA meter with an internal resistance of perhaps 50 Ω. In this case, a 3-V battery would be necessary in order to obtain a full-scale deflection with the unknown terminals open. R₁ can be an adjustable resistor, to permit setting the open-terminal current to exact full scale.

A third circuit for measuring resistance is shown in Fig 25.6C. In this case a high-resistance voltmeter is used to measure the voltage drop across a reference resistor, R₂, when the unknown resistor is connected so that current flows through it, R₂ and the battery in series. With suitable R₂s (low values for low-resistance, high values for high-resistance unknowns), this circuit gives equally good results for resistance values in the range from one ohm to several megohms. The voltmeter resistance, R_m, must be much greater (50 times or more) than that of R₂. A 20-kΩ/V instrument (50-μA movement) is generally used. If the current through the voltmeter is negligible compared with the current through R₂, the formula for the unknown is

$$R = \frac{eR_2}{E} - R_2 \quad (5)$$

where

- R and R₂ are in ohms

e = voltmeter reading with R removed and A shorted to B.

E = voltmeter reading with R connected.

R₁ sets the voltmeter reading exactly to full scale when the meter is calibrated in ohms. A 10-kΩ pot is suitable with a 20-kΩ/V meter. The battery voltage is usually 3 V for ranges to 100 kΩ and 6 V for higher ranges.

Four-Wire Resistance Measurements

In situations where a very low resistance, like a 50-Ω dummy load, is to be measured, the resistance of the test leads can be significant. The average lead resistance is about 0.9 Ω through both leads, which would make a 50.5-Ω dummy load appear to be 51.4 Ω. To compensate for lead resistance, some meters allow for four-wire measurements. Briefly, two wires from the current source and two wires from the measuring circuit exit the meter case separately and connect directly to the unknown resistance (see Fig 25.6D). This eliminates the voltage drop in the current-source leads from the measurement. In practice, four-wire systems use special test clips that are similar to alligator clips, except that the jaws are insulated from each other and a meter lead is attached to each jaw. In some meters, an additional control allows the operator to short the test leads together and adjust the meter for a zero reading before making low-resistance measurements.

Bridge Circuits

Bridges are an important class of measurement circuits. They perform measurement by comparison with some known component or quantity, rather than by direct reading. VOMs, DVMs and other meters are convenient, but their accuracy is limited. The accuracy of manufactured analog meters is determined at the factory, while digital meters are accurate only to some percentage ±1 in the least-significant digit. The accuracy of comparison measurements, however, is determined only by the comparison standard and bridge sensitivity.

Bridge circuits are useful across most of the frequency spectrum. Most amateur applications are at RF, as shown later in this chapter. The principles of bridge operation are easier to understand at dc, however, where bridge operation is simple.

The Wheatstone Bridge

A simple resistance bridge, known as the Wheatstone bridge, is shown in Fig 25.7. All other bridge circuits are based on this design. The four resistors, R₁, R₂, R₃

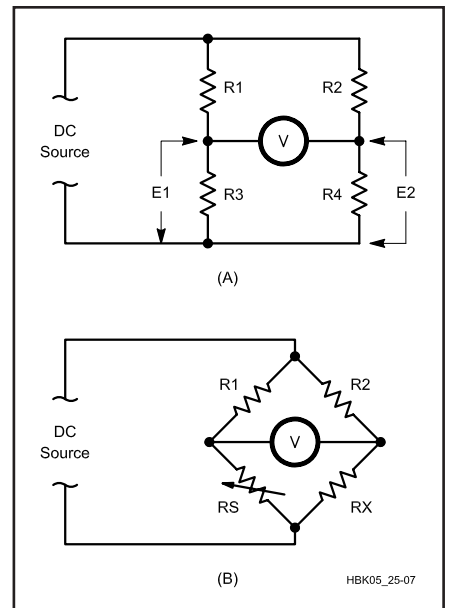

Fig 25.7 — A Wheatstone bridge circuit. A bridge circuit is actually a pair of voltage dividers (A). B shows how bridges are normally drawn.

and R₄ in Fig 25.7A, are known as the bridge arms. For the voltmeter reading to be zero (null) the voltage dividers consisting of the pairs R₁-R₃ and R₂-R₄ must be equal. This means

$$\frac{R_1}{R_3} = \frac{R_2}{R_4} \quad (6)$$

When this occurs the bridge is said to be *balanced*.

The circuit is usually drawn as shown at Fig 25.7B when used for resistance measurement. Equation 6 can be rewritten

$$R_X = R_S \left(\frac{R_2}{R_1} \right) \quad (7)$$

R_X is the unknown resistor. R₁ and R₂ are usually made equal; then the calibrated adjustable resistance (the standard), R_S, will have the same value as R_X when R_S is set to show a null on the voltmeter.

Note that the resistance ratios, rather than the actual resistance values, determine the voltage balance. The values do have important practical effects on the sensitivity and power consumption, however. Bridge sensitivity is the ability of the meter to respond to slight unbalance near the null point; a sharper null means a more accurate setting of R_S at balance. Bridge circuits with narrower bandwidths tend to exhibit a sharper, more precise null, and therefore potentially greater measurement accuracy in contrast to a bridge with a wider bandwidth and a

poorly defined or broader null.

The Wheatstone bridge is rarely used by amateurs for resistance measurement, since it is easier to measure resistances with VOMs and DVMs. Nonetheless, it is worthwhile to understand its operation as the basis of more complex bridges.

ELECTRONIC VOLTMETERS

We have seen that the resistance of a simple voltmeter (as in Fig 25.3) must be extremely high in order to avoid “loading” errors caused by the current that necessarily flows through the meter. The use of high-resistance meters tends to cause difficulty in measuring relatively low

voltages because multiplier resistance progressively lessens as the voltage range is lowered.

Voltmeter resistance can be made independent of voltage range by using vacuum tubes, FETs or op amps as dc amplifiers between the circuit under test (CUT) and the indicator, which may be a conventional meter movement or a digital display. Because the input resistance of the electronic devices mentioned is extremely high (hundreds of megohms) they have negligible loading effect on the CUT. They do, however, require a closed dc path in their input circuits (although this path can have very high resistance). They are also limited in

the voltage level that their input circuits can handle. Because of this, the device actually measures a small voltage across a portion of a high-resistance voltage divider connected to the CUT. Various voltage ranges are obtained from appropriate taps on the voltage divider.

In the design of electronic voltmeters it has become standard practice to use a voltage divider with a total resistance of 10 M Ω , tapped as required, in series with a 1-M Ω resistor incorporated in the meter. The total voltmeter resistance, including probe, is therefore 11 M Ω . The 1-M Ω resistor serves to isolate the voltmeter circuit from the CUT.

AC Instruments and Circuits

Most ac measurements differ from dc measurements in that the accuracy of the measurement depends on the purity of the sine wave. It is fairly easy to measure an ac voltage to between 1% and 5%, but getting down to 0.01% is difficult. Measurements to less than 0.01% must be left to precision laboratories. In general, amateurs measure ac voltages in household circuits, audio stages and RF power measurements, and 1% to 5% accuracy is usually close enough.

This section covers basic measurements, the nature of sine waves and meters. There are four common ways to measure ac voltage:

- Use a rectifier to change the ac to dc and then measure the dc.
- Heat a resistor in a Wheatstone bridge with the ac and measure the bridge unbalance.
- Heat a resistor surrounded by oil and measure the temperature rise.
- Use electronic circuits (such as multipliers and logarithmic amplifiers) with mathematical ac-to-dc conversion formulas. This method is not common, but it's interesting.

Calorimetric Meters

In a calorimetric meter, power is applied to a resistor that is immersed in the flow path of a special oil. This oil transfers the heat to another resistor that is part of a bridge. As the resistor heats, its resistance changes and the bridge becomes unbalanced. An attached meter registers the unbalance of the bridge as ac power. This type of meter is accurate for both dc and ac. They frequently operate from dc well into the GHz range. For calibration, an accurate dc voltage is applied and the reading is noted; a similar ac voltage is applied and the readings are compared. Some

calorimetric meters are complicated, but others are simple.

Thermocouple Meters and RF Ammeters

In a thermocouple meter, alternating current flows through a low-resistance heating element. The power lost in the resistance generates heat that warms a thermocouple, which consists of a pair of junctions of two different metals. When one junction is heated a small dc voltage is generated in response to the difference in temperature of the two junctions. This voltage is applied to a dc milliammeter that is calibrated in suitable ac units. The heater-thermocouple/dc-meter combination is usually housed in a regular meter case.

Thermocouple meters are available in ranges from about 100 mA to many amperes. Their useful upper frequency limit is in the neighborhood of 100 MHz. Amateurs use these meters mostly to measure current through a known load resistance and calculate the RF power delivered to the load.

RECTIFIER INSTRUMENTS

The response of a rectifier RF ammeter is proportional (depending on the design) to either the peak or average value of the rectified ac wave, but never directly to the RMS value. These meters cannot be calibrated in RMS without knowing the relationship that exists between the real reading and the RMS value. This relationship may not be known for the circuit under test.

Average-reading ac meters work best with pure sine waves and RMS meters work best with complicated wave forms. Since many practical measurements involve nonsinusoidal forms, it is necessary to know what your instrument is actually

reading, in order to make measurements intelligently. Most VOMs and VTVMs use averaging techniques, while DVMs may use either one. In all cases, check the meter instruction manual to be sure what it reads.

Peak and Average with Sine-Wave Rectification

Peak, average and RMS values of ac waveforms are discussed in the **Electrical Fundamentals** chapter. Because the positive and negative half cycles of the sine wave have the same shape, half-wave rectification of either the positive half or the negative half gives exactly the same result.

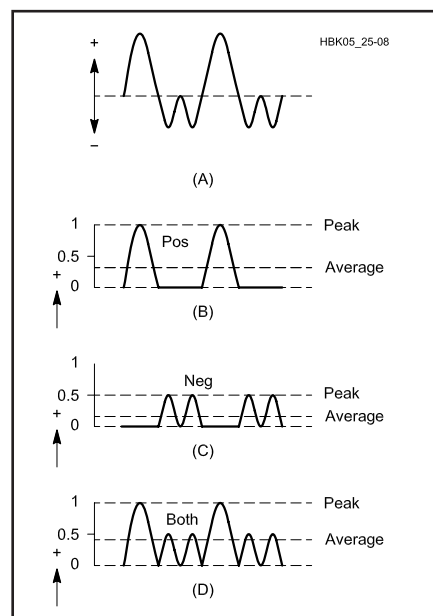

Fig 25.8 — Peak vs average ac values for an asymmetrical wave form. Note that the peak values are different with positive or negative half-cycle rectification.

With full-wave rectification, the peak reading is the same, but the average reading is doubled, because there are twice as many half cycles per unit of time.

Asymmetrical Wave Forms

A nonsinusoidal waveform is shown in Fig 25.8A. When the positive half cycles of this wave are rectified, the peak and average values are shown at B. If the polarity is reversed and the negative half cycles are rectified, the result is shown in Fig 25.8C. Full-wave rectification of such a lopsided wave changes the average value, but the peak reading is always the same as that of the half cycle that produces the highest peak in half-wave rectification.

Effective-Value Calibration

The actual scale calibration of commercially made rectifier voltmeters is very often (almost always, in fact) in terms of RMS values. For sine waves, this is satisfactory and useful because RMS is the standard measurement at power-line frequencies. It is also useful for many RF applications when the waveform is close to sinusoidal. In other cases, particularly in the AF range, the error may be considerable when the waveform is not pure.

Turn-Over

From Fig 25.8 it is apparent that the calibration of an average-reading meter will be the same whether the positive or negative sides are rectified. A half-wave peak-reading instrument, however, will indicate different values when its connections to the circuit are reversed (turn-over effect). Very often readings are taken both ways, in which case the sum of the two is the peak-to-peak (P-P) value, a useful figure in much audio and video work.

Average- vs Peak-Reading Circuits

For traditional analog displays, the basic difference between average- and peak-reading rectifier circuits is that the output is not filtered for averaged readings, while a filter capacitor is charged to the peak value of the output voltage in order to measure peaks. Fig 25.9A and B show typical average-reading circuits, one half-wave and the other full-wave. In the absence of dc filtering, the meter responds to wave forms such as those shown at B, C and D in Fig 25.8; and since the inertia of the pointer system makes it unable to follow the rapid variations in current, it averages them out mechanically.

In Fig 25.9A, D1 actuates the meter; D2 provides a low-resistance dc return in the meter circuit on the negative half cycles. R1 is the voltmeter multiplier resistance. R2 forms a voltage divider with R1

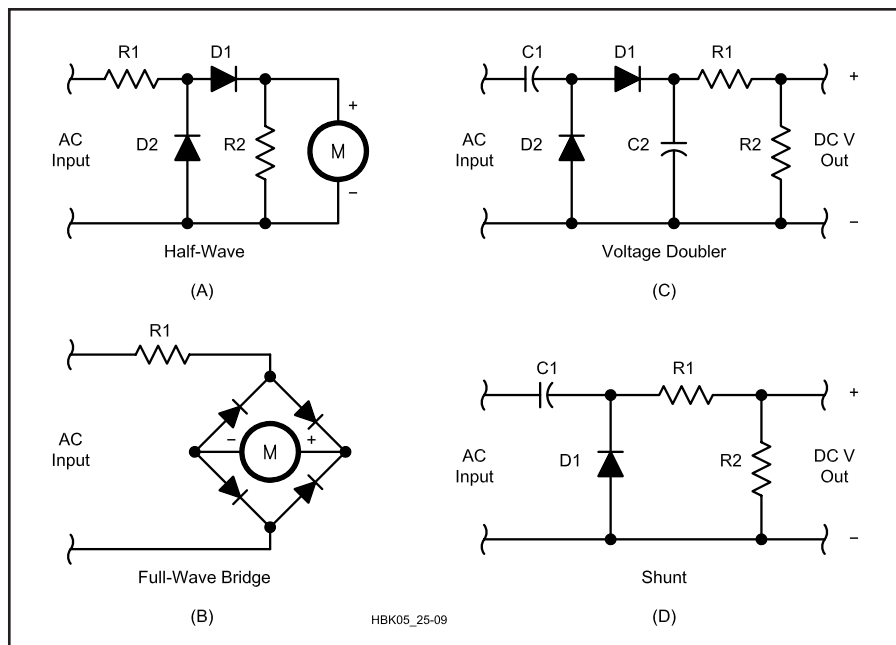

Fig 25.9 — Half (A) and full-wave (B) bridge rectifiers for average-reading, analog-display meters. Peak-reading circuits: a voltage doubler (C) and a shunt circuit (D). All circuits are discussed in the text.

(through D1) that prevents more than a few ac volts from appearing across the rectifier-meter combination. A corresponding resistor can be used across the full-wave bridge circuit.

In these two circuits there is no provision to isolate the meter from any dc voltage in the circuit under test. The resulting errors can be avoided by connecting a large nonpolarized capacitor in series with the hot lead. The reactance must be low compared with the meter impedance (at the lowest frequency of interest, more on this later) in order for the full ac voltage to be applied to the meter circuit. Some meters may require as much as 1 μF at line (60 Hz) frequencies. Such capacitors are usually not included in VOMs.

Voltage doubler and shunt peak-reading circuits are shown in Fig 25.9C and D. In both circuits, C1 isolates the rectifier from dc voltage in the circuit under test. In the voltage-doubler circuit, the time constant of the C2-R1-R2 combination must be very large compared with the period of the lowest ac frequency to be measured; similarly with C1-R1-R2 in the shunt circuit. This is so because the capacitor is charged to the peak value (V_{p-p} in C, V_p in D) when the ac wave reaches its maximum and then must hold the charge (so it can register on a dc meter) until the next maximum of the same polarity. If the time constant is 20 times the ac period, the charge will have decreased by about 5% when the next charge occurs. The average voltage

drop will be smaller, so the error is appreciably less. The error will decrease rapidly with increasing frequency (if there is no change in the circuit values), but it will increase at lower frequencies.

In Fig 25.9C and D, R1 and R2 form a voltage divider that reduces the voltage to some desired value. For example, if R1 is 0 Ω in the voltage doubler, the voltage across R2 is approximately V_{p-p} ; if R1 = R2, the output is approximately V_p (as long as the waveform is symmetrical).

The most common application of the shunt circuit is an RF probe to read V_{RMS} . In that case, R2 is the input impedance of a VTVM or DVM: 11 $M\Omega$. R1 is chosen so that 71% of the peak value appears across R2. This converts the peak reading to RMS for sine-wave ac. R1 is therefore approximately 4.7 $M\Omega$, making the total resistance nearly 16 $M\Omega$. A capacitance of 0.05 μF is sufficient for low audio frequencies under these conditions. Much smaller values of capacitance may be used at RF.

Voltmeter Impedance

The impedance of a voltmeter at the frequency being measured may have an effect on the accuracy similar to that caused by the resistance of a dc voltmeter, as discussed earlier. The ac meter is a resistance in parallel with a capacitance. Since the capacitive reactance decreases with increasing frequency, the impedance also decreases with frequency. The resistance does change with voltage level, particu-

Sources for RF Ammeters

When it comes to getting your own RF ammeter, there's good news and bad news. First, the bad news. New RF ammeters are expensive, and even surplus pricing can vary widely between \$10 and \$100 in today's market. AM radio stations are the main users of new units. The FCC defines the output power of AM stations based on the RF current in the antenna, so new RF ammeters are made mainly for that market. They are quite accurate, and their prices reflect that!

The good news is that used RF ammeters are often available. For example, Fair Radio Sales in Lima, Ohio has been a consistent RF-ammeter source. Ham flea markets are also worth trying. Some grubbing around in your nearest surplus store or some older ham's junk box may provide just the RF ammeter you need.

RF Ammeter Substitutes

Don't despair if you can't find a used RF ammeter. It's possible to construct your own. Both hot-wire and thermocouple units can be homemade.

Pilot lamps in series with antenna wires, or coupled to them in various ways, can indicate antenna current* or even forward and reflected power.†

Another approach is to use a small low-voltage lamp as the heat/light element and use a photo detector driving a meter as an indicator. (Your eyes and judgment can serve as the indicating part of the instrument.) A feed-line balance checker could be as simple as a couple of lamps with the right current rating and the lowest voltage rating available. You should be able to tell fairly well by eye which bulb is brighter or if they are about equal. You can calibrate a lamp-based RF ammeter with 60-Hz or dc power.

As another alternative, you can build an RF ammeter that uses a dc meter to indicate rectified RF from a current transformer that you clamp over a transmission line wire.††

Copper-Top Battery Testers as RF Ammeters

Finally, there are the *free* RF ammeters that come as the testers with Duracell batteries! For 1.5-V cells, these are actually 3 to 5- Ω resistors with built-in liquid-crystal displays. The resistor heats the liquid-crystal strip; the length of the "lighted" portion (heat turns the strip clear, exposing the fluorescent ink beneath) indicates the magnitude of the current.

Despite their "+" and "-" markings, these indicators are not polarized. Their resistance is low enough to have relatively little effect on a 50- Ω system. (For example, putting one in series with a 50- Ω dummy load would increase the system SWR from 1 to 1.1:1. These testers can measure about 200 to 400 mA. (You can achieve higher ranges by means of a shunt.) Best of all, if you burn out one of these "meters" during your tests, you can replace it at any drugstore, hardware store or supermarket for a few dollars, with some batteries thrown in free. — *John Stanley, K4ERO*

Fig 25.10 — Voltage vs current characteristics for a typical semiconductor diode. Actual values vary with different part numbers, but the forward current will always be increasing steeply with 1 V applied. Note that the forward current scale (mA) is 1000 times larger than that for reverse leakage current (μ A). Breakdown voltage varies from 15 V to several hundred volts.

reading circuits the effective capacitance may range from 1 or 2 to a few hundred pF, with 100 pF typical in most instruments.

Scale Linearity

Fig 25.10 shows a typical current/voltage chart for a small semiconductor diode, which shows that the forward dynamic resistance of the diode is not constant, but rapidly decreases as the forward voltage increases from zero. The change from high to low resistance happens at much less than 1 V, but is in the range of voltage needed for a dc meter. With an average-reading circuit the current tends to be proportional to the square of the applied voltage. This makes the readings at the low end of the meter scale very crowded. For most measurement purposes, however, it is far more desirable for the output to be linear (that is, for the reading to be directly proportional to the applied voltage), which means that the markings on the meter are more evenly spaced.

To obtain that kind of linearity it is necessary to use a relatively large load resistance for the diode: Large enough that this resistance, rather than the diode resistance, will determine how much current flows. With this technique you can have a linear reading meter, but at the expense of sensitivity. The resistance needed depends on the type of diode; 5 k Ω to 50 k Ω is usually enough for a germanium rectifier, depending on the dc meter sensitivity, but several times as much may be needed for silicon diodes. Higher resistances require greater meter sensitivity; that is, the basic

larly at very low voltages (10 V or less) depending on the sensitivity of the meter and the kind of rectifier used.

The ac load resistance represented by a diode rectifier is about one-half of its dc-load resistance. In Fig 25.9A the dc load is essentially the meter resistance, which is generally quite low compared with the multiplier resistance R1. Hence, the total resistance will be about the same as the multiplier resistance. The capacitance depends on the components and construction, test-lead length and location, and other such factors. In general, the capaci-

tance has little or no effect at lower line and audio frequencies, but ordinary VOMs lose accuracy at high audio frequencies and are of little use at RF. Rectifiers with very low inherent capacitance are used at RF and they are usually located at the probe tip to reduce losses.

Similar limitations apply to peak-reading circuits. In the shunt circuit, the resistive part of the impedance is smaller than in the voltage-doubler circuit because the dc load resistance, R1/R2, is directly across the circuit under test and in parallel with the diode ac load resistance. In both peak-

meter must be a microammeter rather than a low-range milliammeter.

Reverse Current

When semiconductor diodes are reverse biased, a small leakage current flows. This reverse current flows during the half cycle when the diode should appear open, and the current causes an error in the dc meter reading. The quantity of reverse current is indicated by a diode's *back resistance* specification. This back resistance is so high that reverse current is negligible with silicon diodes, but back resistance may be less than 100 k Ω for germanium diodes.

The practical effect of semiconductor back resistance is to limit the amount of resistance that can be used in the dc load. This in turn affects the linearity of the meter scale. For practical purposes, the back resistance of vacuum-tube diodes is infinite.

RF Voltage

Special precautions must be taken to minimize the capacitive component of the voltmeter impedance at RF. If possible, the rectifier circuit should be installed permanently at the point where the RF voltage is to be measured, using the shortest possible RF connections. The dc meter can be remotely located, however.

For general RF measurements an RF probe is used in conjunction with a 10 M Ω electronic voltmeter. The circuit of Fig 25.11, which is basically the shunt peak-reading circuit of Fig 25.9D, is generally used. The series resistor, which is installed in the probe close to the rectifier, prevents RF from being fed through the probe cable to the electronic voltmeter. (In addition, the capacitance of the coaxial cable serves as a bypass for any RF on the lead.) This resistor, in conjunction with the 10-M Ω divider resistance of the electronic voltmeter, reduces the peak rectified voltage to a dc value equivalent to the RMS of the RF signal. Therefore, the RF readings are consistent with the regular dc calibration.

Of the diodes readily available to amateurs, the germanium point-contact or Schottky diode is preferred for RF-probe

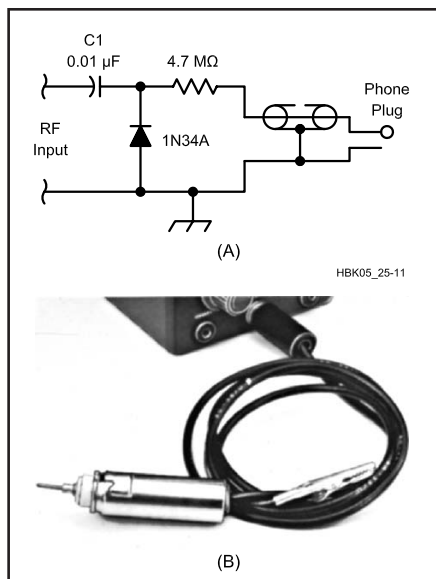

Fig 25.11 — At A is the schematic, at B a photo, of an RF probe for electronic voltmeters. The case of this probe is a seven-pin ceramic tube socket and a 2¼-inch tube shield. A grommet protects the cable where it leaves the tube shield, and an alligator clip on the cable braid connects the probe to the ground of the circuit under test.

applications. It has low capacitance (on the order of 1 pF) and in high-back-resistance Schottky diodes, the reverse current is not serious. The principal limitation is that its safe reverse voltage is only about 50 to 75 V, which limits the applied voltage to 15 or 20 V RMS. Diodes can be series connected to raise the overall rating. At RF, however, it is more common to use capacitors or resistors as voltage dividers and apply the divider output to a single diode.

RF Power

RF power can be measured by means of an accurately calibrated RF voltmeter connected across a dummy load in which the power is dissipated. If the load is a known pure resistance, the power, by Ohm's Law, is equal to E^2/R , where E is the RMS voltage.

making *relative* power measurements. The range of the meter can be extended by using an attenuator or by adding a broadband RF amplifier.

There are many uses for this meter. Combined with a signal generator, you can use it to characterize crystal and LC filters, for direct, on-air checks of field strength

The Hewlett-Packard 410B/C VTVM

The Hewlett-Packard 410B and 410C VTVMs have been standards of bench measurement for industry, and they are now available as industrial surplus. These units are not only excellent VTVMs, but they are also good wide-range RF power meters. Both models use a vacuum-tube detector mounted in a low-loss probe for ac measurements. With an adapter that allows the probe to contact the center conductor of a transmission line, it will give very good RF voltage measurements from 50 mV to 300 V and from 20 Hz to beyond 500 MHz. Very few other measuring instruments provide this range in a single sensor/meter. In addition to the 410B or C, you will also need a probe adapter HP model #11042A.

Do not take the probe apart for inspection because that can change the calibration. You can quickly check the probe by feeling it after it has been warmed up for about 15 minutes. If the body of it feels warm it is probably working. Inside, the 410B is quite different from the C model, with the B being simpler. The meter scales are also different; the 410C offers better resolution and perhaps better accuracy.

To make RF power measurements, remove the ac probe tip and twist lock the probe into the 11042A probe adapter. Attach the output of the adapter to a dummy load and use the formula

$$P = \frac{E^2}{R} \quad (8)$$

where

P = power, in watts

E = value given by the meter, in volts

R = resistance of the dummy load, in ohms.

The resistance of the dummy load should be accurately known to at least $\pm 0.1 \Omega$, preferably measured with a four-wire arrangement as described in the section on ohmmeters. For frequent measurements, make a chart of voltage vs power at your most often used wattages.

and measuring antenna patterns. If you are fortunate enough to have a 50- Ω oscilloscope probe (or a high-impedance probe), you can also use the Microwatter as an RF voltmeter for circuit testing.

Design

The circuit concept is quite simple (see

THE MICROWATTER

This simple, easy to build terminating microwattmeter by Denton Bramwell, W7DB appeared in June 1997 *QST*.¹ It can measure power levels from below -50 dBm (10 nW) to -20 dBm (10 μ W) with an accuracy of within 1 dB at frequencies from below the broadcast band up to 2 meters. Beyond that, it's still capable of

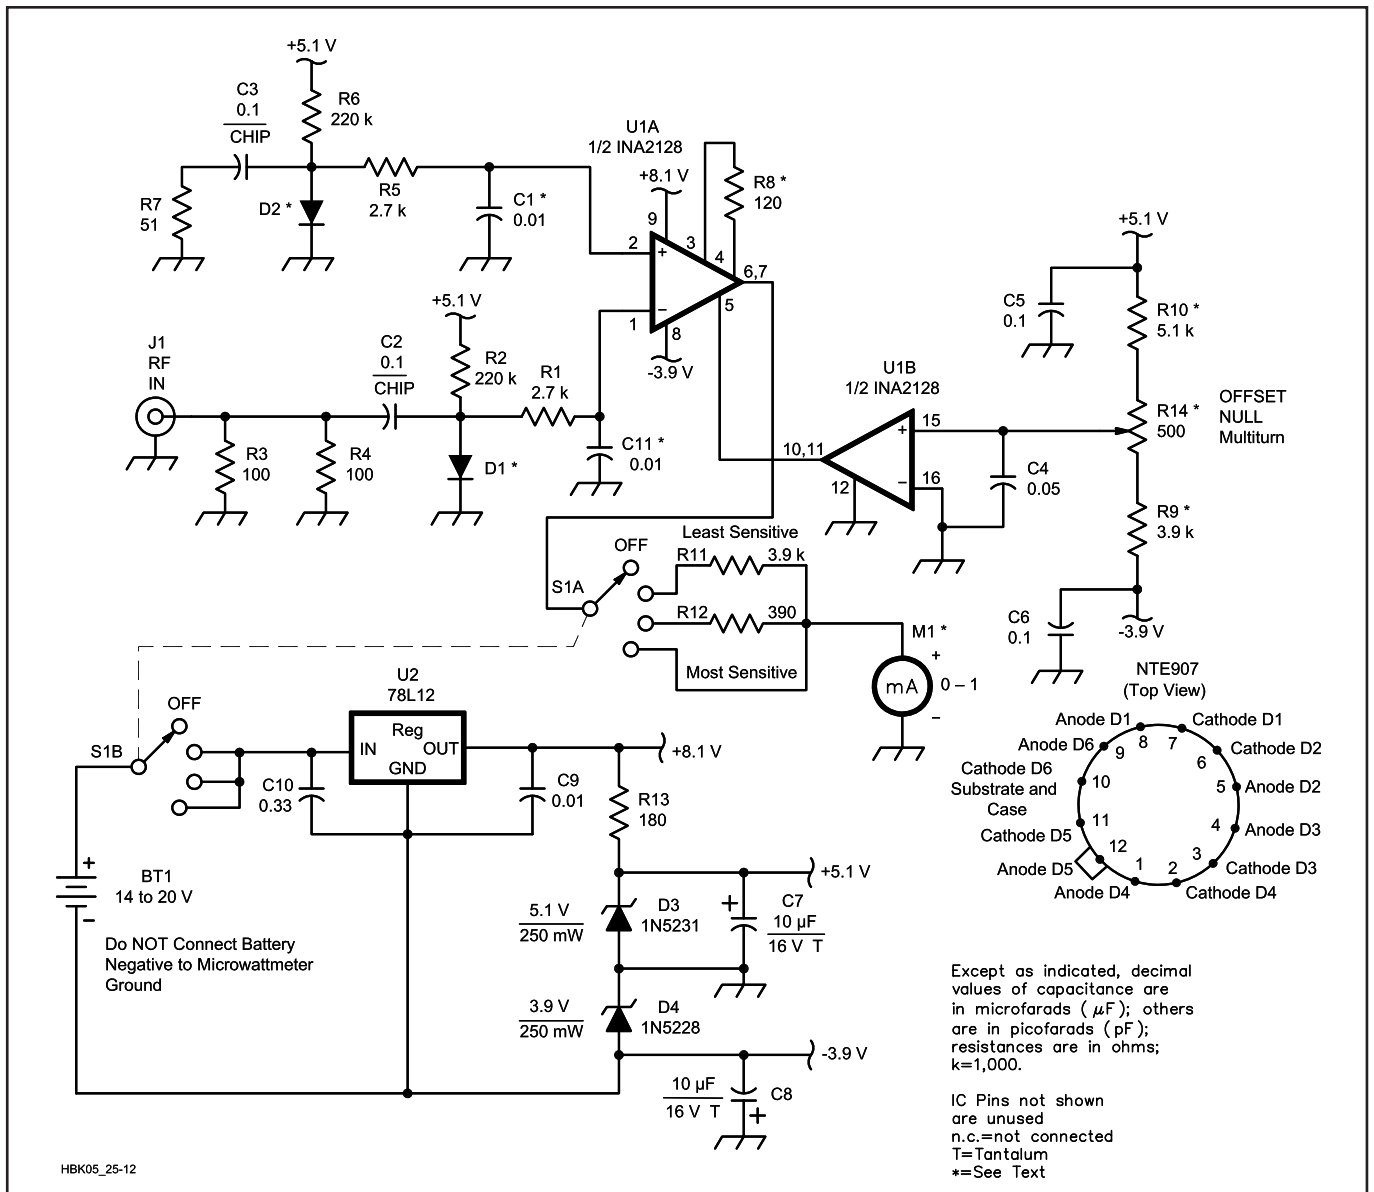

Fig 25.12 — Schematic of the Microwatt circuit. Equivalent parts can be substituted. Unless otherwise specified, resistors are 1/4-W, 5%-tolerance carbon-composition or film units.

D1, D2 — Part of CA3039 or NTE907 diode array; see text and Notes 1 and 2. The NTE907 is available from Mouser Electronics.
M1 — 1-mA meter movement, 50- Ω internal resistance; see text.

R14 — 500- Ω , 10-turn (or more) potentiometer; see text.
S1 — 2-pole, 4-position rotary switch.
U1 — Burr Brown amplifier INA2128P; Digi-Key INA2128P; available from Digi-Key Corp.

U2 — 78L12, positive 12-V, 100-mA voltage regulator; Digi-Key LM78L12ACZ.

Fig 25.12). Two nearly identical diodes (D1 and D2) are biased by a small dc current. RF energy is coupled to one of the diodes, which then acts as a square-law detector. The difference between the voltages present on the two diodes is amplified by a differential amplifier (U1) and applied to an analog voltmeter equipped with hand-calibrated ranges. Getting adequate stability requires careful selection of parts.

D1 and D2 must have a low junction capacitance and a fast response in order

to provide the desired bandwidth. Their temperature coefficients must also be extremely well matched. The solution is to use a very old part: the CA3039 diode array.² The diodes in this device are very fast silicon types, with exceptional thermal matching.³ Any two diodes of the array—except the one tied to the substrate—can be used for D1 and D2. Unused IC pins can be cut off or bent out of the way. Similarly rated arrays of hot-carrier diodes may provide a better frequency response.

The Burr-Brown INA2128 provides two

differential amplifiers with exceptional specifications: low thermal drift, superb common-mode rejection and low noise. In this circuit, one half of the INA2128 provides dc amplification of the detected voltage; the other half serves as a low-impedance offset-voltage source used for error nulling.

The RF-input terminating resistor is composed of two 100- Ω resistors (R3 and R4), providing a cleaner 50- Ω termination than a single resistor does. If you have them, use chip resistors. If not, clip the

leads off two standard 100- Ω resistors and carefully scrape away any paint at the ends. After installing the resistors, verify the input resistance with an ohmmeter.

A stable power source is required. Operating the circuit from an unregulated battery supply allows slight relative changes in the local ground as the terminal voltage drops, creating drift in the reading. The Zener diodes (D3 and D4) following regulator U2 provide a simple, dynamic means of splitting the 12-V supply into the three voltages required to power the circuit.

C1 and C11 should be as close as physically possible to U1 pins 1 and 2. In combination with R1 and R5, these capacitors provide good immunity to unwanted RF. R14, the OFFSET NULL potentiometer, allows nulling the dc amplifier offset and any offset from slight mismatches in the CA3039 diodes. Use a multiturn potentiometer for R14—10 turns or more. Whether you use a panel-mount pot, or a PC-board-mounted trimmer as I did, R14 must be accessible. On the most-sensitive range, the instrument must be zeroed before each use.

The forward voltage drop difference between any two diodes in the CA3039 is specified as “typically less than 0.5 mV.” If your device is typical, the nominal values of 5.1 k Ω for R10 and 3.9 k Ω for R9 will do just fine. The manufacturer does not reject parts until the forward voltage drop difference is 5 mV—so the 0.5 mV figure isn’t totally dependable. You can always rotate the diode array so that pins 1, 2, 3 and 4 occupy the spots designated for pins 5, 6, 7 and 8. That gives you a second set of diodes from which to choose. The simplest general solution for a homebrew project is to use nonidentical values for R9 and R10.

If your diode array isn’t typical, your Microwatter won’t zero properly. The solution is simple. Remove R14 from the circuit. Temporarily connect one end of a 10-k Ω potentiometer to the +8.1 V supply and attach the other end to the -3.9 V supply. Connect the pot arm to the PC-board point of R14’s arm. With this arrangement, you’ll be able to zero your Microwatter, although the setting will be sensitive and might not produce an exact zero. Once you have the zero point, turn off the Microwatter and remove the 10-k Ω pot carefully without disturbing its setting. Measure the resistance between the pot arm and end that was connected to the +8.1 V point—this is the value of R10. R9’s value is that measured between the pot arm and the end previously connected to the -3.9 V point. The combined value of these two resistors and that of R14 provides a total resistance of

about 10.5 k Ω , and the resistance ratios will allow easy meter zeroing.

The Meter Movement

The specified meter movement has a 50- Ω internal resistance. Hence, on the most sensitive scale, a 50 mV output from U1 provides full-scale deflection. The middle and upper scales require 440 mV and 3.95 V, respectively, for full-scale deflection. Here’s how you can use a meter that has a different internal resistance or current sensitivity.

Take, for example, a 25- μ A meter movement with an internal resistance of 1910 Ω . A signal level of 47.8 mV (25 μ A \times 1910 Ω) provides full-scale deflection, so this meter can be substituted directly for the 1-mA, 50- Ω meter on the most sensitive scale. On the middle and top scales, the values of R12 and R11 should be 15.69 k Ω and 156.1 k Ω , or values close to those.

If the most sensitive meter you can find requires 80 to 100 mV to drive it to full scale deflection, don’t worry. The Microwatter’s most-sensitive scale will be compressed, but quite usable. The middle and top scales will still run full scale, probably not even requiring a change in the values of R11 and R12, if you use a 1-mA movement.

Construction and Calibration

For the prototype, components are mounted on double-sided PC board (see Note 1) with one side acting as a ground-plane. The cabinet is a 5 \times 7 \times 3-inch aluminum box, primed and painted gray (see Fig 25.13). Power is supplied by a set of NiCd batteries glued to the inside rear of the cabinet. The PC board is small enough to be mounted on the back of the input BNC connector without other support. Once you have completed PC-board assembly, remove the solder flux from the board.

To calibrate the Microwatter, you’ll need a 50- Ω RF source with a known output

level. A suitable signal source can be made from a crystal oscillator and an attenuator, using at least 6 dB of attenuation between the oscillator and the Microwatter at all times. The output of such a system can be calibrated with an oscilloscope, or with a simple RF meter. Any frequency in the mid-HF range is suitable for calibration—W7DB used 10 MHz.

Remove the meter-face cover and prepare the face for new markings. You can paint it white and use India ink to make the meter scale arcs and incremental marks. Before calibrating the Microwatter, let it stabilize at room temperature for an hour, and turn it on at least 15 minutes before use. (At these low power levels, even the heat generated by the small dc bias on the diodes needs time to stabilize.) Set the Microwatter to its most sensitive scale. Use R14 to set the meter needle to your chosen meter zero point and mark that point with a pencil. Then apply a -40 dBm signal and mark the top end of the scale. Decrease the input signal level in 1-dB steps, marking each step. Recheck your meter zeroing, switch the Microwatter to the middle scale, apply a -30 dBm signal and mark this point. Again, decrease drive in 1-dB steps, marking each. Repeat with the least-sensitive scale, starting with -20 dBm. Once this is done, replace the meter-face cover and your Microwatter is ready to use.

DIRECTIONAL WATTMETERS

Directional wattmeters of varying quality are commonly used by the amateur community. The high quality standard is made by the Bird Electronic Corporation, who call their proprietary line THRULINE. The units are based on a sampling system built into a short piece of 50- Ω transmission line with plug-in elements for various power and frequency ranges.

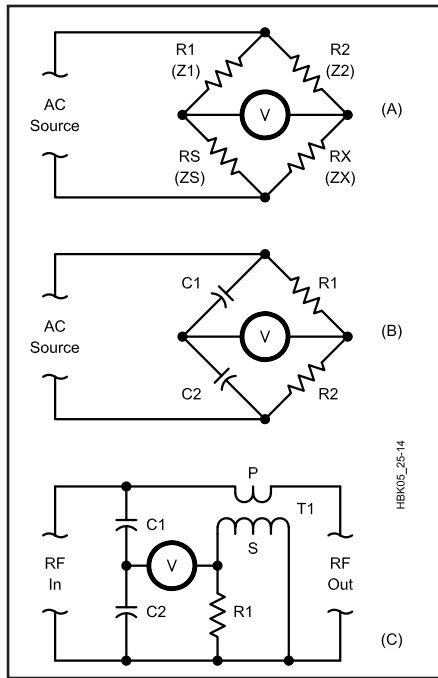

AC BRIDGES

In its simplest form, the ac bridge is exactly the same as the Wheatstone bridge discussed earlier in the dc measurement section of this chapter. However, complex impedances can be substituted for resistances, as suggested by Fig 25.14A. The same bridge equation holds if Z (complex impedance) is substituted for R in each arm. For the equation to be true, however, both phase angles and magnitudes of the impedances must balance; otherwise, a true null voltage is impossible to obtain. This means that a bridge with all “pure” arms (pure resistance or reactance) cannot measure complex impedances; a combination of R and X must be present in at least one arm aside from the unknown.

The actual circuits of ac bridges take

Fig 25.13 — Photo of the Microwatter.

many forms, depending on the intended measurement and the frequency range to be covered. As the frequency increases, stray effects (unwanted capacitances and inductances) become more pronounced. At RF, it takes special attention to minimize them.

Most amateur built bridges are used for RF measurements, especially SWR measurements on transmission lines. The circuits at Fig 25.14B and C are favorites for this purpose.

Fig 25.14B is useful for measuring both transmission lines and lumped constant components. Combinations of resistance and capacitance are often used in one or more arms; this may be required for elimi-

Fig 25.14 — A shows a bridge circuit generalized for ac or dc use. B is a form of ac bridge for RF applications. C is an SWR bridge for use in transmission lines.

nating the effects of stray capacitance. The bridge shown in Fig 25.14C is used only on transmission lines and only on those lines having the characteristic impedance for which the bridge is designed.

SWR Measurement

The theory behind SWR measurement is covered in the **Transmission Lines** chapter and more fully in *The ARRL Antenna Book*. Projects to measure SWR appear in the **Station Layout and Accessories** chapter of this *Handbook*.

Notes

- ¹A PC board and some components for this project is available from FAR Circuits. A PC-board template package is not available.
- ²The NTE907 replacement is available from Mouser Electronics.
- ³The absolute value of the difference in forward drop between any two diodes is 1 mV/°C.

Frequency Measurement

The FCC Rules for Amateur Radio require that transmitted signals stay inside the frequency limits of bands consistent with the operator's license privileges. The exact frequency need not be known, as long as it is within the limits. On these limits there are no tolerances: Individual amateurs must be sure that their signal stays safely inside. The current limits for each license class can be found in Chapter 1 of this *Handbook* and in the current edition of *The FCC Rule Book*, published by the ARRL.

Staying within these limits is not difficult; many modern transceivers do so automatically, within limits. If your radio uses a PLL synthesized frequency source, just tune in WWV or another frequency standard occasionally.

Checks on older equipment require some simple equipment and careful adjusting. The equipment commonly used is the frequency marker generator and the method involves use of the station receiver, as shown in Fig 25.15.

FREQUENCY MARKER GENERATORS

A marker generator, in its simplest form, is a high-stability oscillator that generates a series of harmonic signals. When an appropriate fundamental is chosen, harmonics fall near the edges of the amateur frequency allocations.

Most US amateur band and subband limits are exact multiples of 25 kHz. A 25-kHz fundamental frequency will therefore produce the right marker signals if its harmonics are strong enough. But since harmonics appear at 25-kHz intervals throughout the spectrum, there is still a problem of identifying particular markers. This is easily solved if the receiver has reasonably good calibration. If not, most marker circuits provide a choice of fundamental outputs, say 100 and 50 kHz as well as 25 kHz. Then the receiver can be first set to a 100-kHz interval. From there, the desired 25-kHz (or 50-kHz) points can be counted. Greater frequency intervals are rarely re-

quired. Instead, tune in a signal from a station of known frequency and count off the 100-kHz points from there.

Transmitter Checking

To check transmitter frequency, tune in the transmitter signal on a calibrated receiver and note the dial setting at which it is heard. To start, reduce the transmitter to its lowest possible level to avoid receiver overload. Also, place a direct short across the receiver antenna terminals, reduce the RF gain to minimum and switch in any available receiver attenuators to help prevent receiver IMD, overload and possible false readings.

Place the transmitter on standby (not transmitting) and use the marker generator as a signal source. Tune in and identify the nearest marker frequencies above and below the transmitter signal. The transmitter frequency is between these two known frequencies. If the marker frequencies are accurate, this is all you need to know, except that the transmitter frequency must not be so close to a band (or subband) edge that sidebands extend past the edge.

If the transmitter signal is inside a marker at the edge of an assignment, to the extent that there is an audible beat note with the receiver BFO turned off, normal CW sidebands are safely inside the edge. (So long as there are no abnormal sidebands such as those caused by clicks and chirps.) For

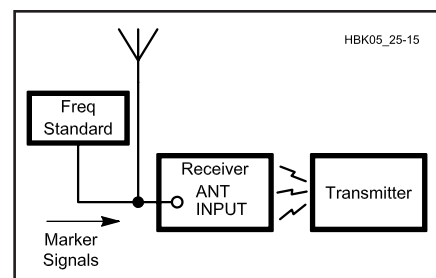

Fig 25.15 — A setup for checking transmitter frequency. Use care to ensure that the transmitter does not overload the receiver. False signals would result; see text.

phone the safety allowance is usually taken to be about 3 kHz, the usual width of one sideband. A frequency difference of this much can be estimated by noting the receiver dial settings for the two 25-kHz markers that are either side of the signal and dividing 25 by the number of dial divisions between them. This will give the number of kilohertz per dial division. It is a prudent practice to allow an extra kHz margin when setting the transmitter close to a band or subband edge (5-kHz is a safe HF margin for most modes on modern transmitters).

Transceivers

The method described above is good when the receiver and transmitter are separate pieces of equipment. When a transceiver is used and the transmitting frequency is automatically the same as that to which the receiver is tuned, setting the tuning dial to a spot between two known marker frequencies is all that is required. The receiver incremental tuning control (RIT) must be turned off.

The proper dial settings for the markers

are those at which, with the BFO on, the signal is tuned to zero beat (the spot where the beat note disappears as tuning makes its pitch progressively lower). Exact zero beat can be determined by a very slow rise and fall of background noise, caused by a beat of a cycle or less per second. In receivers with high selectivity it may not be possible to detect an exact zero beat, because low audio frequencies from beat notes may be prevented from reaching the speaker or headphones.

Most commercial equipment has some way to match either the equipment's internal oscillator or marker generator with the signal received from WWV on one of its short-wave frequencies. It is a good idea to do this check on a new piece of gear. A recheck about a month later will show if anything has changed. Normal commercial equipment drifts less than 1 kHz after warm up.

Also check the dial linearity of equipment that has an analog dial or subdial. Often analog dials do not track frequency accurately across an entire band. Such radios usually provide for pointer adjust-

ment so that dial error can be minimized at the most often used part of a band.

Frequency-Marker Circuits

The frequency in most amateur frequency markers is determined by a 100-kHz or 1-MHz crystal. Although the marker generator should produce harmonics every 25 kHz and 50 kHz, crystals (or other high-stability resonators) for frequencies lower than 100 kHz are expensive and rare. There is really no need for them, however, since it is easy to divide the basic frequency down to the desired frequency; 50- and 25-kHz steps require only two successive divisions by two (from 100 kHz). In the division process, the harmonics of the generator are strengthened so they are useful up to the VHF range. Even so, as frequency increases the harmonics weaken.

Current marker generators are based on readily available crystals. A 1-MHz basic oscillator would first be divided by 10 to produce 100 kHz and then followed by two successive divide-by-two stages to produce 50 kHz and 25 kHz.

A MARKER GENERATOR WITH SELECTABLE OUTPUT

Fig 25.16 shows a marker generator with selectable output for 100, 50 or 25-kHz intervals. It provides marker signals well up into the 2-m band. The project was first built by Bruce Hale, KB1MW, in the ARRL Lab. A more detailed presentation appeared in the **Station Accessories** chapter of *Handbooks* from 1987 through 1994. An etching pattern and parts-placement diagram are available for this project. See the **Project Templates** section on the *Handbook* CD-ROM.

A 1, 2 or 4-MHz computer-surplus crystal is suitable for Y1. Several prototypes were built with such crystals and all could be tuned within 50 Hz at 100 kHz. The marker division ratio must be chosen once the crystal frequency is selected. This is accomplished by means of several jumpers that disable part or all of U2A, the dual flip-flop IC. When Y1 is a 1-MHz crystal, U2 may be omitted entirely. **Table 25.2** gives the jumper placement for each crystal frequency.

The prototypes were built with TTL logic ICs. Unused TTL gate inputs should always be connected either to ground or to

VCC through a pull-up resistor. If low-power Schottky (they have "LS" as part of their numerical designator) parts are available for U1 through U4, use them. They draw much less current than plain TTL, and will greatly extend battery life.

DIP METERS

This device is often called a grid-dip meter or oscillator (from vacuum-tube days) or a transistor dip meter. Most dip

meters can also serve as absorption frequency meters (in this mode measurements are read at the current peak, rather than the dip). Further, some dip meters have a connection for headphones. The operator can usually hear signals that do not register on the meter. Because the dip meter is an oscillator, it can be used as a signal generator in certain cases where high accuracy or stability are not required.

A dip meter may be coupled to a circuit either inductively or capacitively. Inductive coupling results from the magnetic field generated by current flow. Therefore, inductive coupling should be used when a conductor with relatively high current is convenient. Maximum inductive coupling results when the axis of the pick-up coil is placed perpendicular to a nearby current path (see Fig 25.17).

Capacitive coupling is required when current paths are magnetically confined or shielded. (Toroidal inductors and coaxial cables are common examples of magnetic self shielding.) Capacitive coupling depends on the electric field produced by voltage. Use capacitive coupling when a

Table 25.2
Marker Generator Jumper Placement

Crystal Frequency	Jumper Placement
1 MHz	A to F (U2 not used)
2 MHz	A to B C to F D to +5 V, via 1-kΩ resistor
4 MHz	A to B C to D E to F

Fig 25.16A—The generator enclosure and views of the circuit board.

point of relatively high voltage is convenient. (An example might be the output of a 12-V powered RF amplifier. *Do not* attempt dip-meter measurements on true high-voltage equipment such as vacuum-tube amplifiers or switching power supplies while they are energized.) Capacitive coupling is maximum when the end of the pick-up coil is near a point of high voltage (see Fig 25.17). In either case, the circuit under test is affected by the presence of the dip meter. Always use the minimum coupling that yields a noticeable indication.

Use the following procedure to make reliable measurements. First, bring the dip meter gradually closer to the circuit while slowly varying the dip-meter frequency.

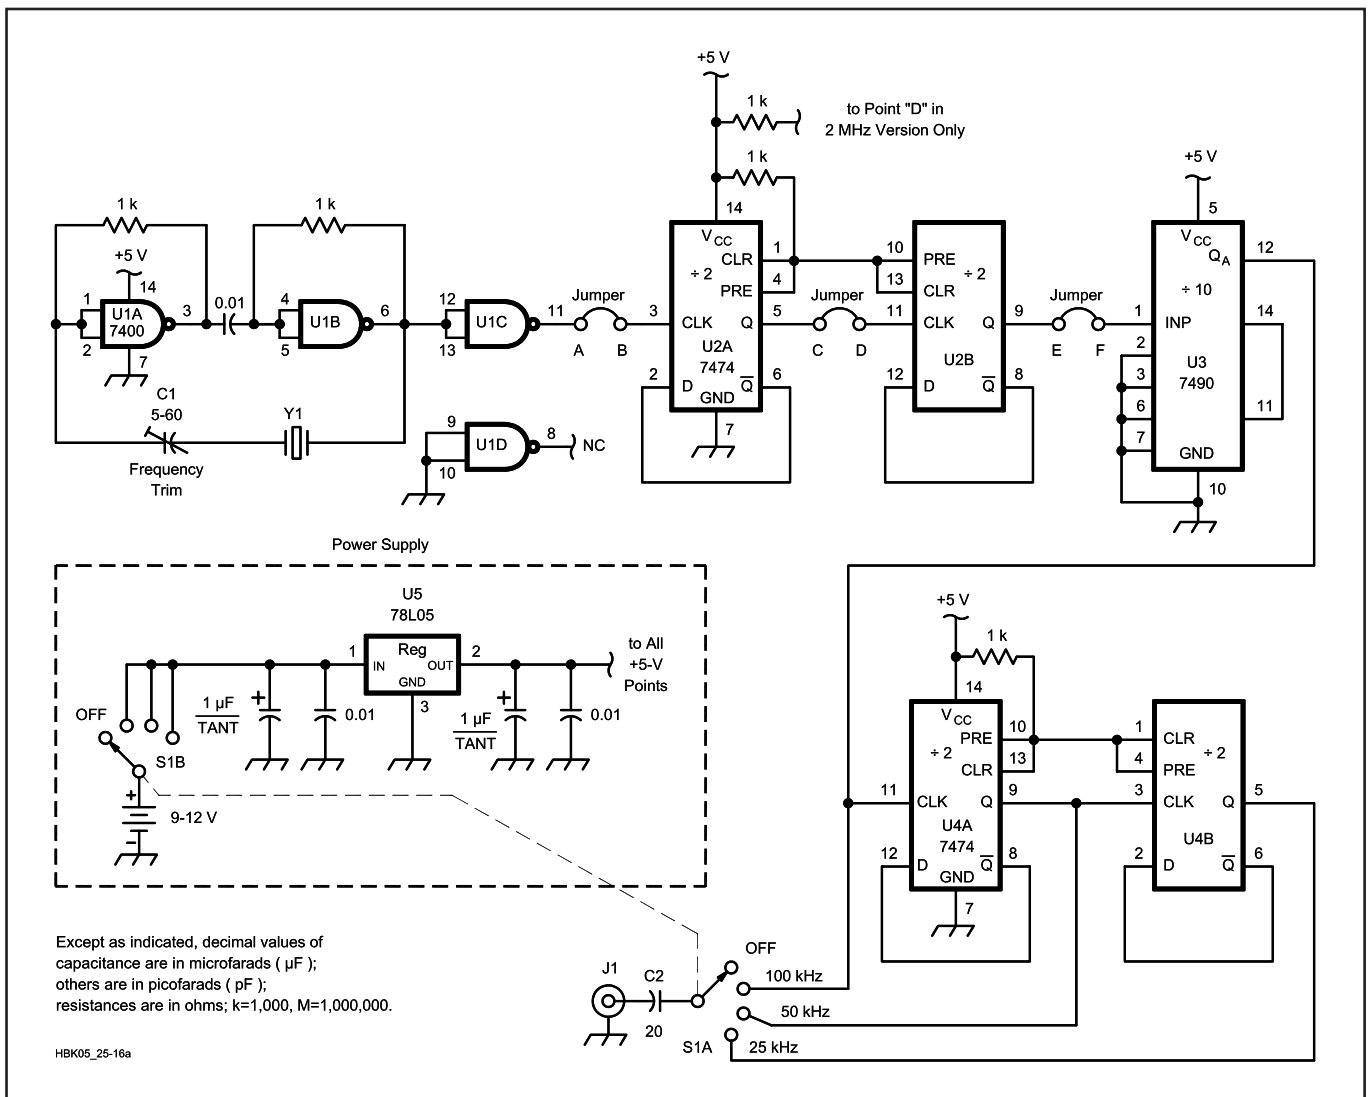

Fig 25.16B — Schematic diagram of the marker generator.

- C2 — 20-pF disc ceramic.
- U1 — 7400 or 74LS00 quad NAND gate.

- U2, U4 — 7474 or 74LS74 dual D flip-flop.
- U3 — 7490 or 74LS90 decade counter.
- U5 — 78L05, 7805 or LM340-T5 5-V voltage regulator.

Y1 — 1, 2 or 4-MHz crystal in HC-25, HC-33 or HC-6 holder.

Fig 25.17 — Dip meter coupling. (A) uses inductive coupling and (B) uses capacitive coupling.

When a current dip occurs, hold the meter steady and tune for minimum current. Once the dip is found, move the meter away from the circuit and confirm that the dip comes from the circuit under test (the current reading should increase with distance from the circuit until the dip is gone). Finally, move the meter back toward the circuit until the dip is just noticed. Retune the meter for minimum current and read the dip-meter frequency with a calibrated receiver or frequency meter.

The current dip of a good measurement is smooth and symmetrical. An asymmetrical dip indicates that the dip-meter oscillator frequency is being significantly influenced by the test circuit. Such conditions do not yield usable readings.

A measurement of effective unloaded inductor Q can be made with a dip meter and an RF voltmeter (or a dc voltmeter with an RF probe). Make a parallel resonant circuit using the inductor and a capacitance equal to that of the application circuit. Connect the RF voltmeter across this parallel combination and measure the resonant frequency. Adjust the dip-meter/circuit cou-

pling for a convenient reading on the voltmeter, then maintain this dip-meter/circuit relationship for the remainder of the test. Vary the dip meter frequency until the voltmeter reading drops to 0.707 times that at resonance. Note the frequency of the dip meter and repeat the process, this time varying the frequency on the opposite side of resonance. The difference between the two dip meter readings is the test-circuit bandwidth. This can be used to calculate the circuit Q :

$$Q = \frac{f_0}{BW} \quad (9)$$

where

f_0 = operating frequency,

BW = measured bandwidth in the same units as the operating frequency.

When purchasing a dip meter, look for one that is mechanically and electrically stable. The coils should be in good condition. A headphone connection is helpful. Battery-operated models are convenient for antenna measurements.

A DIP METER WITH DIGITAL DISPLAY

An up-to-date dip meter was described by Larry Cicchinelli in the October 1993 issue of *QEX*. It consists of a dip meter with a three-digit frequency display. The analog portion of the circuit consists of an FET oscillator, voltage-doubler detector, dc-offset circuit and amplifier. The digital portion of the circuit consists of a high-impedance buffer, prescaler, counter, display driver, LED display and control circuit.

Circuit Description

The dip meter shown in **Fig 25.18** has four distinct functional blocks. The RF oscillator is a standard Colpitts using a common junction FET, Q1, as the active element. Its range is about 1.7 to 45 MHz. The 200-pF tuning capacitor gives a 2:1 tuning range. A 2:1 frequency range requires a capacitor with a 4:1 range. The sum of the minimum capacitance of the variable, the capacitors across the inductor and the strays must therefore be in the order of 70 pF. The values of L1 were determined experimentally by winding the coils and observing the lower and upper frequency values. [Table 25.3 shows winding data calculated from the author's schematic. — Ed.] The coil sizes were experimentally

determined, and the coils are constructed on 1/4-inch-diameter plug-in coil forms with #20 enameled wire. They are close wound. The number of turns shown are only a starting point; you may need to change them slightly in order to cover the desired frequency range.

The tapped capacitors are mounted inside the coil forms so that their values could be different for each band if required. The frequency spread of the lowest band is less than 2:1 because the tapped capacitor values are larger than those for the other bands. The frequency spread of the highest band is greater than 2:1 because its capacitors are smaller.

The analog display circuit begins with a voltage-doubler detector in order to get

higher sensitivity. It drives a dc-offset circuit, U1A. R1 inserts a variable offset that is subtracted from the detector voltage. This allows the variable gain stage, U1B, to be more sensitive to variations in the detector output voltage. Q9 follows U1C to get an output gating voltage closer to ground. The resistor in series with the meter is chosen to limit the meter current to a safe value. For example, if a 1-mA meter is used, the resistor should be 8.2 kΩ.

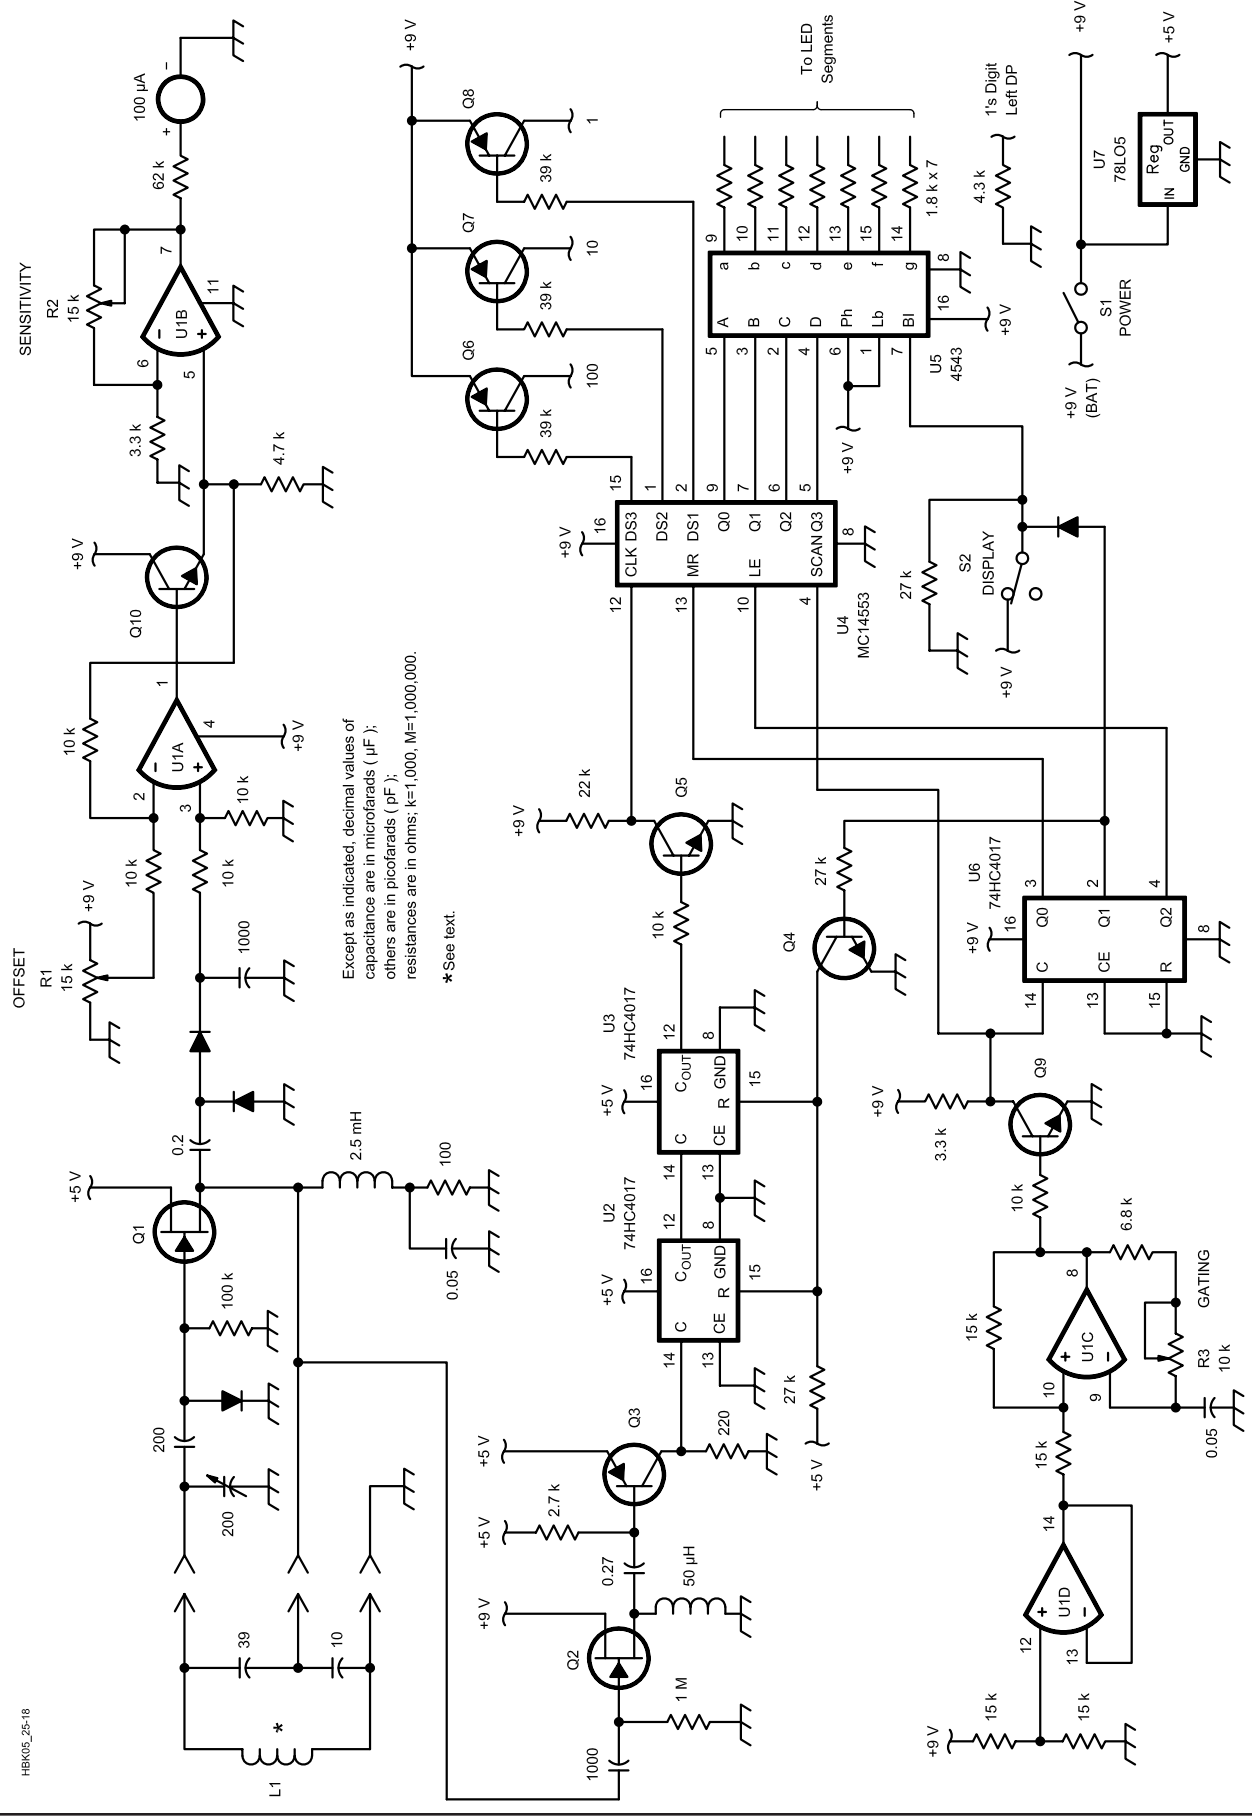

The prescaler begins with a high-impedance buffer and amplifier, Q2 and Q3. If you are going to use the meter for the entire frequency range described, take care in the layout of both the oscillator and buffer/ amplifier circuits. The digital portion of the prescaler is a divide-by-100 circuit consisting of two divide-by-10 devices, U2 and U3. The devices used were selected because they were available. Any similar devices may be used as long as the reset circuit is compatible. Q5 is a level translator that shifts the 5-V signal to 9 V.

The first part of the digital display block is the oscillator circuit of U1C, which creates the gate time for the frequency counter. R3 adjusts the oscillator to a frequency of 500 Hz, yielding a 1-ms gate. The best way to set this frequency is to

Table 25.3
Calculated Coil Data for the Dip Meter

Frequency (MHz)	L (μH)	Turns
1.7 to 3.1	48.6	52
2.8 to 5.9	16.3	23
5.6 to 11.9	4.0	9
9.7 to 20.7	1.3	5
19.0 to 45.0	0.3	2

listen for the dip-meter output on a communications receiver and adjust R3 until the display agrees with the receiver. Once this calibration has been made for one of the bands, all the bands are calibrated. U1D gives a low-impedance voltage reference for U1C. Q9 was added to the output of the oscillator to remove a small glitch, which can cause the counter to trigger incorrectly. This type of oscillator has the advantage of simplicity. This circuit is fairly stable, easy to adjust and has a low parts count.

The digital system controller, U6, is a divide-by-10 counter. It has 10 decoded outputs, each of which goes high for one period of the input clock. The Q0 output is used to reset the frequency counter, U4. The Q1 output is used to enable the prescaler and disable the display and the Q2 output latches the count value into the frequency counter. Since the prescaler can only count while Q1 is high, it will be enabled for only 1 ms. Normally a 1-ms gate will yield 1-kHz resolution. Since the circuit uses a divide-by-100 prescaler, the resolution becomes 100 kHz.

The frequency counter, U4, is a three-digit counter with multiplexed BCD outputs. The clock input is driven from the prescaler, hence it is the RF oscillator frequency divided by 100. This signal is present for only 1 ms out of every 10 ms. The digit scanning is controlled by the 500-Hz oscillator of U1C.

U5 is a BCD-to-seven-segment de-

coder/driver. Its outputs are connected to each of the three common-anode, seven-segment displays in parallel. Only the currently active digit will be turned on by the digit strobe outputs of U5, via Q6, Q7 and Q8. The diode connected to the blanking input of U5 disables the display while U4 is counting. U7 is a 5-V regulator that allows the use of a single 9-V battery for both the circuit and the LEDs. S2 turns on the displays once the unit has been adjusted for a dip.

The circuit draws about 20 mA with the LEDs off and up to 35 mA with the LEDs on.

Many of the resistor values are not critical, and those used were chosen based upon availability; the op-amp circuits depend primarily on resistance ratios. The resistor at the collector of Q3 is critical and should not be varied. Use 0.27- μ F monolithic capacitors. They have the required good high-frequency characteristics over the range of the meter.

Most of the parts can be purchased from Digi-Key. They did not have the '4543 IC, which was purchased from Hosfelt Electronics in Steubenville, OH. The 74HC4017 may be substituted with a 74HCT4017. The circuit is built on a 4-inch-square perf board (with places for up to 12 ICs) and is housed in a 7 \times 5 \times 3-inch minibox.

Operation

To use the unit, set the gain, R2, fully clockwise for maximum sensitivity. With this setting, the output of the offset circuit (Q10 emitter) is at ground. As R1 is rotated, the voltage on the arm approaches and then becomes less than, the detector output. At this point the meter will start to deflect upward. Adjust R1 so that the meter reads about center scale. (Manual adjustment allows for variations in the output level of the RF oscillator.) As L1 is brought closer to the circuit under test, the meter will deflect downward as energy is absorbed by the circuit. For best results use the minimum possible coupling to the circuit being tested. If the dip meter is overcoupled to the test circuit, the oscillator frequency will be pulled.

FREQUENCY COUNTERS

One of the most accurate means of measuring frequency is a frequency counter. This instrument is capable of numerically displaying the frequency of the signal supplied to its input. For example, if an oscillator operating at 8.244 MHz is connected to a counter input, 8.244 would be displayed. At present, counters are usable well up into the gigahertz range. Most counters that are used at high frequencies make use of a prescaler ahead of a basic low-frequency counter. A prescaler divides the high-frequency signal by 10, 100, 1000 or some other fixed amount so that a low-frequency counter can display the operating frequency.

The accuracy of the counter depends on its internal crystal reference. A more accurate crystal reference yields more accurate readings. Crystals for frequency counters are manufactured to close tolerances. Most counters have a trimmer capacitor so that the crystal can be set exactly on frequency. Crystal frequencies of 1 MHz, 5 MHz or 10 MHz have become more or less standard. For calibration, harmonics of the crystal can be compared to a known reference station, such as those shown in Table 25.1, or other frequency standard and adjusted for zero beat.

Many frequency counters offer options to increase the accuracy of the counter timebase; this directly increases the counter accuracy. These options usually employ temperature-compensated crystal oscillators (TCXOs) or crystals mounted in constant temperature ovens that keep the crystal from being affected by changes in ambient (room) temperature. Counters with these options may be accurate to 0.1 ppm (part per million) or better. For example, a counter with a timebase accuracy of 5.0 ppm and a second counter with a TCXO accurate to 0.1 ppm are available to check a 436-MHz CW transmitter for satellite use. The counter with the 5-ppm timebase could have a frequency error of as much as 2.18 kHz, while the possible error of the counter with the 0.1 ppm timebase is only 0.0436 kHz.

Other Instruments and Measurements

This section covers a variety of test equipment that is useful in receiver and transmitter testing. It includes RF and audio generators, an inductance meter, a capacitance meter, oscilloscopes, spectrum analyzers, a calibrated noise source, and hybrid combiners. A number of applications of this equipment for basic transmitter and receiver testing is also included.

RF OSCILLATORS FOR CIRCUIT ALIGNMENT

Receiver testing and alignment uses equipment common to ordinary radio service work. Inexpensive RF signal generators are available, both complete and in kit form. However, any source of signal that is weak enough to avoid overloading the receiver usually will serve for alignment work. The frequency marker generator is a satisfactory signal source. In addition, its frequencies, although not continuously adjustable, are far more precise, since the usual signal-generator calibration is not highly accurate. When buying a used or inexpensive signal generator, look for these attributes: output level is calibrated, the output doesn't "ring" too badly when tapped, and doesn't drift too badly when warmed up. Many military surplus units are available that can work quite well. Commercial units such as the HP608 are big and stable, and they may be inexpensive.

Fig 25.19 — Values for the twin-T audio oscillator circuit range from 18 k Ω for R1-R2 and 0.05 μ F for C1 (750 Hz) to 15 k Ω and 0.02 μ F for 1800 Hz. For the same frequency range, R3 and C2-C3 vary from 1800 Ω and 0.02 μ F to 1500 Ω and 0.01 μ F. R4 is 3300 Ω and C4, the output coupling capacitor, can be 0.05 μ F for high-impedance loads.

AUDIO-FREQUENCY OSCILLATORS

An audio signal generator should provide a reasonably pure sine wave. The best oscillator circuits for this use are RC coupled, operating as close to a class-A amplifier as possible. Variable frequencies covering the entire audio range are needed for determining frequency response of audio amplifiers.

An oscillator generating one or two frequencies with good waveform is sufficient for most phone-transmitter testing and simple troubleshooting in AF amplifiers. A two-tone (dual) oscillator is very useful for testing and adjusting sideband transmitters.

A circuit of a simple RC oscillator that is useful for general testing is given in Fig 25.19. This Twin-T arrangement gives a waveform that is satisfactory for most purposes. The oscillator can be operated

at any frequency in the audio range by varying the component values. R1, R2 and C1 form a low-pass network, while C2, C3 and R3 form a high-pass network. As the phase shifts are opposite, there is only one frequency at which the total phase shift from collector to base is 180°. Oscillation will occur at this frequency. When C1 is about twice the capacitance of C2 or C3 the best operation results. R3 should have a resistance about 0.1 that of R1 or R2 (C2 = C3 and R1 = R2). Output is taken across C1, where the harmonic distortion is least. Use a relatively high impedance load — 100 k Ω or more.

Most small-signal AF transistors can be used for Q1. Either NPN or PNP types are satisfactory if the supply polarity is set correctly. R4, the collector load resistor may be changed a little to adjust the oscillator for best output waveform.

A WIDE-RANGE AUDIO OSCILLATOR

A wide-range audio oscillator that will provide a moderate output level can be built from a single 741 operational amplifier (Fig 25.20). Power is supplied by two 9-V batteries from which the circuit draws

4 mA. The frequency range is selectable from 8 Hz to 150 kHz. Distortion is approximately 1%. The output level under a light load (10 k Ω) is 4 to 5 V. This can be increased by using higher battery volt-

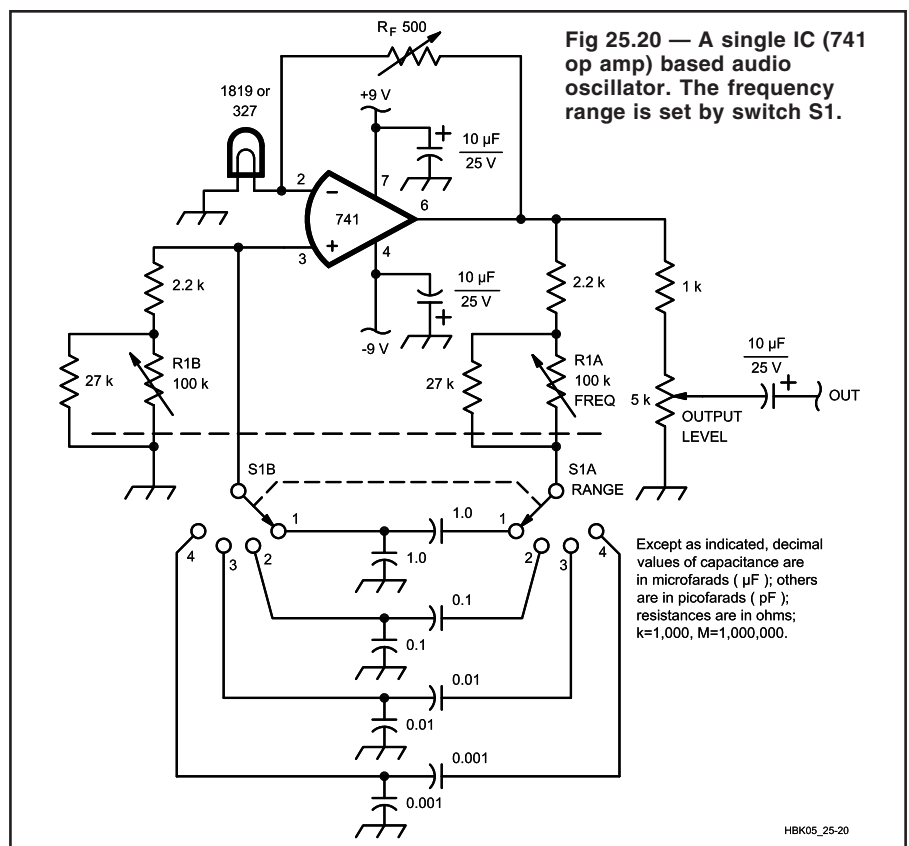

Fig 25.20 — A single IC (741 op amp) based audio oscillator. The frequency range is set by switch S1.

Except as indicated, decimal values of capacitance are in microfarads (μ F); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

ages, up to a maximum of plus and minus 18 V, with a corresponding adjustment of R_F .

Pin connections shown are for the TO-5 case and the eight-pin DIP package.

Variable resistor R_F is trimmed for an output level of about 5% below clipping as seen on an oscilloscope. This should be done for the temperature at which the oscillator will normally operate, as the lamp

is sensitive to ambient temperature. This unit was originally described by Shultz in November 1974 *QST*; it was later modified by Neben as reported in June 1983 *QST*.

MEASURE INDUCTANCE AND CAPACITANCE WITH A DVM

Many of us have a DVM (Digital volt-meter) or VOM (volt-ohm meter) in the shack, but few of us own an inductance or capacitance meter. If you have ever looked into your junk box and wanted to know the value of the unmarked parts,

these simple circuits will give you the answer. They may be built in one evening (Fig 25.21 and Fig 25.22), and will adapt your DVM or VOM to measure inductance or capacitance. The units are calibrated against a known part. Therefore,

the overall accuracy depends only on the calibration values and not on the components used to build the circuits. If it is carefully calibrated, an overall accuracy of 10% may be expected if used with a DVM and slightly less with a VOM.

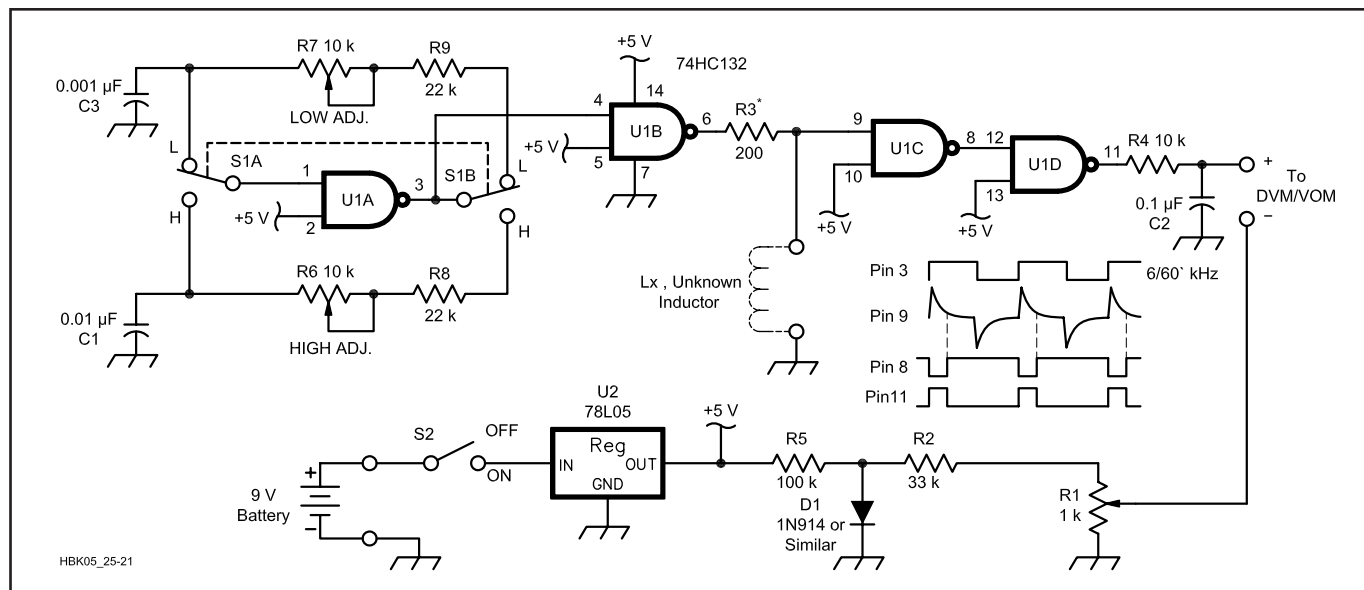

Fig 25.21 — All components are 10% tolerance. 1N4148 or equivalent may be substituted for D1. A LM7805 may be substituted for the 78L05. All fixed resistors are 1/4-W carbon composition. Capacitors are in μF . R_3 value may need to be increased or decreased slightly if calibration cannot be achieved as described in text.

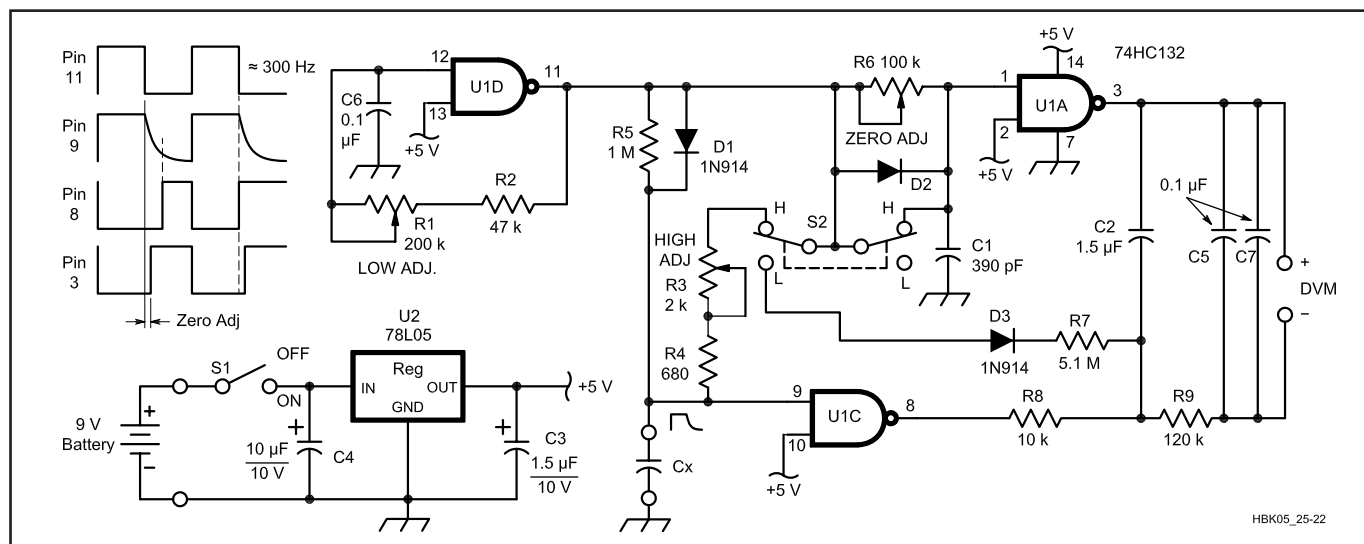

Fig 25.22 — All components are 10% tolerance. An LM7805 may be substituted for the 78L05. All fixed resistors are 1/4-W carbon composition. Capacitors are in μF unless otherwise indicated.

CONSTRUCTION

The circuits may be constructed on a small perf board (RadioShack dual mini board, #276-168), or if you prefer, on a PC board. A template and parts layout may be obtained from the ARRL.¹ Layout is non-critical—almost any construction technique will suffice. Wire-wrapping or point-to-point soldering may be used.

The circuits are available in kit form from Electronic Rainbow Inc., Indianapolis, IN. The IA inductance adapter kit is sold separately, but a cabinet is also available. The PC board is 1.75 × 2.5 inches. The CA-1 capacitance adapter kit comes with a 1.80 × 2.0-inch PC board.

INDUCTANCE ADAPTER FOR DVM/VOM

Description

The circuit shown in Fig 25.21 converts an unknown inductance into a voltage that can be displayed on a DVM or VOM. Values between 3 and 500 μH are measured on the low range and from 100 μH to 7 mH on the high range. NAND gate U1A is a two frequency RC square-wave oscillator. The output frequency (pin 3) is approximately 60 kHz in the low range and 6 kHz in the high range. The square-wave output is buffered by U1B and applied to a differentiator formed by R3 and the unknown inductor, LX. The stream of spikes produced at pin 9 decay at a rate proportional to the time constant of R3-LX. Because R3 is a constant, the decay time is directly proportional to the value of LX. U1C squares up the positive going spikes, producing a stream of negative going pulses at pin 8 whose width is proportional to the value of LX.

They are inverted by U1D (pin 11) and

integrated by R4-C2 to produce a steady dc voltage at the + output terminal. The resulting dc voltage is proportional to LX and the repetition rate of the oscillator. R6 and R7 are used to calibrate the unit by setting a repetition rate that produces a dc voltage corresponding to the unknown inductance. D1 provides a 0.7 volt constant voltage source that is scaled by R1 to produce a small offset reference voltage for zeroing the meter on the low inductance range.

When S1 is low, *mV* corresponds to μH and when high, *mV* corresponds to *mH*. A sensitive VOM may be substituted for the DVM with a sacrifice in resolution.

Test and Calibration

Short the LX terminals with a piece of wire and connect a DVM set to the 200-mV range to the output. Adjust R1 for a zero reading. Remove the short and substitute a known inductor of approximately 400 μH . Set S1 to the low (in) position and adjust R7 for a reading equal to the known inductance. Switch S1 to the high position and connect a known inductor of about 5 mH. Adjust R6 for the corresponding value. For instance, if the actual value of the calibration inductor is 4.76 mH, adjust R7 so the DVM reads 476 mV.

CAPACITANCE ADAPTER FOR DVM/VOM

Description

The circuit shown in Fig 25.22 measures capacitance from 2.2 to 1000 pF in the low range, from 1000 pF to 2.2 μF in the high range. U1D of the 74HC132 (pin 11) produces a 300 Hz square-wave clock. On the rising edge CX rapidly charges through

D1. On the falling edge CX slowly discharges through R5 on the low range and through R3-R4 on the high range. This produces an asymmetrical waveform at pin 8 of U1C with a duty cycle proportional to the unknown capacitance, CX. This signal is integrated by R8-R9-C2 producing a dc voltage at the negative meter terminal proportional to the unknown capacitance. A constant reference voltage is produced at the positive meter terminal by integrating the square-wave at U1A, pin 3. R6 alters the symmetry of this square-wave producing a small change in the reference voltage at the positive meter terminal. This feature provides a zero adjustment on the low range. The DVM measures the difference between the positive and negative meter terminals. This difference is proportional to the unknown capacitance.

Test and Calibration

Without a capacitor connected to the input terminals, set SW2 to the low range (out) and attach a DVM to the output terminals. Set the DVM to the 2-volt range and adjust R6 for a zero meter reading. Now connect a 1000 pF calibration capacitor to the input and adjust R1 for a reading of 1.00 volt. Switch to the high range and connect a 1.00 μF calibration capacitor to the input. Adjust R3 for a meter reading of 1.00 volts. The calibration capacitors do not have to be exactly 1000 pF or 1.00 μF , as long as you know their exact value. For instance, if the calibration capacitor is known to be 0.940 μF , adjust the output for a reading of 940 mV.

Note

¹See the **Project Templates** section of the *Handbook* CD-ROM.

OSCILLOSCOPES

Most engineers and technicians will tell you that the most useful single piece of test and design equipment is the triggered-sweep oscilloscope (commonly called just a “scope”). This section was written by Dom Mallozzi, N1DM.

Oscilloscopes can measure and display voltage relative to time, showing the waveforms seen in electronics textbooks. Scopes are broken down into two major classifications: analog and digital. This does not refer to the signals they measure, but rather to the methods used inside the scope to process signals for display.

ANALOG OSCILLOSCOPES

Fig 25.23 shows a simplified diagram

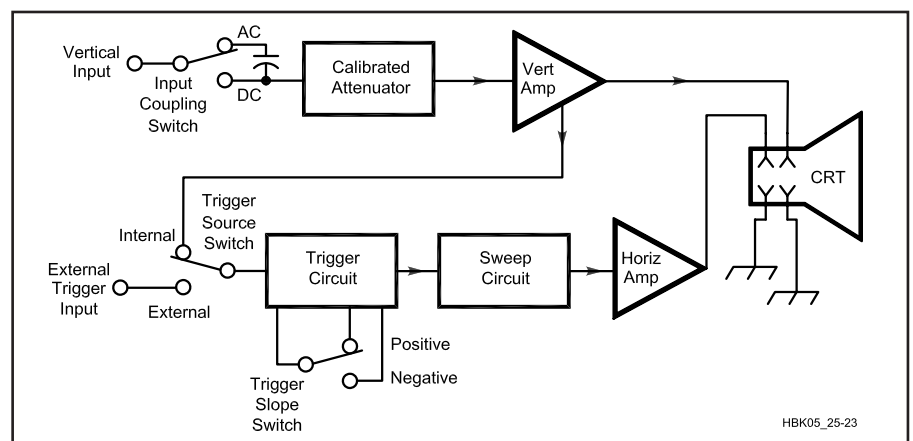

Fig 25.23 — Typical block diagram of a simple triggered-sweep oscilloscope.

of a triggered-sweep oscilloscope. At the heart of nearly all scopes is a cathode-ray tube (CRT) display. The CRT allows the visual display of an electronic signal by taking two electric signals and using them to move (deflect) a beam of electrons that strikes the screen. Unlike a television CRT, an oscilloscope uses electrostatic deflection rather than magnetic deflection. Wherever the beam strikes the phosphorescent screen of the CRT it causes a small spot to glow. The exact location of the spot is a result of the voltage applied to the vertical and horizontal inputs.

All of the other circuits in the scope are used to take the real-world signal and convert it to a form usable by the CRT. To trace how a signal travels through the oscilloscope circuitry start by assuming that the trigger select switch is in the INTERNAL position.

The input signal is connected to the input COUPLING switch. The switch allows selection of either the ac part of an ac/dc signal or the total signal. If you wanted to measure, for example, the RF swing at the collector of an output stage (referenced to the dc level), you would use the dc-coupling mode. In the ac position, dc is blocked from reaching the vertical amplifier chain so that you can measure a small ac signal superimposed on a much larger dc level. For example, you might want to measure a 25 mV 120-Hz ripple on a 13 Vdc power supply. Note that you should not use ac coupling at frequencies below 30 Hz, because the value of the blocking capacitor represents a considerable series impedance to very low-frequency signals.

After the coupling switch, the signal is connected to a calibrated attenuator. This is used to reduce the signal to a level that can be tolerated by the scope's vertical amplifier. The vertical amplifier boosts the signal to a level that can drive the CRT and also adds a bias component to locate the waveform on the screen.

A small sample of the signal from the vertical amplifier is sent to the trigger circuitry. The trigger circuit feeds a start pulse to the sweep generator when the input signal reaches a certain level. The sweep generator gives a precisely timed signal that looks like a triangle (see Fig 25.24). This triangular signal causes the scope trace to sweep from left to right, with the zero-voltage point representing the left side of the screen and the maximum voltage representing the right side of the screen.

The sweep circuit feeds the horizontal amplifier that, in turn, drives the CRT. It is also possible to trigger the sweep system from an external source (such as the system clock in a digital system). This is done by using an external input jack with

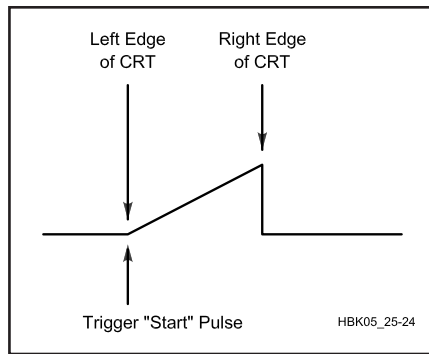

Fig 25.24 — The sweep trigger starts the ramp waveform that sweeps the CRT electron beam from side to side.

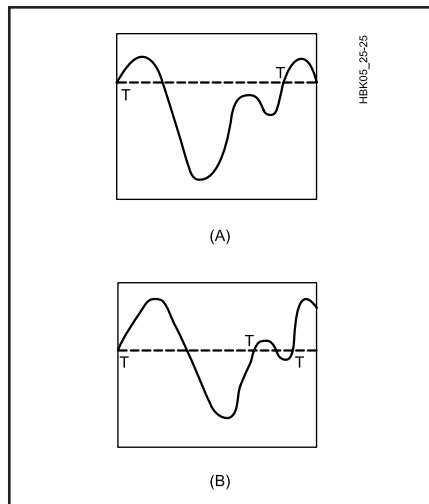

Fig 25.25 — In order to produce a stable display the selection of the trigger point is very important. Selecting the trigger point in A produces a stable display, but the trigger shown at B will produce a display that “jitters” from side to side.

Fig 25.26 — Oscilloscopes with a calibrated sweep rate can be used to measure frequency. Here the waveform shown has a period of 80 microseconds (8 divisions \times 10 μ s per division) and therefore a period of 1/80 μ s or 12.5 kHz.

the trigger select switch in the EXTERNAL position.

The trigger system controls the horizontal sweep. It looks at the trigger source (internal or external) to find out if it is positive- or negative-going and to see if the signal has passed a particular level. Fig 25.25A shows a typical signal and the dotted line on the figure represents the trigger level. It is important to note that once a trigger circuit is “fired” it cannot fire again until the sweep has moved all the way across the screen from left to right. In normal operation, the TRIGGER LEVEL control is manually adjusted until a stable display is seen. Some scopes have an AUTOMATIC position that chooses a level to lock the display in place without manual adjustment.

Fig 25.25B shows what happens when the level has not been properly selected. Because there are two points during a single cycle of the waveform that meet the triggering requirements, the trigger circuit will have a tendency to jump from one trigger point to another. This will make the waveform jitter from left to right. Adjustment of the TRIGGER control will fix this problem.

The horizontal travel of the trace is calibrated in units of time. If the time of one cycle is known, we can calculate the frequency of the waveform. In Fig 25.26, for example, if the SWEEP speed selector is set at 10 μ s/division and we count the number of divisions (vertical bars) between peaks of the waveform (or any similar well defined points that occur once per cycle) we can find the period of one cycle. In this case it is 80 μ s. This means that the frequency of the waveform is 12,500 Hz (1/80 μ s). The accuracy of the measured frequency depends on the accuracy of the scope's sweep oscillator (usually approximately 5%) and the linearity of the ramp generator. This accuracy cannot compete with even the least-expensive frequency counter, but the scope can still be used to determine whether a circuit is functioning properly.

Dual-Trace Oscilloscopes

Dual-trace oscilloscopes can display two waveforms at once. This type of scope has two vertical input channels that can be displayed either alone, together or one after the other. Fig 25.27 shows a simplified block diagram of a dual-trace oscilloscope. The only differences between this scope and the previous example are the additional vertical amplifier and the “channel switching circuit.” This block determines whether we display channel A, channel B or both (simultaneously). The dual display is not a true dual display

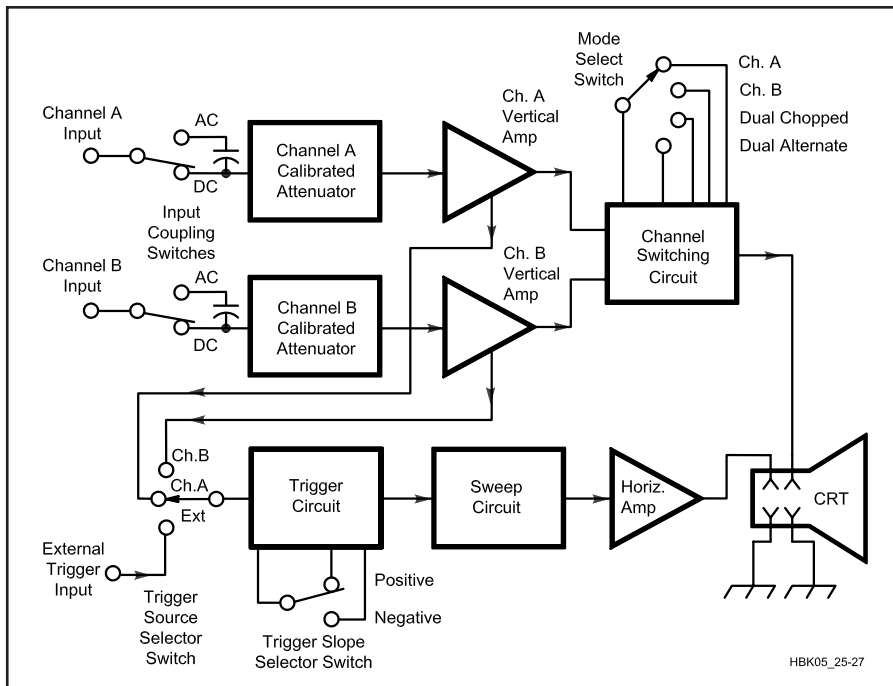

Fig 25.27 — Simplified Dual-trace oscilloscope block diagram. Note the two identical input channels and amplifiers.

(there is only one electron gun in the CRT) but the dual traces are synthesized in the scope.

There are two methods of synthesizing a dual-trace display from a single-beam scope. These two methods are referred to as *chopped mode* and *alternate mode*. In the chopped mode a small portion of the channel A waveform is written to the CRT, then a corresponding portion of the channel B waveform is written to the CRT. This procedure is continued until both waveforms are completely written on the CRT. The chopped mode is especially useful where an actual measure of the phase difference between the two wave-

forms is required. The chopped mode is usually most useful on slow sweep speeds (times greater than a few microseconds per division).

In the alternate mode, the complete channel A waveform is written to the CRT followed immediately by the complete channel B waveform. This happens so quickly that it appears that the waveforms are displayed at the same time. This mode of operation is not useful at very slow sweep speeds, but is good at most other sweep speeds.

Most dual-trace oscilloscopes also have a feature called “X-Y” operation. This feature allows one channel to drive the

horizontal amplifier of the scope (called the X channel) while the other channel (called Y in this mode of operation) drives the vertical amplifier. Some oscilloscopes also have an external Y input. X-Y operation allows the scope to display Lissajous patterns for frequency and phase comparison and to use specialized test adapters such as curve tracers or spectrum analyzer front ends. Because of frequency limitations of most scope horizontal amplifiers the X channel is usually limited to a 5 or 10-MHz bandwidth.

DIGITAL OSCILLOSCOPES

The classic analog oscilloscope just discussed has existed for over 50 years. In the last 15 years, the digital oscilloscope has advanced from a specialized laboratory device to a very useful general-purpose tool, with a price attractive to an active experimenter. It uses digital circuitry and microprocessors to enhance the processing and display of signals. These result in dramatically improved accuracy for both amplitude and time measurements. When configured as a digital storage oscilloscope (DSO) it can read a stored waveform for as long as you wish without time limitations incurred by an analog type of storage scope.

Examine the simplified block diagram shown in **Fig 25.28**. After the signal goes through the vertical input attenuators and amplifiers, it arrives at the analog-to-digital converter (ADC). The ADC assigns a digital value to the level of the analog input signal and puts this in a memory similar to computer RAM. This value is stored with an assigned time, determined by the trigger circuits and the crystal timebase. The digital oscilloscope takes discrete amplitude samples at regular time intervals. If you were to take this data directly from memory, it would put a series

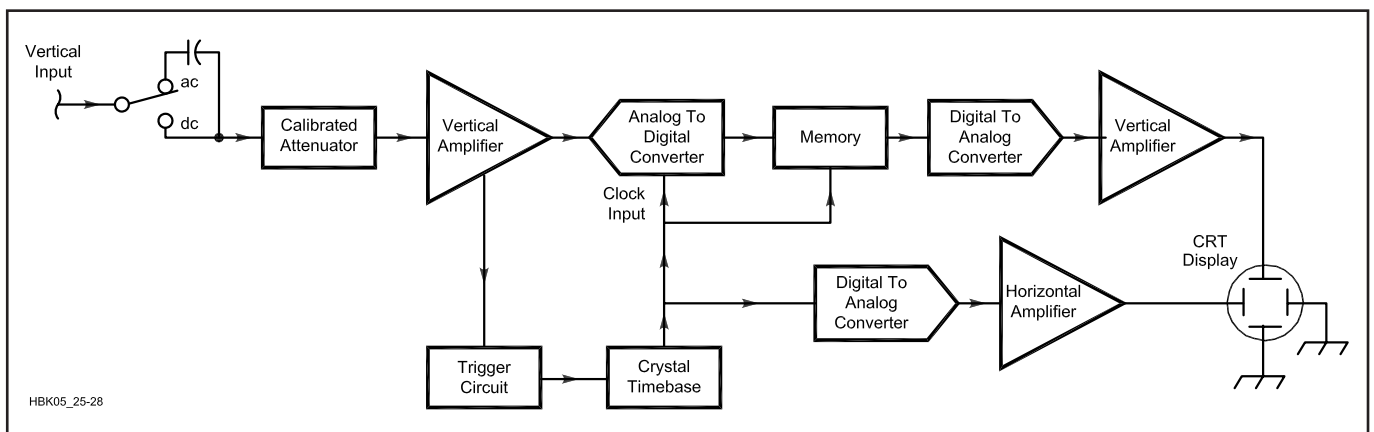

Fig 25.28 — Simplified block diagram of a digital oscilloscope. Note: The microprocessors are not shown for clarity. From “ABC’s of Oscilloscopes,” copyright Fluke Corporation (reproduced with permission).

of dots on the screen. You would then have to connect the dots to reconstruct the original waveform. The digital scope's microprocessor does this for you by mathematically processing the signal while reading it back from the memory and driving a digital-to-analog converter (DAC), which then drives the vertical deflection amplifier. A DAC also takes the digital stored time data and uses it to drive the horizontal deflection amplifier.

For the vertical signals you will see manufacturers refer to "8-bit digitizing," or perhaps "10-bit resolution." This is a measure of how many digital levels that are shown along the vertical (voltage) axis. More bits give you better resolution and accuracy of measurement. An 8-bit vertical resolution means each vertical screen has 2^8 (or 256) discrete values; similarly, 10 bits resolution yields 2^{10} (or 1024) discrete values.

It is important to understand some of the limitations resulting from sampling the signal rather than taking a continuous, analog measurement. When you try to reconstruct a signal from individual discrete samples, you must take samples at least twice as fast as the highest frequency signal being measured. If you digitize a 100-MHz sine wave, you should take samples at a rate of 200 million samples a second (referred to as 200 Megasamples/

second). Actually, you really would like to take samples even more often, usually at a rate at least five times higher than the input signal.

If the sample rate is not high enough, very fast signal changes between sampling points will not appear on the display. For example, **Fig 25.29** shows one signal measured using both analog and digital scopes. The large spikes seen in the analog-scope display are not visible on the digital scope. The sampling frequency of the digital scope is not fast enough to store the higher frequency components of the waveform. If you take samples at a rate less than twice the input frequency, the reconstructed signal has a wrong apparent frequency; this is referred to as *aliasing*. In **Fig 25.29** you can see that there is about one sample taken per cycle of the input waveform. This does not meet the 2:1 criteria established above. The result is that the scope reconstructs a waveform with a different apparent frequency.

Many older digital scopes had potential problems with aliasing. Newer scopes use advanced techniques to check themselves. A simple manual check for aliasing is to use the highest practical sweep speed (shortest time per division) and then to change to other sweep speeds to verify that the apparent frequency doesn't change.

LIMITATIONS

Oscilloscopes have fundamental limits, primarily in frequency of operation and range of input voltages. For most purposes the voltage range of a scope can be ex-

Fig 25.29 — Comparison of an analog scope waveform (A) and that produced by a digital oscilloscope (B). Notice that the digital samples in B are not continuous, which may leave the actual shape of the waveform in doubt for the fastest rise time displays the scope is capable of producing.

panded by the use of appropriate probes. The frequency response (also called the bandwidth) of a scope is usually the most important limiting factor. At the specified maximum response frequency, the response will be down 3 dB (0.707 voltage). For example, a 100-MHz 1-V sine wave fed into a 100-MHz bandwidth scope will read approximately 0.707 V on the scope display. The same scope at frequencies below 30 MHz (down to dc) should be accurate to about 5%.

A parameter called *rise time* is directly related to bandwidth. This term describes a scope's ability to accurately display voltages that rise very quickly. For example, a very sharp and square waveform may appear to take some time in order to reach a specified fraction of the input voltage level. The rise time is usually defined as the time required for the display to show a change from the 10% to 90% points of the input waveform, as shown in **Fig 25.30**. The mathematical definition of rise time is given by:

$$t_r = \frac{0.35}{BW} \quad (10)$$

where

$$t_r = \text{rise time, } \mu\text{s}$$

$$BW = \text{bandwidth, MHz}$$

It is also important to note that all but the most modern (and expensive) scopes are not designed for precise measurement of either time or frequency. At best, they will not have better than 5% accuracy in these applications. This does not change the usefulness of even a moderately priced oscilloscope, however. The most important value of an oscilloscope is that it presents an image of what is going on in a circuit and quickly shows which component or stage is at fault. It can show modulation levels, relative gain between stages and oscillator output.

Oscilloscope Probes

Oscilloscopes are usually connected to a circuit under test with a short length of shielded cable and a probe. At low frequencies, a piece of small-diameter coax cable and some sort of insulated test probe might do. Unfortunately, at higher frequencies the capacitance of the cable would produce a capacitive reactance much less than the one-megohm input impedance of the oscilloscope. In addition each scope has a certain built-in capacitance at its input terminals (usually between 5 and 35 pF). These two capacitances cause problems when probing an RF circuit with a relatively high impedance.

The simplest method of connecting a signal to a scope is to use a specially de-

Fig 25.30 — The bandwidth of the oscilloscope vertical channel limits the rise time of the signals displayed on the scope.

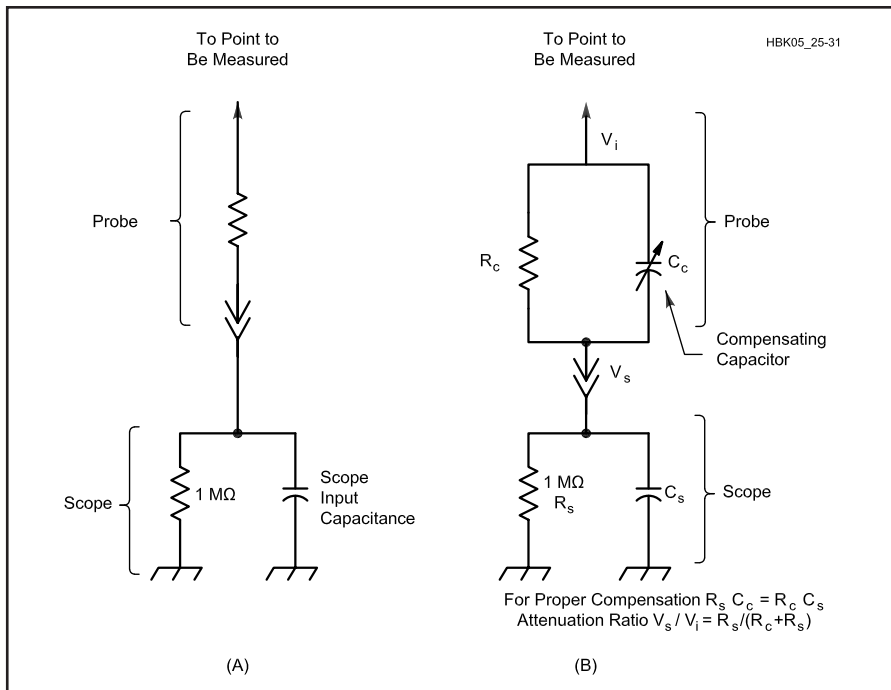

Fig 25.31 — Uncompensated probes such as the one at A are sufficient for low-frequency and slow-rise-time measurements. However, for accurate display of fast rise times with high-frequency components the compensated probe at B must be used. The variable capacitor is adjusted for proper compensation (see text for details).

signed probe. The most common scope probe is a $\times 10$ probe (called a times ten probe). This probe forms a 10:1 voltage divider using the built-in resistance of the probe and the input resistance of the scope. When using a $\times 10$ probe, all voltage readings must be multiplied by 10. For example, if the scope is on the 1 V/division range and a $\times 10$ probe was in use, the signals would be displayed on the scope face at 10 V/division.

Unfortunately a resistor alone in series

with the scope input seriously degrades the scope's rise-time performance and therefore its bandwidth. Since the scope input looks like a parallel RC circuit, the series resistor feeding it causes a significant reduction in available charging current from the source. This may be corrected by using a compensating capacitor in parallel with the series resistor. Thus two dividers are formed: one resistive voltage divider and one capacitive voltage divider. With these two dividers con-

as Fast Fourier Transforms (FFT). This allows limited spectrum analysis or other advanced mathematical techniques to be applied to the displayed waveform.

BUYING A USED SCOPE

Many hams will end up buying a used scope due to price. If you buy a scope and intend to service it yourself, be aware all scopes that use tubes or a CRT contain lethal voltages. Treat an oscilloscope with the same care you would use with a tube-type high-power amplifier. The CRT should be handled carefully because if dropped it will crack and implode, result-

Fig 25.32 — Displays of a square-wave input illustrating undercompensated, properly compensated and overcompensated probes.

nected in parallel and the RC relationships shown in Fig 25.31, the probe and scope should have a flat response curve through the whole bandwidth of the scope.

To account for manufacturing tolerances in the scope and probe the compensating capacitor is made variable. Most scopes provide a "calibrator" output that produces a known-frequency square wave for the purpose of adjusting the compensating capacitor in a probe. Fig 25.32 shows possible responses when the probe is connected to the oscilloscope's calibrator jack.

If a probe cable is too short, do not attempt to extend the length of the cable by adding a piece of common coaxial cable. The cable usually used for probes is much different than common 50 or 75- Ω coax. In addition the compensating capacitor in the probe is chosen to compensate for the provided length of cable. It usually will not have enough range to compensate for extra lengths.

The shortest ground lead possible should be used from the probe to the circuit ground. Long ground leads are inductors at high frequencies. In these circuits they cause ringing and other undesirable effects.

ing in pieces of glass and other materials being sprayed everywhere in the immediate vicinity. You should wear a full-face safety shield and other appropriate safety equipment to protect yourself.

Another concern when servicing an older scope is the availability of parts. Many scopes made since about 1985 have used special ICs, LCDs and microprocessors. Some of these may not be available or may be prohibitive in cost. You should buy a used scope from a reputable vendor—even better yet, try it out before you buy it. Make sure you get the operators manual also.

AN HF ADAPTER FOR NARROW-BANDWIDTH OSCILLOSCOPES

Fig 25.33 shows the circuit of a simple piece of test equipment that will allow you to display signals that are beyond the normal bandwidth of an inexpensive oscilloscope. This circuit was built to monitor modulation of a 10-m signal on a scope that has a 5-MHz upper-frequency limit. This design features a Mini-Circuits Laboratory SRA-1 mixer. Any stable oscillator or VFO with an output of 10 dBm can be used for the local oscillator (LO), which mixes with the HF signal to produce an IF in the bandwidth of the oscilloscope.

The mixer can handle RF signal levels up to -3 dBm without clipping, so this was set as an upper limit for the RF input. A toroidal transformer coupler is constructed by winding a 31-turn secondary of #28-AWG wire on an FT-37-75 core for RG-174 or an FT-50-75 core for use with slightly larger coax such as RG-58. The primary is the piece of coaxial cable passed through the core center. The coupler gives 30 dB of attenuation and has a flat response from 0.5 to 100 MHz. An additional 20-dB of attenuation was added for a total of 50 dB before the mixer. One-watt resistors will do fine for the attenuator. The completed adapter should be built into a shielded box.

This circuit, with a 25-MHz LO frequency, is useful on frequencies in the 20 to 30-MHz range with transmitters of up to 50-W power output. By changing the frequency of the LO, any frequency in the range of the coupler can be displayed on a 5-MHz-bandwidth oscilloscope. The fre-

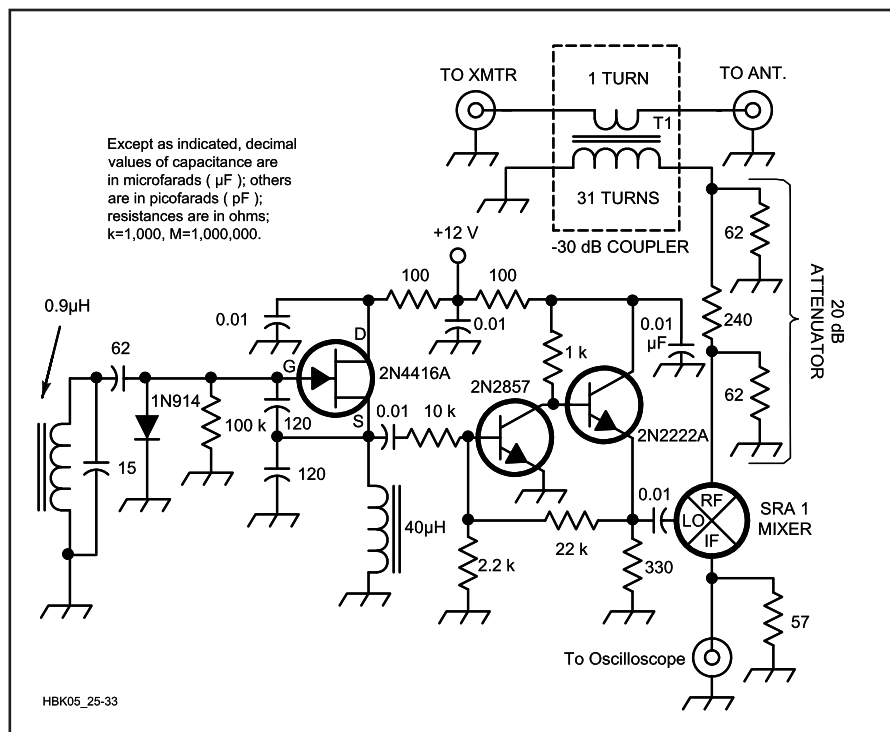

Fig 25.33 — This adapter displays HF signals on a narrow-bandwidth oscilloscope. It uses a 10-dBm 25-MHz LO, -30 -dB coupler, 20-dB attenuator and diode-ring mixer. See text for further information.

quency displayed will be the difference between the LO and the input signal. As an example, a 28.1-MHz input and a 25-MHz LO will be seen as a 3.1-MHz signal on the oscilloscope.

More attenuation will be required for higher-power transmitters. This circuit was described by Kenneth Stringham Jr, AE1X, in the Hints and Kinks column of February 1982 *QST*.

A CALIBRATED NOISE SOURCE

NOISE FIGURE MEASUREMENT

One of the most important measurements in communications is the noise figure of a receiving setup. Relative measurements are often easy, while accurate ones are more difficult and expensive. One EME (moon bounce) station checks noise and system performance by measuring the noise of the sun reflected off the moon. While the measurement source (use of the sun and moon) is not expensive, the measuring equipment on 2 m consists of 48 antennas (each over 30 ft long). This measurement equipment is not for everyone!

The rest of us use more conventional noise sources and measuring techniques. Coverage of noise figure and its measurement appear in the **Receivers and Trans-**

mitters chapter of this *Handbook*.

Most calibrated and stable noise sources are expensive, but not this unit developed by Bill Sabin, WØIYH. It first appeared in May 1994 *QST*. When hams use a noise source, it is usually included in an RF bridge used to measure impedances and adjust antenna tuners. A somewhat different device (an *accurately calibrated and stable* noise source) is also useful. Combining a broadband RF noise source of known power output and a known output impedance with a true-RMS voltmeter, results in an excellent instrument for making interesting and revealing measurements on a variety of circuits hams commonly use. (Later on, some examples will be described.) The true-RMS voltmeter can be

an RF voltmeter, a spectrum analyzer or an AF voltmeter at the output of a linear receiver.¹

Calibrated noise generators and noise-figure meters are available at medium to astronomical prices. Here is a low-cost approach which can be used with reasonable confidence for many amateur applications where accuracy to tenths of a decibel is not needed, but where precision (repeatability) and comparative measurements are much more important. PC boards are available for this project.²

Semiconductor Noise Diodes

Any Zener diode can be used as a source of noise. If, however, the source is to be calibrated and used for reliable mea-

Except as indicated, decimal values of capacitance are in microfarads (μF); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

HBK05_25-34

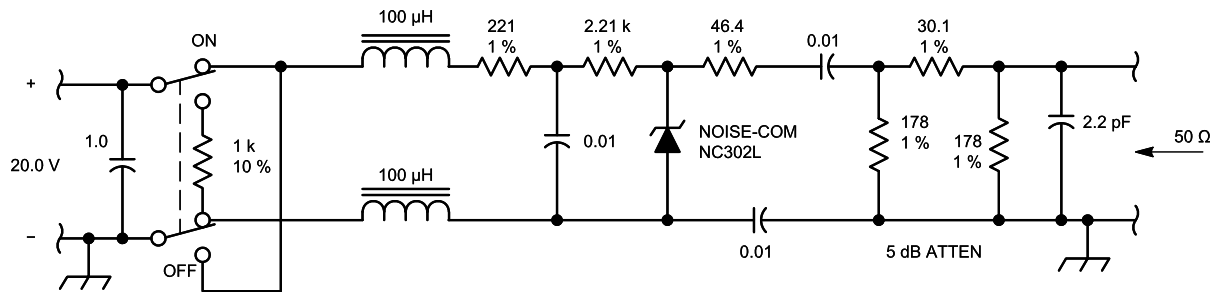

Fig 25.34 — Schematic of the 0.5 to 500-MHz calibrated noise source. Resistors are $\frac{1}{8}$ -W, 1%-tolerance metal-film units. 1% resistors are available from Digi-Key.

surements, avalanche diodes specially designed for this purpose are preferable by far.³ A good noise diode generates its noise through a carefully controlled *bulk avalanche* mechanism which exists *throughout* the PN junction, not merely at the junction surfaces where unstable and unreliable surface effects predominate due to local breakdown and impurity.⁴ A true noise diode has a very low *flicker noise* ($1/f$) effect and tends to create a uniform level of truly *Gaussian noise* over a wide band of frequencies.⁵ In order to maximize its bandwidth, the diode also has very low junction capacitance and lead inductance.

This project uses the NOISE/COM NC302L diode. It consists of a glass, axial-lead DO-35 package and is rated for use from 10 Hz to 3 GHz, if appropriate construction methods are followed. Prior to sale, the diodes are factory aged for 168 hours and are well stabilized. NOISE/

COM has kindly agreed to make these diodes available to amateur experimenters for the special price of \$10 each; the usual low-quantity price is about \$25.⁶

Noise Source Design

The noise source presents two kinds of available output power. One is the thermal noise (-174 dBm/Hz at room temperature) when the diode is turned off. This is called N_{OFF} . The other is the sum of this same thermal noise and an “excess” noise, N_E , which is created by the diode when turned on, called N_{ON} (equivalent to $N_{\text{OFF}} + N_E$). For accurate measurements, the output impedance of the test apparatus must be the same (on or off) so that the device under test (DUT) always sees the same generator impedance. In Amateur Radio work, this impedance is usually 50Ω , resistive. The circuit design must guarantee this condition.

For maximum frequency coverage, a

PC-board layout and coax connector suitable for use at microwaves are needed. For lower frequency usage, a less stringent approach can be employed. Two noise sources are presented here. One is for the 0.5 to 500-MHz region and uses conventional components that many amateurs already have. The other is for the 1-MHz to 2.5-GHz range; it uses chip components and an SMA connector.

Circuit Diagram and Construction

Figs 25.34 and 25.35 show the simple schematics of the two noise sources. In series with the diode is a $46.4\text{-}\Omega$ resistor that combines with the dynamic resistance of the diode in the avalanche, noise generator mode (about 4Ω) to total about 50Ω . When the applied voltage polarity is reversed, the diode is forward conducting and its dynamic resistance is still about 4Ω , but the avalanche noise is now turned off. As a result, the noise source output impedance

Except as indicated, decimal values of capacitance are in microfarads (μF); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

HBK05_25-35

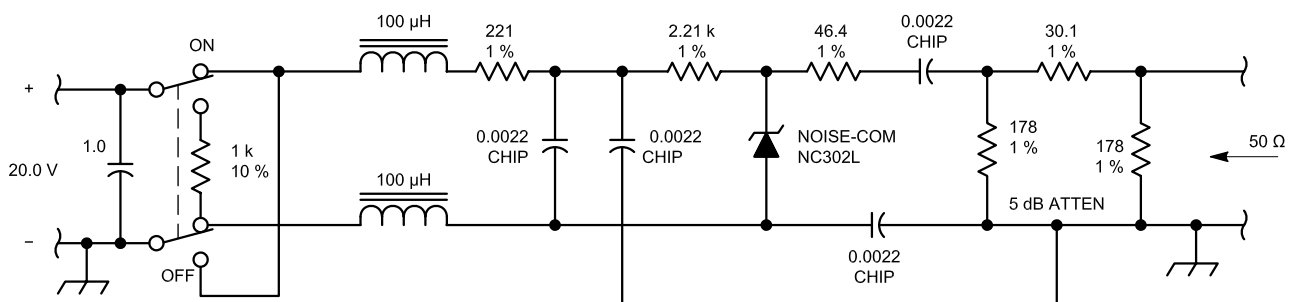

Fig 25.35 — The 1-MHz to 2.5-GHz calibrated noise source uses 1%-tolerance, 0.1-W chip resistors and chip capacitors. 1% resistors are available from Digi-Key.

is always about 50 Ω. The 5-dB pad reduces the effect of any small impedance differences, so that the output impedance is nearly constant from the *on* to the *off* condition, and the SWR is less than 2:1.

Consider the noise situation of the noise diode when it is forward conducting. The resistance of the forward biased PN junction is a *dynamic* resistance. This dynamic resistance is *not* a source of thermal noise, since it is not an actual physical resistance such as in a resistor or lossy network. However, the 0.6-V forward drop across the PN junction does produce a shot noise effect. The mathematics of this shot noise shows that the noise power associated with this effect is only about 50% of the thermal noise power that would be available

from a physical resistor having the same value as the dynamic resistance. Therefore, the forward biased junction does *not* add excess noise to the system.⁷ There is an 1/f noise effect associated with this shot noise in the diode, but its corner frequency is at about 100 kHz and of no importance at higher frequencies. Also, the small amount of bulk resistance contributes a little thermal noise.

In order to maximize the unit's flatness and frequency response bandwidth, noise-source construction methods should aim for RF circuit lead lengths as close to zero as possible as well as minimum inductance in the ground path and the coupling capacitors. The power-supply voltage must be clean, well bypassed and set accurately. Fig 25.36 shows a 0.5 to 500-MHz unit. This construction method satisfies quite well the electrical requirements wanted for this model. At 500 MHz, the return loss with respect to 50 Ω at the output jack decreased to 10 dB. A calibration chart (Fig 25.37) is attached to the unit's top for easy reference. Fig 25.38 shows the inside of the 1-MHz to 2.5-GHz noise source.

Fig 25.36 — An inside view of the 0.5 to 500-MHz noise source.

Fig 25.37 — Sample calibration chart for the 0.5 to 500-MHz noise source.

Fig 25.38 — A view inside of the 1-MHz to 2.5-GHz noise source.

Calibrating the Noise Source

If the construction is solid, the calibration should last for a long time. There are two ways to calibrate the noise source. If the unit *has been carefully constructed and its correct operation verified*, NOISE/COM will calibrate home-built units over the desired frequency range for \$25 plus return shipping charges. Note that one factory calibrated unit can be used as a reference for many home calibrated units. Fig 25.39 shows the NOISE/COM cali-

bration data for both models of prototype noise sources, including SWR data. The noise data is strictly valid only at room temperature, so it's necessary to avoid extreme temperature environments.

The second calibration method requires a signal generator with known output levels at the various desired calibration frequencies. One approach is to build a tunable weak-signal oscillator that can be compared to some accessible high-quality signal generator, using a sensitive receiver as a detector.⁸ The level of the signal source in dBm is needed.

Access to a multistage attenuator is also desirable. Build the attenuator using the nearest 1% values of metal-film resistors, so that systematic errors are minimized. A total attenuation of 25 dB in 0.1-dB steps is desirable. Attenuator construction must be appropriate for use at the intended frequency range. In some cases, a high-frequency correction chart may be needed.

With the calibrated signal source and the attenuator feeding the receiver in an SSB or CW mode the techniques discussed in the reference of Note 1 should be used to determine the excess noise (N_E) of the noise source and the noise bandwidth (B_N) of the receiver.

Excess Noise Ratio

A few words about excess noise ratio (ENR) are needed. It is defined as the ratio of excess noise to thermal noise. That is,

$$ENR = \frac{N_{ON} - N_{OFF}}{N_{OFF}} = \frac{N_E}{N_{OFF}} \quad (12)$$

When the noise source is turned on, its

Frequency (MHz)	0.5 to 500 MHz Unit		1.0 to 2500 MHz Unit	
	ENR (dB)	SWR	NR (dB)	SWR
0.5	22.33	1.03		
1	22.38	1.03	21.38	1.03
10	22.45	1.04	21.46	1.03
20	22.35	1.06		
30	22.32	1.06		
40	22.32	1.09		
50	22.30	1.11		
60	22.29	1.12		
70	22.25	1.15		
80	22.22	1.17		
90	22.20	1.20		
100	22.15	1.23	21.80	1.07
200	21.65	1.42		
300	20.96	1.62		
400	20.25	1.70		
500	19.60	1.90	20.71	1.44
1000			20.12	1.86
1500			20.00	2.06
2000			20.70	2.14
2500			21.51	1.88

Fig 25.39 — NOISE/COM calibration data for both prototype noise sources. The data is not universal; it varies from unit to unit.

output is $N_{OFF} + N_E$. The ratio of N_{ON} to N_{OFF} is then

$$\frac{N_{ON}}{N_{OFF}} = \frac{N_{OFF} + N_E}{N_{OFF}} = 1 + \frac{N_E}{N_{OFF}} = 1 + ENR \quad (13)$$

Therefore, ENR is a measure of how much the noise increases and the noise generator can be calibrated in terms of its ENR.

Normalizing ENR to a 1-Hz bandwidth and converting to decibels, this is

$$ENR \text{ (dB)} = 174 \text{ (dBm / Hz)} + \frac{N_E \text{ (dBm)}}{B_N \text{ (Hz)}} \quad (14)$$

Prepare a calibration chart and attach it to the top of the unit (see Fig 25.37). If the unit is to be factory calibrated, first perform the calibration procedure to ensure everything is working properly. Remember, a factory calibrated unit can be used as a reference for other home calibrated units, once the calibration-transfer procedures have been worked out. This requires some careful thinking and proper techniques. Generally speaking, a NOISE/COM calibration is the best choice.

Noise-Figure Measurement

The thermal noise power available from the attenuator remains constant for any value of attenuator setting. But the excess noise and therefore the ENR (in dB) due to the noise diode is equal to the calibration point of the source minus the setting (in dB) of the attenuator.

The noise-figure measurement of a device under test (DUT) uses the Y method and the setup in Fig 25.40. If the DUT has a noise-generator input and a true-RMS noise-measuring instrument at the output, then the total output noise (including the contribution of the measuring instrument) with the noise generator turned off is

$$N_{OFF(TOT)} = kTB_N F_{TOT} G_{DUT} G_{NMI} \quad (15)$$

where

kTB_N = thermal noise,

G_{DUT} = gain of the DUT,

G_{NMI} = gain of the noise-measuring instrument, and

F_{TOT} = noise factor of the combination of the DUT and the noise-measuring instrument.

When the noise generator is turned on, the output noise is

$$N_{ON(TOT)} = kTB_N F_{TOT} G_{DUT} G_{NMI} + (ENR)kTB_N G_{DUT} G_{NMI} \quad (16)$$

Where the last term is the contribution of excess noise by the noise generator. Note that none of these values is in dB or dBm.

If we divide equation 16 by equation 15 and say that the ratio

$$\frac{N_{ON(TOT)}}{N_{OFF(TOT)}} = Y \quad (17)$$

then,

$$\frac{F_{TOT} + ENR}{F_{TOT}} = 1 + \frac{ENR}{F_{TOT}}$$

Note that kTB_N , G_{DUT} and G_{NMI} disappear, so that these quantities need not be known to measure noise factor. If we solve equation 17 for F_{TOT} , we get the noise factor

$$F_{TOT} = \frac{ENR}{Y - 1} \quad (18)$$

If the noise output doubles (increases by 3 dB) when we turn on the noise source, then $Y = 2$ and the noise factor is numerically equal to the excess noise ratio (ENR). If the attenuator steps are not fine enough or if the attenuator is not reliable over the entire frequency range, use equation 18 to get a better answer. (It's much simpler to use a good fine-step attenuator.) The value of F_{TOT} is that of the DUT in cascade with the noise-measuring instrument. To find F_{DUT} , we must know the noise factor F_{NMI}

of the noise-measuring instrument and G_{DUT} and then use the Friis formula, unless G_{DUT} is very large (as it would be if the DUT were a high-gain receiver (see Note 1).

$$F_{DUT} = F_{TOT} - \frac{F_{NMI} - 1}{G_{DUT}} \quad (19)$$

The validity of equation 19 (if we need to use it) requires that the noise bandwidth of the noise-measuring instrument be less than the noise bandwidth of the DUT (see the reference of Note 1). Verify this before proceeding.

There's another advantage to using the power-doubling method. If the 3-dB attenuator of Fig 25.40 is used to maintain a constant noise level into the following stages and the RMS meter, this means that the noise factor, using the calibration scale and the input attenuator (without using equation 18), is

$$F_{DUT} = ENR + \frac{1}{G_{DUT}} \quad (20)$$

If G_{DUT} is large, then the last term can be neglected. If G_{DUT} is small, we need to know its value. However, we do not need to know the noise factor F_{NMI} of the circuitry after the DUT, as we did in the previous discussion.

The 3-dB attenuator method also removes all restrictions regarding the type of noise measuring instrument, since the meter reading is now used only as a reference point. This last statement applies only when two noise (or two signal generator) inputs are being compared.

Frequency Response Measurements

The noise generator, in conjunction with a spectrum analyzer, is an excellent tool for measuring the frequency response of a DUT, if the noise source is much stronger than the internal noise of the DUT and that of the spectrum analyzer. Many spectrum analyzers are not equipped with tracking generators, which can be quite expensive for an amateur's budget.

The spectrum analyzer needs to be calibrated for a noise input, if accurate amplitude measurements are needed, because it responds differently to noise signals than to sine-wave signals. The envelope detection of noise, combined with the logarithmic amplification of the spectrum analyzer, creates an error of about 2.5 dB for a noise signal (the noise is that much greater than the instrument indicates). Also, the noise bandwidth of the IF filter is different from its resolution bandwidth. Some modern spectrum analyzers have internal DSP algorithms that make the corrections so that external noise sources and

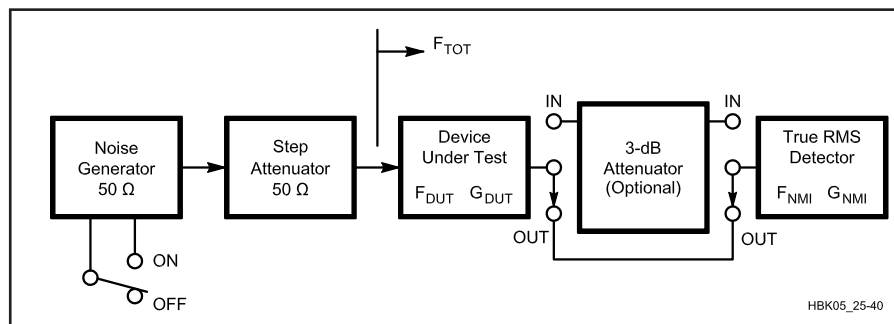

Fig 25.40 — Setup for measuring noise figure of a device under test (DUT).

also carrier-to-noise ratios, normalized to some noise bandwidth like 1.0 Hz, can be measured with fair accuracy if the input noise is a few decibels above thermal. One example is the Tektronix Model 2712. If only relative response readings are needed, then these corrections are not needed.

Also, the noise source itself can be used to establish an accurate reference level (in dBm) on the screen. An accurate, absolute measurement with the DUT in place will then be this reference level (in dBm), plus the increment in decibels produced by the DUT.

The noise-generator output can be viewed as a collection of sine waves separated by, say, 1 Hz. Each separated frequency “bin” has its own Gaussian amplitude and random phase with respect to all the others. So the DUT is simultaneously looking at a collection or “ensemble,” of input signals. As the spectrum analyzer frequency sweeps, it looks simultaneously at all of the DUT frequencies that fall within the spectrum analyzer’s IF noise bandwidth. The spectrum display is thus the “convolution” of the IF filter frequency response and the DUT frequency response. If the DUT is a narrow filter, a very narrow resolution and a slow sweep are needed in the spectrum analyzer. In addition, the analyzer’s video, or post-detection, filter has a narrow bandwidth and also requires some settling time to get an accurate reading. So, some experience and judgment are required to use a spectrum analyzer this way.

Using Your Station Receiver

Your station receiver can also be used

as a spectrum analyzer. Place a variable attenuator between the DUT and the receiver. As you tune your receiver, in a narrow CW mode, adjust the attenuator for a constant reference level receiver output. The attenuator values are inversely related to the frequency response.

A calibrated noise source with an adjustable attenuator that can be easily switched into a receiver antenna jack is an excellent tool for measuring antenna noise level or incoming weak signal level (in dBm) or for establishing correct receiver operation.

The noise source can also be combined with a locally generated data-mode waveform of a known dBm value to get an approximate check on modem performance or to make adjustments that might assure correct operation of the system. The rigorous evaluation of system performance requires special equipment and techniques that may be unavailable at most amateur stations. Or, you could evaluate the intelligibility improvement of your SSB transmitter’s speech processor in a noise background.

Summary

The calibrated, flat-spectrum noise generator described in this article is quite a useful instrument for amateur experimenters. Its simplicity and low cost make it especially attractive. Getting a good calibration is the main challenge, but once it is achieved, the calibration lasts a long time, if the right diode is used. The ENR of the units described here is in the range of 20 dB. Use of a high-quality, external, 10-dB attenuator barrel will get into the range of 10-dB ENR. If the unit is sent to

NOISE/COM the attenuator should also be sent, with the request that it be included in the calibration. That attenuator then “belongs” to the noise source and should be so tagged. If the attenuator is of high quality, the output SWR will also be improved. NOISE/COM suggests periodic recalibration, at your discretion.

²PC boards are available from FAR Circuits, Dundee, IL. A PC board template for the Sabin noise source is available at: www.arrrl.org/notes.

³The term Zener diode is commonly used to denote a diode that takes advantage of avalanche effect, even though the Zener effect and the avalanche effect are not exactly the same thing at the device-physics level.

⁴The term bulk avalanche refers to the avalanche multiplication effect in a PN junction. A carrier (electron or hole) with sufficient energy collides with atoms and causes more carriers to be knocked loose. This effect “avalanches” and it occurs throughout the volume of the PN junction. This mechanism is responsible for the high-quality noise generation in a true noise diode.

⁵Gaussian noise refers to the instantaneous values of a noise voltage. These values conform to the Gaussian probability density function of statistics.

A SIGNAL GENERATOR FOR RECEIVER TESTING

The oscillator shown in **Fig 25.41** and **Fig 25.42** was designed for testing high-performance receivers. Parts cost for the oscillator has been kept to a minimum by careful design. While the stability is slightly less than that of a well-designed crystal oscillator, the stability of the unit should be good enough to measure most amateur receivers. In addition, the ability to shift frequency is important when dealing with receivers that have spurious responses. More importantly, LC oscillators with high-Q components often have much

better phase noise performance than crystal oscillators, because of power limitations in the crystal oscillators (crystals are easily damaged by excessive power).

The circuit is a Hartley oscillator followed by a class-A buffer amplifier. A 5-V regulator is used to keep the power supply output stable. The amplifier is cleaned up by a seven-element Chebyshev low-pass filter, which is terminated by a 6-dB attenuator. The attenuator keeps the filter working properly, even with a receiver that has an input impedance other

than 50 Ω . A receiver designed to work with a 50- Ω system may not have a 50- Ω input impedance. The +4 dBm output is strong enough for most receiver measurements. It may even be too strong for some receivers. Note that sensitive components like crystal filters may require a step attenuator to lower the output level.

Construction

This unit is built in a box made of double-sided circuit board. Its inside dimensions are 1 \times 2.2 \times 5 inches (HWD). The copper

- C1** — 1.4 to 9.2-pF air trimmer (value and type not critical).
- C2** — 270-pF silver-mica or NP0 capacitor. Value may be changed slightly to compensate for variations in L1.
- C3** — 56-pF silver mica or NP0 capacitor. Value may be changed to adjust output power.

- C4** — 1000 pF solder-in feedthrough capacitor. Available from Microwave Components of Michigan.
- C5-C8** — Silver-mica, NP0 disc or polystyrene capacitor.
- D1** — 1N914, 1N4148.
- L1** — 31t #18 enameled wire on T-94-6 core. Tap 8 turns from ground end ($7.5 \mu\text{H}$).

- L2, L4** — 21t #22 enameled wire on a T-50-2 core ($2.5 \mu\text{H}$, $2.43 \mu\text{H}$ ideal).
- L3** — 23t #22 enameled wire on a T-50-2 core. ($2.9 \mu\text{H}$, $3.01 \mu\text{H}$ ideal).
- T1** — 7t #22 enameled wire bifilar wound on an FT-37-43 core.
- Q1** — 2N5486 JFET. MPF102 may give reduced output.
- Q2** — 2N5109.
- U1** — 78L05 low-current 5-V regulator.

Return Loss Bridges

Return loss is a measure of how closely one impedance matches a reference impedance in phase angle and magnitude. If the reference impedance equals the measured impedance level with a 0° phase difference it has a return loss of infinity. **Fig A** shows basic return-loss measurement setups. Return-loss bridges are good for measuring filter response because return loss measurements are a more sensitive measure of passband response than insertion-loss measurements.

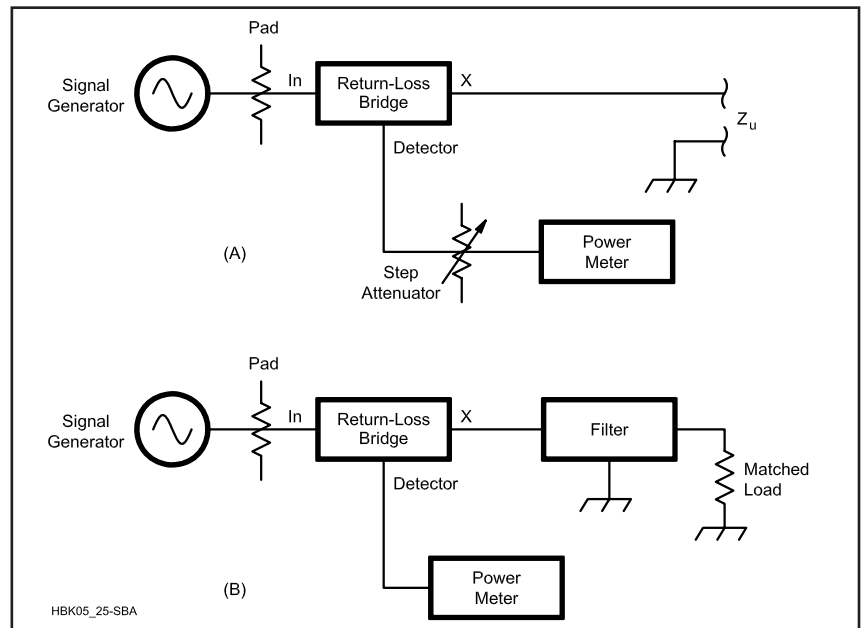

A 100 Hz to 100-kHz Return-Loss Bridge

Ed Wetherhold, W3NQN, has developed a low-frequency return-loss bridge (RLB) that can be adapted to different impedance levels. (See **Fig B**.) This bridge is used primarily for testing passive-LC filters that have

Fig A — A shows a setup to measure an unknown impedance with a return loss bridge. B is for measuring filter response.

been designed to work at a certain impedance level. Return-loss measurements require that the signal generator and RLB match the specific filter impedance level.

The characteristic impedance of this RLB is set by the values of four resistors ($R1 = R2 = R3 = R4 =$ characteristic impedance). Ed mounted the four resistors on a plug-

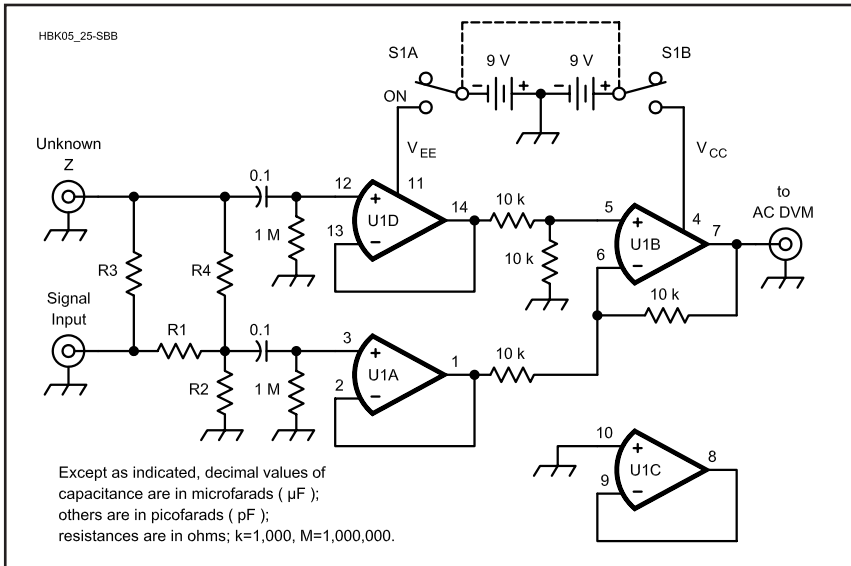

Fig B — An active low-frequency RLB. U1 is an LM324 quad op amp. R1, R2, R3 and R4 are 1/4-W, 1% resistors with the same value as the output impedance of the signal generator and the input impedance of the test circuit.

in module and placed their interconnections on the socket. Additional modules may be built for any impedance.

Table A provides computed values of return loss for several known loads and a 500-Ω RLB. If you build this RLB, use the values in the table to check its operation. For this frequency range, use an ac voltmeter in place of the power meter shown in Fig A. Choose one with good ac response well above 100 kHz.

Ed originally described this bridge circuit in an article published in 1993. That article provides complete construction details. Reprints are available for \$3 from Ed Wetherhold (W3NQN), 1426 Catlyn Place, Annapolis, MD 21401-4208. The RLB shown is useful from 100 Hz to 100 kHz.

An RF Return-Loss Bridge

At HF and higher frequencies, return-loss bridges are used as shown in Fig A for making measurements in RF circuits. The schematic of a simple bridge is shown in Fig C. (Notice that the circuit is identical to that of a hybrid combiner.) It is built in a small box with short leads to the coax connectors. Either 49.9-Ω 1% metal-film or 51-Ω 1/4-W carbon resistors may be used. The transformer is wound with 10 bifilar turns of #30 enameled wire on a high permeability ferrite core such as an FT-23-43 or similar.

Apply the output of the signal generator to the RF INPUT port of the RLB. It may be necessary to attenu-

ate the generator output to avoid overloading the amplifier under test. Connect the bridge DETECTOR port to a power meter through a step attenuator and leave the UNKNOWN port of the bridge open circuited. Set the step attenuator for a relatively high level of attenuation and note the power meter indication.

Now connect the unknown impedance, Z_u, to the bridge. The power meter reading will decrease. Adjust the step attenuator to produce the same reading obtained when the UNKNOWN port was open circuited. The difference between

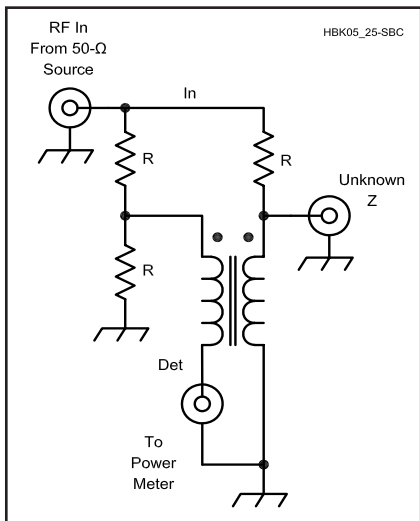

Fig C — An RLB for RF. Keep the lead lengths short. Wind the transformer on a high-permeability ferrite core. Use either 51-Ω carbon or 49.9-Ω 1% metal-film resistors.

Table A Performance and Test Data for the 100-Hz to 100-kHz RLB

Bridge and signal-generator impedance = 500 Ω

Bridge Directivity

Frequency	Return Loss (dB, Unknown = 500 Ω)
100 Hz to 10 kHz	> 45
10 kHz to 80 kHz	40
80 kHz to 100 kHz	30

Return Loss of Known Resistive Loads

$$R_{LOAD} = LF \times Z_{BRIDGE}$$

where

R_{LOAD} = Load resistance, ohms
 LF = Load factor
 Z_{BRIDGE} = characteristic bridge impedance, ohms.

LF Return Loss (dB)

5.848	3
3.009	6
1.925	10
1.222	20
1.065	30

the two settings of the attenuator is the return loss, measured in dB.

The unknown impedance measured by this technique is not limited to amplifier inputs. Coax cable attached to an antenna, a filter, or any other fixed impedance device can be characterized by return loss. Return loss is measured in dB, and it is related to a quantity known as the voltage reflection coefficient, ρ:

$$RL = -20 \log |\rho|$$

$$|\rho| = 10^{\frac{-RL}{20}}$$

where

RL = return loss, dB
 ρ = voltage reflection coefficient.

The relationship of return loss to SWR is:

$$SWR = \frac{1 + 10^{\frac{-x}{20}}}{1 - 10^{\frac{-x}{20}}}$$

where $x = \frac{-RL}{20}$

For example, if RL = 20 dB then

$$SWR = \frac{(1 + .1)}{(1 - .1)} = \frac{1.1}{0.9} = 1.22$$

Fig 25.42 — A low-cost LC oscillator for receiver measurements. Toroidal cores are used for all of the inductances.

foil of the circuit board makes an excellent shield, while the fiberglass helps temperature stability. Capacitor C2 should be soldered directly across L1 to ensure high Q.

Since this is an RF circuit, leads should be kept short. While silver mica capacitors have slightly better Q, NP0 capacitors may offer better stability. Mounting the three

inductors orthogonal (axis of the inductors 90° from each other) reduced the second-order harmonic by 2 dB when it was compared to the first unit that was made.

Alignment and Testing

The output of the regulator should be +5 V. The output of the oscillator should be +4 dBm (2.5 mW) into a 50-Ω load. Increasing the value of C3 will increase the power output to a maximum of about 10 mW. The frequency should be around 3.7 MHz. Additional capacitance across L1 (in parallel with C2) will lower the frequency if desired, while the trimmer capacitor (C1) specified will allow adjustment to a specific frequency. The drift of one of the first units made was 5 Hz over 25 minutes after a few minutes of warm up. If the warm-up drift is large, changing C2 may improve the situation somewhat. For most receivers, a drift of 100 Hz while you are doing measurements is not bad.

HYBRID COMBINERS FOR SIGNAL GENERATORS

Many receiver performance measurements require two signal generators to be attached to a receiver simultaneously. This, in turn, requires a combiner that isolates the two signal generators (to keep one generator from being frequency or phase modulated by the other). Commercially made hybrid combiners are available from Mini-Circuits Labs, Brooklyn, NY.

Alternatively, a hybrid combiner is not difficult to construct. The combiners described here (see **Fig 25.43**) provide 40 to 50 dB of isolation between ports (connections) while attenuating the desired signal paths (each input to output) by 6 dB. The 50-Ω impedance of the system is kept constant (very important if accurate measurements are to be made).

The combiners are constructed in small boxes made from double-sided circuit-board material. Each piece is soldered to the next one along the entire length of the seam. This makes a good RF-tight enclosure. BNC coaxial fittings are used on the units shown. However, any type of coaxial

connector can be used. Leads must be kept as short as possible and precision resistors (or matched units from the junk box) should be used. The circuit diagram for the combiners is shown in **Fig 25.44**.

Fig 25.43 — The hybrid combiner on the left is designed to cover the 1 to 50-MHz range; the one on the right 50 to 500 MHz.

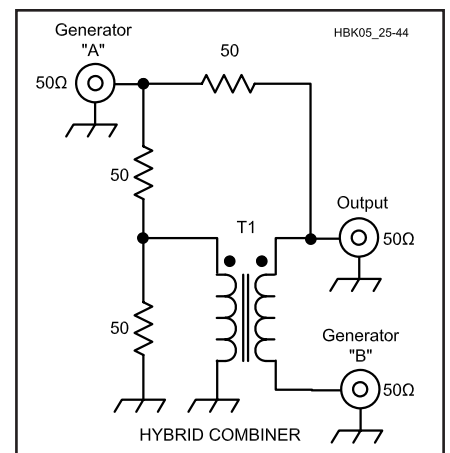

Fig 25.44 — A single bifilar wound transformer is used to make a hybrid combiner. For the 1 to 50-MHz model, T1 is 10 turns of #30 enameled wire bifilar wound on an FT-23-77 ferrite core. For the 50 to 500-MHz model, T1 consists of 10 turns of #30 enameled wire bifilar wound on an FT-23-67 ferrite core. Keep all leads as short as possible when constructing these units.

A COMPENSATED, MODULAR RF VOLTMETER

This versatile and yet simple voltmeter measures levels from 100 mV to 300 V, from 30 MHz to audio frequencies, and is accurate to ± 0.5 dB. The design allows for either a built-in analog meter or an externally connected DVM—or both! This portable, simple, and inexpensive project was originally featured in the March/April 2001 issue of *QEX*. Like the original article, the project described below includes several refinements implemented by its author, Sid Cooper, K2QHE that evolved from a suggestion by *QEX* Managing Editor, Robert Schetgen, KU7G, to increase the voltage range of the instrument.

The requirements for this RF voltmeter (RFVM, Fig 25.46) are many:

- Provide accurate, stable measurements
- Measure voltage at frequencies from audio through HF
- Measure voltage levels from QRP to QRO
- Measure voltages inside equipment or in coax
- Operate portably or from ac lines
- Be flexible: work with digital voltmeters already in the shack, or independently
- Be inexpensive

DESIGN APPROACH

To achieve stability, the RFVM uses op amps and any drift in the probe's diode detector is compensated by a matched diode in the RF op amp. This stretches the sensitivity to QRP levels. The dynamic range extends linearly from 0.1 V to 300 V (RMS) by using a series of compensated voltage multipliers.

The frequency response was flattened by using Schottky diodes, which easily reach from 60 Hz to 30 MHz. Both the basic probe and the multipliers very simply adapt to function as a probe, clip to various measurement points on chassis or to screw onto UHF connectors. The active devices are only two op amps. They draw 800 μ A of resting current and a maximum of 4.0 mA during operation from a 9-V battery, which is disconnected when a 9-V wall unit is plugged into a jack on the back panel. As designed, the RFVM has a small sloping panel cabinet with a microammeter display. A pair of front-panel banana OUTPUT jacks can be used with a DVM; this eliminates one op amp, the meter and a multiposition switch. Since the meter and switch are the most expensive parts (when they are not bought at a hamfest), how low-cost can this RF voltmeter get?

The Probe

The low-voltage probe is a detector circuit that uses a Schottky diode and a high-

impedance filter circuit (Fig 25.45). The diode is matched with the one in the feedback circuit of the CA3160 shown in Fig 25.64. This match reduces the diode's threshold voltage from about 0.34 V to less than 0.1 V, making the voltage drop comparable to that of a germanium diode. Since I think 0.1 V adequately covers QRP requirements, I made no further tests with germanium diodes to determine how much lower in voltage we could go.¹

Use the low voltage probe and the output of the CA3160 in the meter unit (Fig 25.64) to find a matched diode pair. Build the CA3160 circuit first for this purpose. Select a diode and place it in the feedback loop of the CA3160, then test each of the remaining diodes in the probe with the

three pots set about midrange. Test each diode, first at probe inputs of 100 mV, then at 3.00 V, at 400 Hz. Record the dc output from the CA3160, using the OUTPUT terminals. A bag of 20 diodes from Mouser Electronics² contained seven matched pairs, with identical readings at both low and high voltages. My tests used the ac scale (good to 500 Hz) of a Heath 2372 DVM to read the input voltage, and its dc scale to read the output. The number of matched pairs is surprising, but the diodes in the bag may all be from the same production run.

RF Probe Assembly

After selecting matched diodes, all components of the RF probe are mounted

Fig 25.45 — A schematic diagram of the RF probe.

Fig 25.46 — The RF voltmeter with meter unit, RF probe and voltage multipliers.

Fig 25.47 — RF probe construction showing the grabber clip (RS 270-334), pin tip (Mouser 534-1600), lug (Mouser 571-34120), for #14-#16 wire and a #6 stud), alligator clip (RS 270-1545), plug cap (Mouser 534-7604), grommet (Mouser 5167-208) and four-inch ground lead made from shield of RG-174.

on a piece of perf board that is inserted in an aluminum tube (**Fig 25.47**). Since the circuit board is very light, it is supported on each end only by its input and output wires. The input RF wire is soldered to the center pin of the SO-239 connector. The two dc-output wires are held to the board by a small tie wrap, consisting of a piece of the #26 insulated wire, after having been passed through the plug cap and grommet. Cut a slit in the aluminum tube, perpendicular to its end. Make it at least

$\frac{1}{8}$ -inch long and $\frac{1}{32}$ -inch wide to allow a bare #26 ground wire to pass through it.

Let's look at how the probe is assembled. The aluminum tube just fits around the back end of the SO-239 connector. When the four #6-32 screws, nuts and washers are installed in the four holes of the SO-239 connector, the flat face of the nut bears down strongly on the aluminum tube and rigidly holds it in place. Most standard SO-239 connector holes easily accept #6-32 screws; if yours do not, enlarge them with a #27 bit. The slit cut in the aluminum tube allows the bare ground wire from the perf board to pass from inside the tube to the outside and around the screw that secures the ground lead of the probe. As can be seen in **Fig 25.47**, the threaded part of the SO-239 connector faces away from the aluminum tube.

This probe allows easy voltage measurements in a coaxial cable when the probe SO-239 is secured to a mating T connector. To make a probe reading at any point on a chassis or PC board with this connector, simply insert the larger end of a nicely mating pin tip into the SO-239. The pin tip's diameter is 0.08 inches at the small end and—fittingly—0.14 inches at the mating end. I made this purely fortuitous discovery while rummaging through a very ancient junk box. Further, to make measurements with the probe clipped to a part or test point on a PC board or chassis, a clip or grabber can be mated to the pin tip that protrudes from the SO-239. This is shown in **Figs 25.47** and **25.48**. All this may have been known to people in the connector industry, but it appears not to have been known or used elsewhere. **Fig 25.49** shows the grabber connected to the RF

probe using the pin tip to join the two.

PROBE MEASUREMENTS

The probe can accept RF signals up to 20 V (RMS) when there is no dc voltage or a combination of dc voltage and peak ac of about 28 V without exceeding the reverse-voltage rating of the diode. I made linearity measurements of the RF probe from 100 mV to 8.0 V at 400 Hz. (The range was limited by my available signal generator.) **Fig 25.50** is a plot of the error at the probe output versus the input amplitude. This was measured using a digital voltmeter with a 10-M Ω input resistance. This input resistance and the 4.1-M Ω resistor in the probe converts the peak voltage of a sine wave signal to the RMS reading of the DVM. The error is -44% at 100 mV, then 10% (0.9 dB) at 1.0 V and finally 2.9% at 8.0 V. The RF probe and DVM are obviously intended for higher voltage readings where the diode voltage drop doesn't affect the accuracy significantly.

The frequency response of the probe was measured at the midpoint of each ham band from 1.9 to 30 MHz with 650 mV input (see **Fig 25.51**). This time, because the input voltage was low and the absolute error would have been high, the probe was connected to the meter unit, which will be described later. The compensating diode loop of the meter unit reduces the error that would otherwise be read by the DVM from 90 mV (14%) to 4 mV (0.6%). The frequency response, however, is controlled by the probe. Use of the meter unit—which operates entirely on the dc signal—does not affect the frequency response, but it does improve the sensitivity of the readings. The measured response shown goes from -3.6% (-0.32 dB) to +1.2% (+0.1 dB).

Fig 25.48 — A photo of the grabber clip, pin tip and RF probe.

Fig 25.49 — The RF probe with the pin tip and grabber clip in place. The pin tip is not visible, but it provides the physical bridge and electrical connection between the clip and SO-239 of the RF probe.

Fig 25.50 — Amplitude linearity of the RF probe alone and in combination with the RF voltmeter.

Fig 25.51 — A frequency-response plot for the RF voltmeter. The response of the probe determines the overall system response.

MULTIPLIERS

To extend the voltage range of the RF probe, use a 10× multiplier, which is a compensated divider, shown in **Fig 25.52**. The electrical design is straightforward and includes a small trimmer capacitor to adjust for a flat frequency response. These components are very lightweight, so they require no perf board and are easily supported by their leads, which are anchored at the two SO-239 connectors. To make measurements, the input connector can be mated to connectors in a coaxial cable, a pin tip can be inserted for probing PC boards or a grabber can be added for connections to components on a chassis. The multiplier can connect to the RF probe either through a male-to-male UHF fitting or by a piece of coax with a UHF male connector at each end.

The typical way to adjust the trimmer requires a square-wave input and an oscilloscope on the output. The trimmer is then set to produce a flat square-wave output with no overshoots on the leading edges and no droop across the top. An RF signal generator that covers 1.9 MHz to 30 MHz can be used instead, if a square wave generator is not available. Since this is a 10× multiplier, it is reasonable to expect the input to handle up to 200 V (RMS), but the limit is 150 V because the trimmer capacitor is rated at 225 V dc. You may be able to find small trimmers with higher voltage ratings that will take the multiplier to 200 V and still fit inside the tube housing.

Multiplier construction follows the same methods used for the RF probe but with a few differences. My first model

used an aluminum tube like that in the RF probe with #6-32 screws to hold it all together, but the frequency response began to drop off at 21 MHz. By replacing the aluminum tube with a phenolic tube³ hav-

ing the same dimensions, the response is adequate to 30 MHz.

Fig 25.53 shows construction methods. Two slits at the ends of the tube allow the ground wires at the input and output ends

Fig 25.52 — A schematic of the 10x multiplier. The trimmer capacitor is from Ocean State Electronics (see Note 10).

Fig 25.53 — Construction of the 10x multiplier. The phenolic tube is US Plastics #47081, see Note 3. The lug is Mouser 571-34120.

Fig 25.54 — A view showing the 10x multiplier with grabber, pin tip and a male UHF coupler that connects the multiplier to the RF probe.

Fig 25.55 — The complete RF probe and 10x multiplier assembly.

Fig 25.56 — The RF probe and multiplier can be separated by a piece of coax less than 12 inches long if it makes measurements more convenient.

to exit and wrap around the screws of each connector. A hole in the phenolic tube allows adjustment of the trimmer capacitor.

Fig 25.54 shows the exploded view of the pin tip and grabbers at the input end of the multiplier and a UHF male-to-male connector on the output side to mate with the RF probe. The assembled multiplier and probe are shown in **Fig 25.55**. The whole assembly is only 3½ inches long and is comfortable in the hand. If more flexibility is desired, the two pieces may be separated by as much as one foot of coax (**Fig 25.56**) without doing too much damage to the accuracy of the measurement.

The 100x multiplier follows the same design concepts as the 10x multiplier including the obligatory trimmer capacitor,

Fig 25.57 — Schematic of the 100x multiplier (maximum allowable input is 150 V RMS). The trimmer capacitor is from Ocean State Electronics (see Note 10).

Fig 25.58 — 100x multiplier assembly showing the round Nylon spacer (Mouser 561-TSP10), phenolic tube (US Plastics #47081, see Note 3). The lug is Mouser 571-34120.

Fig 25.59 — The assembled 100x multiplier.

as in **Fig 25.57**. Here too, the 225 V dc rating of the trimmer limits the maximum RF to 150 V RMS. So, this is not useful should it be used only with the probe and your DVM because the 10x multiplier already covers this range. Later, we will see how it is useful with the RF probe and the meter unit.

The 100x unit also uses a phenolic-tube housing with a hole to adjust the trimmer

and a slit at each end to bring out the ground wires, which then wrap around screws in the connectors. In order to reach at least 30 MHz, however, the two-inch steel screws between the two SO-239 connectors must be insulated. Using plastic washers at the connector holes could do this job but would have required #4-40x 2-inch-long screws. After a long search at the biggest hardware stores and catalogs, I found nothing longer than 1½ inches. That's the best way to assemble this multiplier, if you can find the screws. Otherwise, use nylon spacers and shorter screws as shown in **Figs 25.58** and **25.59**. The pin tip and grabber at the input and UHF male-to-male connector or coaxial cable at the output are used as with the 10x multiplier.

The only purpose of the 2x multiplier is to create a 200x multiplier when used with the 100x multiplier in series, so as to extend the voltage range from 150 V to 300 V (1800 W at 50 Ω only under matched conditions⁴). The trimmer in each multiplier now divides in half the input voltage.

Fig 25.60 — A schematic diagram of the 2x multiplier. Its output connects to the input of the 100x multiplier for 200x measurements up to 300 V RMS. This multiplier is used *only* with the 100x multiplier.

Fig 25.61 — 2x multiplier assembly showing the phenolic tube (US Plastics #47081, see Note 3). The lug is 16-14 #6 stud (Mouser 571-34120).

Fig 25.60 shows the 2x multiplier with only one RC section since it relies on the RC sections in the 100x multiplier to complete the division (multiplication).

The construction, **Fig 25.61**, returns to the tubular format as before, but this time there are no slots to pass the ground wires; the four screws are able to do the job. The two multipliers are shown in series in **Fig 25.62**. The input capacitance for each multiplier is shown in **Table 25.4**.

When measurements are made on a load resistance of 50 Ω, the input capacity of the multipliers has no effect on readings below 30 MHz. When the impedance of the load resistance is larger, consider any error it introduces. To get a sense of the affects of the load resistance, use the equation below. It shows the relationship between the resistance, capacitance and

Table 25.4

frequency when the measured voltage is 3 dB down from what it would be if it were read by a meter with no input capacity:

$$f = \frac{1}{2\pi R_L C_P} \quad (21)$$

where

- f = 3-dB loss frequency
- R_L = load resistance
- C_P = probe capacitance

For example, at a load of 1 kΩ and a probe capacity of 13.3 pF, the 3-dB down frequency is about 12 MHz, where the

Table 25.5

* error less than -10% or -0.83 dB

† with error of -45% to -10% or less than 3.2 dB. A trimmer capacitor with a rating of 300 V dc increases the 10x range to 200 V ac and reduces the error from 45% to 10%. The RF probe and meter unit reduces the error to less than -3.5% or less than -0.3 dB.

†† with error less than -6% or -0.54 dB

Fig 25.62 — The 2x and 100x multipliers are joined by a male UHF coupler for readings up to 300 V (RMS, 1800 W, see Note 4).

error is 30%. If an attenuator were used instead of the multiplier, it would not have this problem because it works with either a fixed load of 50 Ω at high frequencies or 600 Ω at low frequencies. Probes cannot select their frequency or load impedance and are thereby more flexible in use, so measurements must be made with consideration, but these multipliers would not have a problem at 50 Ω or 600 Ω either.

Table 25.5 summarizes the voltage ranges using only the multiplier with the RF probe and a DVM that has a 10-MΩ input resistance that's available in the shack.

The multipliers are intended for use at high voltages where safety precautions are a primary consideration to avoid personal injury. See the **Safety** chapter of this *Handbook*. In Tektronics' *ABC's of Probes*,⁵ an entire section thoroughly covers the hazards and necessary precautions when making measurements with probes. It is worth the little effort to get a copy of it and also the Pomona Catalog,⁶ which has some good information on probe use.

The multipliers have panel connectors at both ends and the RF probe has one at one end. Their grounds are connected and brought to the meter unit. This unit is grounded only when the ac-powered 9-V power supply that may be used with it, is grounded. When it is battery operated, the meter unit relies on the ground-clip connection to the ground of the equipment under test. This is satisfactory if there is no unknown break in the chain of ground connections that would make the panel

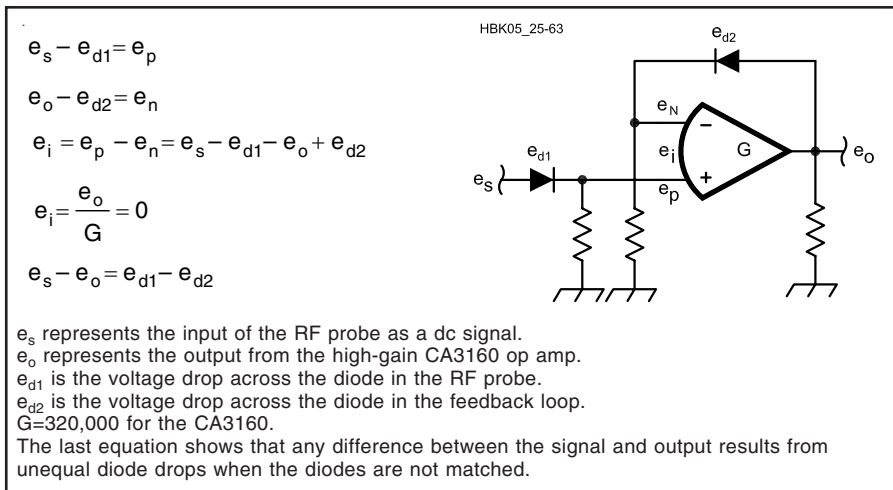

Fig 25.63 — Basics of the diode-compensation method to improve measurement accuracy at low input voltages. It also provides a measure of temperature compensation and drift reduction. See Fig 25.50.

connector hot. Furthermore, as insurance, it is well to wrap these connectors with vinyl tape or to cover the multiplier with a plastic boot to prevent contact with either hands or equipment under test. This is not shown in any photographs because it would have obscured the appearance and construction of the probe and multipliers.

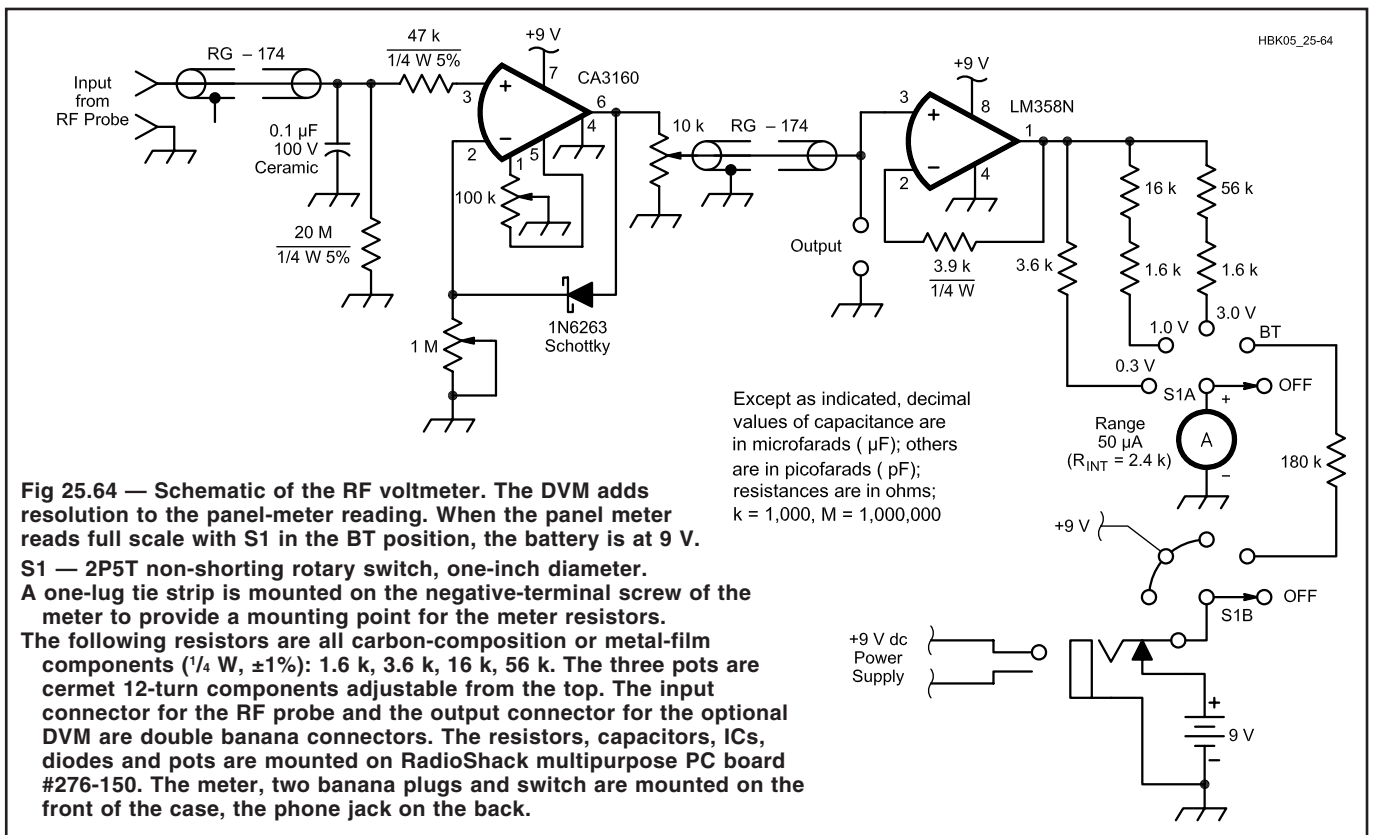

The frequency responses of the multipliers were determined using an RF signal generator set at the midpoint of each ham band from 160 to 10 meters, including

30 MHz. An error of 5.42% (0.46 dB) was measured from 160 to 17 meters, which then decreased to 4.13% (0.35 dB) at 15 meters and then to zero through 30 MHz. The constant error from 160 to 17 meters is probably due to the inherent errors in the test equipment. The oscilloscope has a 60 MHz bandwidth, an input impedance of 1 MΩ and 30 pF, which introduces a load effect on the multiplier outputs. It also has a reading accuracy of ±3%. When the multiplier-components

accuracy of 1% is included, it is not surprising to find the overall inaccuracy to be at most 5.42%.⁷ The error of the multiplier itself could be inherently less than this. Before the overall frequency response was measured, the trimmer capacitor was adjusted with the input frequency set mid-frequency at 15 MHz. If your interest in RF probes and multipliers has been raised and you have more questions, see the references in Notes 5 and 6.

THE METER UNIT

The meter unit serves several purposes when used with the RF probe. It increases the accuracy of the probe and DVM from -45% to -3.5% at a voltage of 100 mV RF. At higher voltages, it maintains a minimum advantage of 5:1 in reducing the error, when the probe is used with a DVM. This is an increase in both sensitivity and accuracy. The usual non-linearity caused by the diode in the probe is reduced when used with the meter unit. The technique also incidentally provides temperature compensation for diode drift. The meter unit has a ±5% panel meter to display measurements, but it also contains a pair of **OUTPUT** terminals for a DVM. Add a DVM when more accuracy is desired at the low end of the range or when you want a bit more resolution. Finally, since the meter unit is fully portable, low-level field-strength measurements are possible

with a whip antenna at the probe input connector. Due to its sensitivity and accuracy, the probe can be adapted for use in many places around the shack.

The non-linear response of the probe diode is compensated (improved) by a circuit in the meter unit. The feedback loop of a CA3160 op amp contains a diode matched to the one in the probe (see Note 1). Fig 25.63 and its sequence of equations present a very simple sketch of how matched diodes do this when dc is applied through a diode. The final equation shows that any difference between the op amp input and output is due to a difference in voltage drops across the two diodes. When the diodes are matched, the error disappears. When RF is applied, the average currents through the diodes must be equal to keep the voltage drops equal. Articles by Kuzdrall (Note 1) Grebenkemper⁸ and Lewallen⁹ are first-class descriptions of the principles used in this RF voltmeter.

Fig 25.64 shows three pots for calibrating the meter unit. This should be performed at 400 Hz to avoid any effects due to RF. The 100-k Ω pot is typically used to null the offset of the CA3160, but is used here to initially set the offset to about 0.5 mV to 1.0 mV with 100 mV input. Then the 1-M Ω pot sets the output to 100 mV with 100 mV input, and the 10 k Ω pot sets the output to 3.0 V when the input is 3.0 V. Finally, the three pots are alternately adjusted until the 100 mV and 3.0 V set points occur together. The 100-k Ω pot is helpful in fine tuning the 100-mV point. A DVM was used at the optional OUTPUT sockets during calibration.

A CA3160 was selected for the input op amp because of its high input impedance of 1.5 T Ω and high gain of 320,000. Although it has diodes that provide protection, I think it could be sensitive to electrostatic discharge, so handle it carefully. Use IC sockets to permit easy replacement of the ICs in case of damage. An LM358N IC follows the CA3160 (see Fig 25.64), primarily to drive the panel

meter. If you use a DVM as the display, you can omit the LM358N circuit, meter and multi-position switch. The only functions lost are the battery-voltage check and power on/off switch. Add an on/off switch to the circuit when the multi-position switch is omitted. The CA3160 op amp circuit easily spans the range from 100 mV to 3.0 V without the need for a range switch.

CONSTRUCTION

A 5 \times 5 \times 4 $\frac{1}{2}$ -inch sloping-front instrument case was used to house the components of the meter unit. The meter on the front panel has a 2 \times 2-inch face and requires a 1 $\frac{1}{2}$ -inch hole in the panel. Although a 50- μ A meter from the junk box is used here, a 1-mA movement will work as well, provided the series resistors are changed accordingly.

The rotary switch has two poles and five positions for changing the meter range, testing the battery condition and switching the power off. Two sets of double banana binding posts are used, the INPUT pair accepts the dc signal from the RF probe. The OUTPUT pair provides a voltage for a DVM display, whether the panel meter is used or not. On the rear of the case, a miniature phone jack accepts 9-V power from either a battery or a 9-V dc supply. The ICs and other parts are mounted on a RadioShack multipurpose PC board that has very convenient holes and traces. The board is bolted to the back of the case via standoff insulators and wired to the front panel components (see Fig 25.65).

Receiver Performance Tests

Comparing the performance of one receiver to another is difficult at best. The features of one receiver may outweigh a second, even though its performance under some conditions is not as good as it could be. Although the final decision on which receiver to purchase will more than likely be based on personal preference and cost, there are ways to compare receiver performance characteristics. Some of the more important parameters are sensitivity, blocking dynamic range and two-tone IMD dynamic range.

Instruments for measuring receiver performance should be of suitable quality and calibration. Always remember that accuracy can never be better than the tools used to make the measurements. Common instruments used for receiver testing include:

- Signal generators
- Hybrid combiner
- Audio ac voltmeter
- Distortion meter (FM measurements only)
- Noise figure meter (only required for noise figure measurements)

- Step attenuators (10 dB and 1 dB steps are useful)

Signal generators must be calibrated accurately in dBm or mV. The generators should have extremely low leakage. That is, when the output of the generator is switched off, no signal should be detected at the operating frequency with a sensitive receiver. Ideally, at least one of the signal generators should be capable of amplitude modulation. A suitable lab-quality piece would be the HP-8640B, no longer manufactured, but a good item to scout on the surplus market.

Fig 25.66 — A general test setup for measuring receiver MDS, or noise floor. Signal levels shown are for an example discussed in the text.

Fig 25.67 — FM SINAD test setup.

While most signal generators are calibrated in terms of microvolts, the real concern is not with the voltage from the generator but with the power available. The unit that is used for most low-level RF work is the milliwatt, and power is often specified in decibels with respect to 1 mW (dBm). Hence, 0 dBm would be 1 mW. The dBm level, in a 50-Ω load, can be calculated with the aid of the following equation:

$$\text{dBm} = 10 \log_{10} \left[20(V)^2 \right] \quad (22)$$

where

dBm = power with respect to 1 mW
 V = RMS voltage available at the output of the signal generator

The convenience of a logarithmic power unit such as the dBm becomes apparent when signals are amplified or attenuated. For example, a -107 dBm signal that is applied to an amplifier with a gain of 20 dB will result in an output increased by 20 dB. Therefore in this example (-107 dBm + 20 dB) = 87 dBm. Similarly, a -107 dBm signal applied to an attenuator with a loss of 10 dB will result in an output of (-107 dBm - 10 dB) or -117 dBm.

A hybrid combiner is a three-port device used to combine the signals from a pair of generators for all dynamic range measurements. It has the characteristic that signals applied at ports 1 or 2 appear at port 3 and are attenuated by 3 dB. However, a signal from port 1 is attenuated 30 or 40 dB when sampled at port 2. Similarly, signals applied at port 2 are isolated from port 1 some 30 to 40 dB. The isolating properties of the box prevent one signal generator from being frequency or phase modulated by the other. A second feature of a hybrid combiner is that a 50-Ω impedance level is maintained throughout the system.

Audio voltmeters should be calibrated in dB as well as volts. This facilitates easy measurements and eliminates the need for cumbersome calculations. Be sure that the step attenuators are in good working order and suitable for the frequencies involved. A distortion meter, such as the Hewlett-Packard 339A, is required for FM sensitivity measurements and a noise figure

meter, such as the Hewlett-Packard 8970A, is excellent for certain kinds of sensitivity measurements.

Receiver Sensitivity

Several methods are used to determine receiver sensitivity. The mode under consideration often determines the best choice. One of the most common sensitivity measurements is minimum discernible signal (MDS) or noise floor. It is suitable for CW and SSB receivers.

This measurement indicates the minimum discernible signal that can be detected with the receiver. This level is defined as that which will produce the same audio-output power as the internally generated receiver noise. Hence, the term “noise floor.”

To measure MDS, use a signal generator tuned to the same frequency as the receiver (see Fig 25.66). With the generator output at 0 or with maximum attenuation of its output note the voltmeter reading. Next increase the generator output level until the ac voltmeter at the receiver audio-output jack shows a 3-dB increase. The signal input at this point is the MDS. Be certain that the receiver is peaked on the generator signal. The filter bandwidth can affect the MDS. Always compare MDS readings taken with identical filter bandwidths. (A narrow bandwidth tends to improve MDS performance.) MDS can be expressed in μV or dBm.

In the hypothetical example of Fig 25.66, the output of the signal generator is -133 dBm and the step attenuator is set to 4 dB. Here is the calculation:

$$\text{Noise floor} = -133 \text{ dBm} - 4 \text{ dB} = -137 \text{ dBm} \quad (23)$$

where the noise floor is the power available at the receiver antenna terminal and 4 dB is the loss through the attenuator.

Receiver sensitivity is also often expressed as 10 dB S+N/N (a 10-dB ratio of signal + noise to noise) or 10 dB S/N (signal to noise). The procedure and measurement are identical to MDS, except that the input signal is increased until the receiver output increases by 10 dB for 10 dB S+N/N

and 9.5 dB for 10 dB S/N (often called “10 dB signal to noise ratio”). AM receiver sensitivity is usually expressed in this manner with a 30% modulated, 1-kHz test signal. (The modulation in this case is keyed on and off and the signal level is adjusted for the desired increase in the audio output.)

SINAD is a common sensitivity measurement normally associated with FM receivers. It is an acronym for “signal plus noise and distortion.” SINAD is a measure of signal quality:

$$\text{SINAD} = \frac{\text{signal} + \text{noise} + \text{distortion}}{\text{noise} + \text{distortion}} \quad (24)$$

where SINAD is expressed in dB. In this example, all quantities to the right of the equal sign are expressed in volts, and the ratio is converted to dB by multiplying the log of the fraction by 20.

SINAD(dB) =

$$20 \log \left(\frac{\text{Signal}(V) + \text{Noise}(V) + \text{Distortion}(V)}{\text{Noise}(V) + \text{Distortion}(V)} \right)$$

Let’s look at this more closely. We can consider distortion to be a part of the receiver noise because distortion, like noise, is an unwanted signal added to the desired signal by the receiving system. Then, if we assume that the desired signal is much stronger than the noise, SINAD closely approximates the signal to noise ratio. The common 12-dB SINAD specification therefore corresponds to a 4:1 S/N ratio (noise + distortion = 0.25 × signal).

The basic test setup for measuring SINAD is shown in Fig 25.67. The level of input signal is adjusted to provide 25% distortion (12 dB SINAD). Narrow-band FM signals, typical for amateur communications, usually have 3-kHz peak deviation when modulated at 1000 Hz.

Noise figure is another measure of receiver sensitivity. It provides a sensitivity evaluation that is independent of the system bandwidth. Noise figure is discussed further in the **Receivers and Transmitters** chapter.

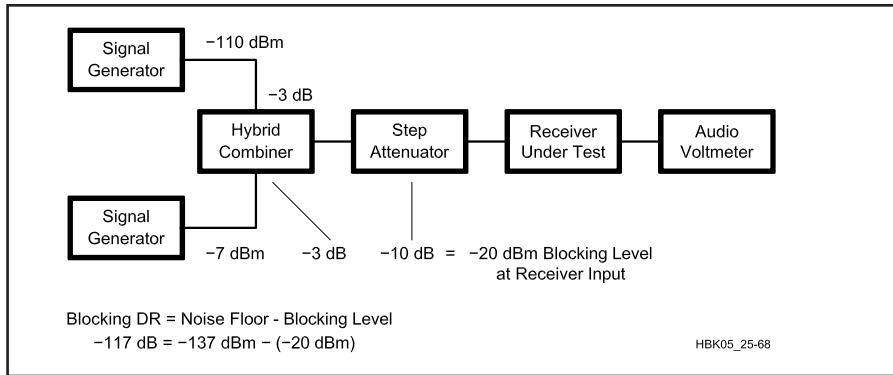

Fig 25.68 — Receiver Blocking DR is measured with this equipment and arrangement. Measurements shown are for the example discussed in the text.

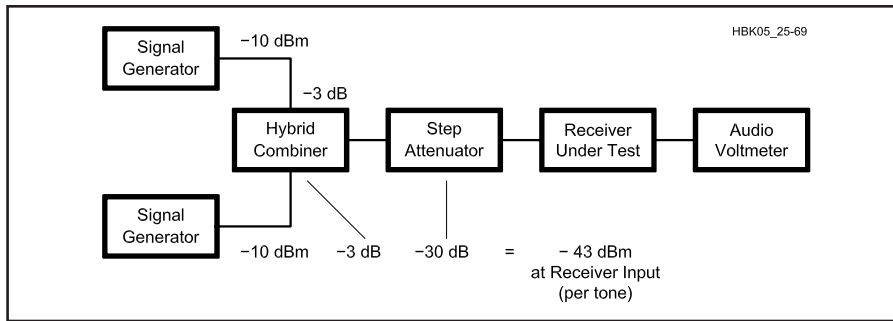

Fig 25.69 — Receiver IMD DR test setup. Signal levels shown are for the example discussed in the text.

Dynamic Range

Dynamic range is the ability of the receiver to tolerate strong signals outside of its band-pass range. Two kinds will be considered:

Blocking dynamic range (blocking DR) is the difference, in dB, between the noise floor and a signal that causes 1 dB of gain compression in the receiver. It indicates the signal level, above the noise floor, that begins to cause desensitization.

IMD dynamic range (IMD DR) measures the impact of two-tone IMD on a receiver. IMD is the production of spurious responses that results when two or more signals mix. IMD occurs in any receiver when signals of sufficient magnitude are present. IMD DR is the difference, in dB, between the noise floor and the strength of two equal incoming signals that produce a third-order product 3 dB above the noise floor.

What do these measurements mean? When the IMD DR is exceeded, false signals begin to appear along with the desired signal. When the blocking DR is exceeded, the receiver begins losing its ability to amplify weak signals. Typically, the IMD DR is 20 dB or more below the blocking DR, so false signals appear well before sensitivity is significantly decreased. IMD DR is one of the most significant parameters that can be specified for a receiver.

It is generally a conservative evaluation for other effects, such as blocking, which will occur only for signals well outside the IMD dynamic range of the receiver.

Both dynamic range tests require two signal generators and a hybrid combiner. When testing blocking DR (see Fig 25.68), one generator is set for a weak signal of roughly -110 dBm. The receiver is tuned to this frequency and peaked for maximum response. (ARRL Lab procedures require this level to be about 10 dB below the 1-dB compression point, if the AGC can be disabled. Otherwise, the level is set to 20 dB above the MDS.)

The second generator is set to a frequency 20 kHz away from the first and its level is increased until the receiver output drops by 1 dB, as measured with the ac voltmeter.

In the example shown, the output of the generator is -7 dBm, the loss through the combiner is fixed at 3 dB and the step attenuator is set to 10 dB. The 1-dB compression level is calculated as follows:

$$\text{Blocking level} = -7 \text{ dBm} - 3 \text{ dB} - 10 \text{ dB} = -20 \text{ dBm} \quad (25)$$

To express this as a dynamic range, the blocking level is referenced to the receiver noise floor (calculated earlier).

Calculate it as follows:

$$\text{Block DR} = \text{noise floor} - \text{blocking level} = -137 \text{ dBm} - (-20 \text{ dBm}) = -117 \text{ dB} \quad (26)$$

This value is usually expressed as an absolute value: 117 dB.

Two-Tone IMD Test

The setup for measuring IMD DR is shown in Fig 25.69. Two signals of equal level, spaced 20-kHz apart are injected into the receiver input. When we call these frequencies f_1 and f_2 , the so-called third-order IMD products will appear at frequencies of $(2f_1 - f_2)$ and $(2f_2 - f_1)$. If the two input frequencies are 14.040 and 14.060 MHz, the third-order products will be at 14.020 and 14.080 MHz. Let's talk through a measurement with these frequencies.

First, set the generators for f_1 and f_2 . Adjust each of them for an output of -10 dBm. Tune the receiver to either of the third-order IMD products. Adjust the step attenuator until the IMD product produces an output 3 dB above the noise level as read on the ac voltmeter.

For an example, say the output of the generator is -10 dBm, the loss through the combiner is 3 dB and the amount of attenuation used is 30 dB. The signal level at the receiver antenna terminal that just begins to cause IMD problems is calculated as:

$$\text{IMD level} = -10 \text{ dBm} - 3 \text{ dB} - 30 \text{ dB} = -43 \text{ dBm} \quad (27)$$

To express this as a dynamic range the IMD level is referenced to the noise floor as follows:

$$\text{IMD DR} = \text{noise floor} - \text{IMD level} = -137 \text{ dBm} - (-43 \text{ dBm}) = -94 \text{ dB} \quad (28)$$

Therefore, the IMD dynamic range of this receiver would be 94 dB.

Third-Order Intercept

Another parameter used to quantify receiver performance is the third-order input intercept (IP^3). This is the point at which the desired response and the third-order IMD response intersect, if extended beyond their linear regions (see Fig 25.70). Greater IP^3 indicates better receiver performance. Calculate IP^3 like this:

$$IP^3 = 1.5 (\text{IMD dynamic range in dB}) + (\text{MDS in dBm}) \quad (29)$$

For our example receiver:

$$IP^3 = 1.5 (94 \text{ dB}) + (-137 \text{ dBm}) = +4 \text{ dBm}$$

The preferred method for the third-

order input intercept, however, is to use S5 signal levels instead of MDS levels. This is due to the tendency for a receiver to exhibit non-linearity at the noise floor level (i.e., near the level where MDS is typically defined).

$$\text{Thus, Third Order Intercept} = (3 \times (\text{S5 IMD Level}) - (\text{S5 Reference}))/2$$

The results of this method should show close correlation with the intercept point determined by the MDS test. If not, the test engineer determines (from further investigation) which method provides a more accurate result.

In the same way (using the S5 method),

$$\text{Second Order Intercept} = 2 \times (\text{S5 IMD Level}) - (\text{S5 Reference})$$

The example receiver we have discussed here is purely imaginary. Nonetheless, its performance is typical of contemporary communications receivers.

Fig 25.70 — A plot of the receiver characteristics that determine third-order input intercept, a measure of receiver performance.

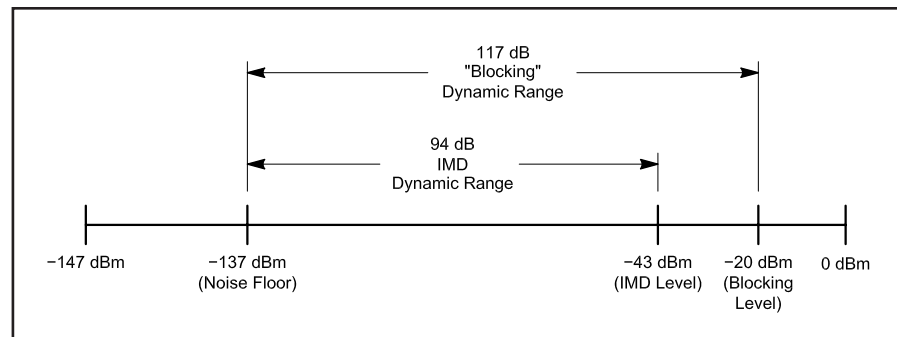

Fig 25.71 — Performance plot of the receiver discussed in the text. This is a good way to visualize the interaction of receiver-performance measurements. Note that -147 dBm is considered the lowest possible noise level in a 500 Hz receiver bandwidth.

Evaluating the Data

Thus far, a fair amount of data has been gathered with no mention of what the numbers really mean. It is somewhat easier to understand exactly what is happening by arranging the data as shown in Fig 25.71. The base line represents power levels with a very small level at the left and a higher level (0 dBm) at the right.

The noise floor of our hypothetical receiver is at -137 dBm, the IMD level (the level at which signals will begin to create spurious responses) at -43 dBm and the blocking level (the level at which signals will begin to desensitize the receiver) at -20 dBm. The IMD dynamic range is some 23 dB smaller than the blocking dynamic range. This means IMD products will be heard long before the receiver begins to desensitize, some 23 dB sooner.

SPECTRUM ANALYZERS

A spectrum analyzer is similar to an oscilloscope. Both visually present an electrical signal through graphic representation. The oscilloscope is used to observe electrical signals in the time domain (amplitude as a function of time). The time domain, however, gives little information about the frequencies that make up complex signals. Amplifiers, mixers, oscillators, detectors, modulators and filters are best characterized in terms of their frequency response. This information is obtained by viewing electrical signals in the *frequency domain* (amplitude as a function of frequency). One instrument that can display the frequency domain is the spectrum analyzer.

Time and Frequency Domain

To better understand the concepts of time and frequency domain, see Fig 25.72. The three-dimensional coordinates show time (as the line sloping toward the bot-

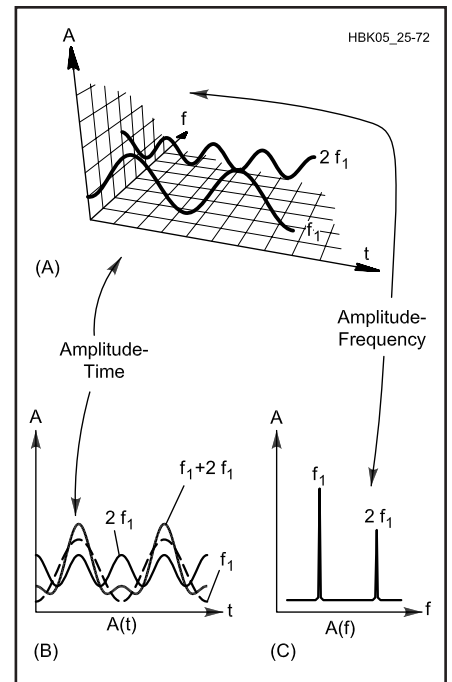

Fig 25.72 — A complex signal in the time and frequency domains. A is a three-dimensional display of amplitude, time and frequency. B is an oscilloscope display of time vs amplitude. C is spectrum analyzer display of the frequency domain and shows frequency vs amplitude.

tom right), frequency (as the line rising toward the top right) and amplitude (as the vertical axis). The two discrete frequencies shown are harmonically related, so we'll refer to them as f_1 and $2f_1$.

In the representation of time domain at B, all frequency components of a signal are summed together. In fact, if the two discrete frequencies shown were applied to the input of an oscilloscope, we would see the solid line (which corresponds to $f_1 + 2f_1$) on the display.

In the frequency domain, complex signals (signals composed of more than one frequency) are separated into their individual frequency components. A spectrum analyzer measures and displays the power level at each discrete frequency; this display is shown at C.

The frequency domain contains information not apparent in the time domain and therefore the spectrum analyzer offers advantages over the oscilloscope for certain measurements. As might be expected, some measurements are best made in the time domain. In these cases, the oscilloscope is a valuable instrument.

Spectrum Analyzer Basics

There are several different types of spectrum analyzers, but by far the most

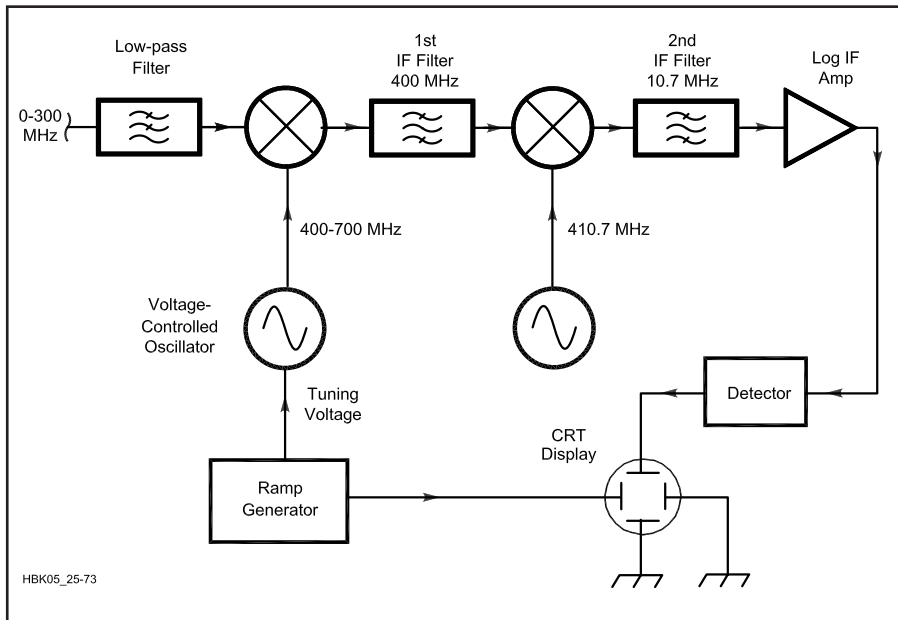

Fig 25.73 — A block diagram of a superheterodyne spectrum analyzer. Input frequencies of up to 300 MHz are up converted by the local oscillator and mixer to a fixed frequency of 400 MHz.

common is nothing more than an electronically tuned superheterodyne receiver. The receiver is tuned by means of a ramp voltage. This ramp voltage performs two functions: First, it sweeps the frequency of the analyzer local oscillator; second, it deflects a beam across the horizontal axis of a CRT display, as shown in **Fig 25.73**. The vertical axis deflection of the CRT beam is determined by the strength of the received signal. In this way, the CRT displays frequency on the horizontal axis and signal strength on the vertical axis.

Most spectrum analyzers use an up-converting technique so that a fixed tuned input filter can remove the image. Only the first local oscillator need be tuned to tune the receiver. In the up-conversion design, a wide-band input is converted to an IF higher than the highest input frequency. As with most up-converting communications receivers, it is not easy to achieve the desired ultimate selectivity at the first IF, because of the high frequency. For this reason, multiple conversions are used to generate an IF low enough so that the desired selectivity is practical. In the example shown, dual conversion is used: The first IF is at 400 MHz; the second at 10.7 MHz.

In the example spectrum analyzer, the first local oscillator is swept from 400 MHz to 700 MHz; this converts the input (from nearly 0 MHz to 300 MHz) to the first IF of 400 MHz. The usual rule of thumb for varactor tuned oscillators is that

the maximum practical tuning ratio (the ratio of the highest frequency to the lowest frequency) is an octave, a 2:1 ratio. In our example spectrum analyzer, the tuning ratio of the first local oscillator is 1.75:1, which meets this specification.

The image frequency spans 800 MHz to 1100 MHz and is easily eliminated using a low-pass filter with a cut-off frequency around 300 MHz. The 400-MHz first IF is converted to 10.7 MHz where the ultimate selectivity of the analyzer is obtained. The image of the second conversion, (421.4 MHz), is eliminated by the first IF filter. The attenuation of the image should be great, on the order of 60 to 80 dB. This requires a first IF filter with a high Q; this is achieved by using helical resonators, SAW resonators or cavity filters. Another method of eliminating the image problem is to use triple conversion; converting first to an intermediate IF such as 50 MHz and then to 10.7 MHz. As with any receiver, an additional frequency conversion requires added circuitry and adds potential spurious responses.

Most of the signal amplification takes place at the lowest IF; in the case of the example analyzer this is 10.7 MHz. Here the communications receiver and the spectrum analyzer differ. A communications receiver demodulates the incoming signal so that the modulation can be heard or further demodulated for RTTY or packet or other mode of operation. In the spectrum analyzer, only the signal strength is needed.

In order for the spectrum analyzer to be most useful, it should display signals of widely different levels. As an example, signals differing by 60 dB, which is a thousand to one difference in voltage or a million to one in power, would be difficult to display. This would mean that if power were displayed, one signal would be one million times larger than the other (in the case of voltage one signal would be a thousand times larger). In either case it would be difficult to display both signals on a CRT. The solution to this problem is to use a logarithmic display that shows the relative signal levels in decibels. Using this technique, a 1000:1 ratio of voltage reduces to a 60-dB difference.

The conversion of the signal to a logarithm is usually performed in the IF amplifier or detector, resulting in an output voltage proportional to the logarithm of the input RF level. This output voltage is then used to drive the CRT display.

Spectrum Analyzer Performance Specifications

The performance parameters of a spectrum analyzer are specified in terms similar to those used for radio receivers, in spite of the fact that there are many differences between a receiver and a spectrum analyzer.

The sensitivity of a receiver is often specified as the minimum discernible signal, which means the smallest signal that can be heard. In the case of the spectrum analyzer, it is not the smallest signal that can be heard, but the smallest signal that can be seen. The dynamic range of the spectrum analyzer determines the largest and smallest signals that can be simultaneously viewed on the analyzer. As with a receiver, there are several factors that can affect dynamic range, such as IMD, second- and third-order distortion and blocking. IMD dynamic range is the maximum difference in signal level between the minimum detectable signal and the level of two signals of equal strength that generate an IMD product equal to the minimum detectable signal.

Although the communications receiver is an excellent example to introduce the spectrum analyzer, there are several differences such as the previously explained lack of a demodulator. Unlike the communications receiver, the spectrum analyzer is not a sensitive radio receiver. To preserve a wide dynamic range, the spectrum analyzer often uses passive mixers for the first and second mixers. Therefore, referring to **Fig 25.73**, the noise figure of the analyzer is no better than the losses of the input low-pass filter plus the first mixer, the first IF filter, the second mixer and the

loss of the second IF filter. This often results in a combined noise figure of more than 20 dB. With that kind of noise figure the spectrum analyzer is obviously not a communications receiver for extracting very weak signals from the noise but a measuring instrument for the analysis of frequency spectrum.

The selectivity of the analyzer is called the resolution bandwidth. This term refers to the minimum frequency separation of two signals of equal level that can be resolved so there is a 3-dB dip between the two. The IF filters used in a spectrum analyzer differ from a communications receiver in that the filters in a spectrum analyzer have very gentle skirts and rounded passbands, rather than the flat passband and very steep skirts used on an IF filter in a high-quality communications receiver. This rounded passband is necessary because the signals pass into the filter passband as the spectrum analyzer scans the desired frequency range. If the signals suddenly pop into the passband (as they would if the filter had steep skirts), the filter tends to ring; a filter with gentle skirts is less likely to ring. This ringing, called scan loss, distorts the display and

requires that the analyzer not sweep frequency too quickly. All this means that the scan rate must be checked periodically to be certain the signal amplitude is not affected by fast tuning.

Spectrum Analyzer Applications

Spectrum analyzers are used in situations where the signals to be analyzed are very complex and an oscilloscope display would be an indecipherable jumble. The spectrum analyzer is also used when the frequency of the signals to be analyzed is very high. Although high-performance oscilloscopes are capable of operation into the UHF region, moderately priced spectrum analyzers can be used well into the gigahertz region.

A spectrum analyzer can also be used to view very low-level signals. For an oscilloscope to display a VHF waveform, the bandwidth of the oscilloscope must extend from zero to the frequency of the waveform. If harmonic distortion and other higher-frequency distortions are to be seen the bandwidth of the oscilloscope must exceed the fundamental frequency of the waveform. This broad bandwidth can also admit a lot of noise power. The spectrum analyzer, on the

other hand, analyzes the waveform using a narrow bandwidth; thus it is capable of reducing the noise power admitted.

Probably the most common application of the spectrum analyzer is the measurement of the harmonic content and other spurious signals in the output of a radio transmitter. **Fig 25.74** shows two ways to connect the transmitter and spectrum analyzer. The method shown at A should not be used for wide-band measurements since most line-sampling devices do not exhibit a constant-amplitude output over a broad frequency range. Using a line sampler is fine for narrow-band measurements, however. The method shown at B is used in the ARRL Lab. The attenuator must be capable of dissipating the transmitter power. It must also have sufficient attenuation to protect the spectrum analyzer input. Many spectrum analyzer mixers can be damaged by only a few milliwatts, so most analyzers have an adjustable input attenuator that will provide a reasonable amount of attenuation to protect the sensitive input mixer from damage. The power limitation of the attenuator itself is usually on the order of a watt or so, however. This means that 20 dB of additional attenuation is required for a 100-W transmitter, 30 dB for a 1000-W transmitter and so on, to limit the input to the spectrum analyzer to 1 W. There are specialized attenuators that are made for transmitter testing; these attenuators provide the necessary power dissipation and attenuation in the 20 to 30-dB range.

When using a spectrum analyzer it is very important that the maximum amount of attenuation be applied before a measurement is made. In addition, it is a good practice to start with maximum attenuation and view the entire spectrum of a signal before the attenuator is adjusted. The signal being viewed could appear to be at a safe level, but another spectral component, which is not visible, could be above the damage limit. It is also very important to limit the input power to the analyzer when pulse power is being measured. The average power may be small enough so the input attenuator is not damaged, but the peak pulse power, which may not be readily visible on the analyzer display, can destroy a mixer, literally in microseconds.

When using a spectrum analyzer it is necessary to ensure that the analyzer does not generate additional spurious signals that are then attributed to the system under test. Some of the spurious signals that can be generated by a spectrum analyzer are harmonics and IMD. If it is desired to measure the harmonic levels of a transmitter at a level below the spurious level of the analyzer itself, a notch filter can be inserted between the attenuator and the

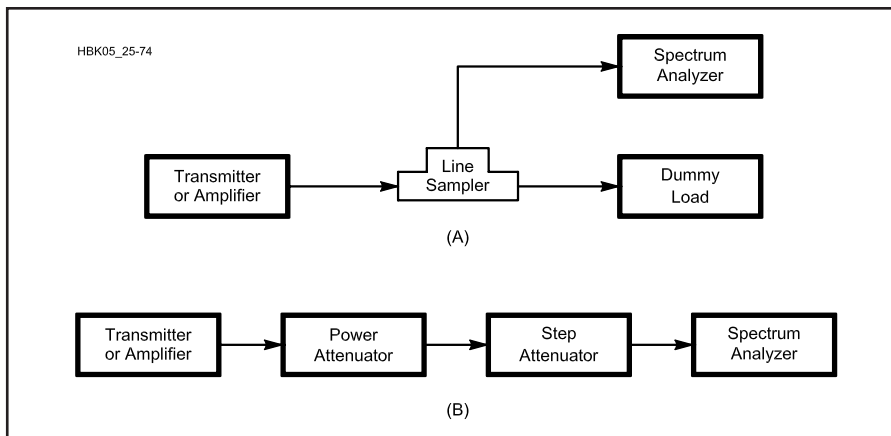

Fig 25.74 — Alternate bench setups for viewing the output of a high power transmitter or oscillator on a spectrum analyzer. A uses a line sampler to pick off a small amount of the transmitter or amplifier power. In B, most of the transmitter power is dissipated in the power attenuator.

Fig 25.75 — A notch filter is another way to reduce the level of a transmitter's fundamental signal so that the fundamental does not generate harmonics within the analyzer. However, in order to know the amplitude relationship between the fundamental and the transmitter's actual harmonics and spurs, the attenuation of the fundamental in the notch filter must be known.

spectrum analyzer as shown in **Fig 25.75**. This reduces the level of the fundamental signal and prevents that signal from generating harmonics within the analyzer, while still allowing the harmonics from the transmitter to pass through to the analyzer without attenuation. Use caution with this technique; detuning the notch filter or inadvertently changing the transmitter frequency will allow potentially high levels of power to enter the analyzer. In addition, use care when choosing filters; some filters (such as cavity filters) respond not only to the fundamental but notch out odd harmonics as well.

It is good practice to check for the generation of spurious signals within the spectrum analyzer. When a spurious signal is generated by a spectrum analyzer, adding attenuation at the analyzer input will cause the internally generated spurious signals to decrease by an amount greater than the added attenuation. If attenuation added ahead of the analyzer causes all of the visible signals to decrease by the same amount, this indicates a spurious-free display.

The input impedance for most RF spectrum analyzers is 50 Ω ; not all circuits have convenient 50- Ω connections that can be accessed for testing purposes, however. Using a probe such as the one shown in **Fig 25.76** allows the analyzer to be used as a troubleshooting tool. The probe can be used to track down signals within a transmitter or receiver, much like an oscilloscope is used. The probe shown offers a 100:1 voltage reduction and loads the circuit with 5000 Ω . A different type of probe is shown in **Fig 25.77**. This inductive pickup coil (sometimes called a “sniffer”) is very handy for troubleshooting. The coil is used to couple signals from the radiated magnetic field of a circuit into the analyzer. A short length of miniature coax is wound into a pick-up loop and soldered to a larger piece of coax. The use of the coax shields the loop from coupling energy from the electric field component. The dimensions of the loop are not critical, but smaller loop dimensions make the loop more accurate in locating the source of radiated RF. The shield of the coax provides a complete electrostatic shield without introducing a shorted turn.

The sniffer allows the spectrum analyzer to sense RF energy without contacting the circuit being analyzed. If the loop is brought near an oscillator coil, the oscillator can be tuned without directly contacting (and thus disturbing) the circuit. The oscillator can then be checked for reliable starting and the generation of spurious sidebands. With the coil brought near the tuned circuits of amplifiers or fre-

Fig 25.76 — A schematic representation of a voltage probe designed for use with a spectrum analyzer. Keep the probe tip (resistor and capacitor) and ground leads as short as possible.

Fig 25.77 — A “sniffer” probe consisting of an inductive pick-up. It has an advantage of not loading the circuit under test. See text for details.

quency multipliers, those stages can be tuned using a similar technique.

Even though the sniffer does not contact the circuit being evaluated, it does extract some energy from the circuit. For this reason, the loop should be placed as far from the tuned circuit as is practical. If the loop is placed too far from the circuit, the signal will be too weak or the pick-up loop will pick up energy from other parts of the circuit and not give an accurate indication of the circuit under test.

The sniffer is very handy to locate sources of RF leakage. By probing the shields and cabinets of RF generating equipment (such as transmitters) egress

and ingress points of RF energy can be identified by increased indications on the analyzer display.

One very powerful characteristic of the spectrum analyzer is the instrument’s capability to measure very low-level signals. This characteristic is very advantageous when very high levels of attenuation are measured. **Fig 25.78** shows the setup for tuning the notch and passband of a VHF duplexer. The spectrum analyzer, being capable of viewing signals well into the low microvolt region, is capable of measuring the insertion loss of the notch cavity more than 100 dB below the signal generator output. Making a measurement of this sort requires care in the interconnection of the equipment and a well designed spectrum analyzer and signal generator. RF energy leaking from the signal generator cabinet, line cord or even the coax itself, can get into the spectrum analyzer through similar paths and corrupt the measurement. This leakage can make the measurement look either better or worse than the actual attenuation, depending on the phase relationship of the leaked signal.

Extensions of Spectral Analysis

What if a signal generator is connected to a spectrum analyzer so that the signal generator output frequency is exactly the same as the receiving frequency of the spectrum analyzer? It would certainly ap-

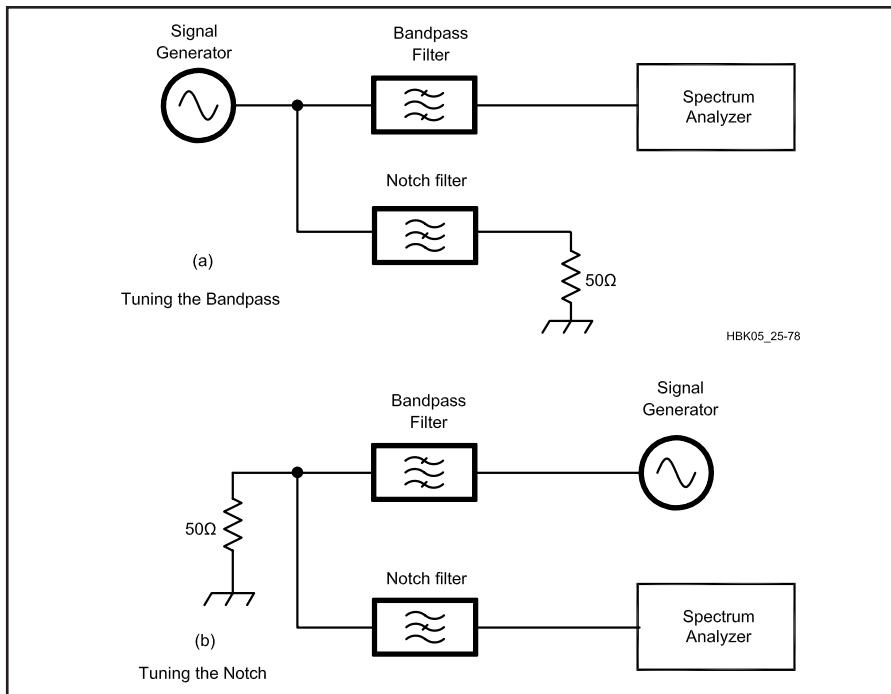

Fig 25.78 — Block diagram of a spectrum analyzer and signal generator being used to tune the band-pass and notch filters of a duplexer. All ports of the duplexer must be properly terminated and good quality coax with intact shielding used to reduce leakage.

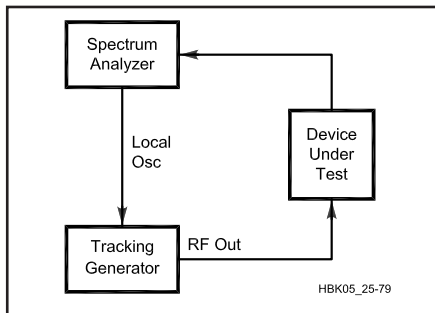

Fig 25.79 — A signal generator (shown in the figure as the “Tracking Generator”) locked to the local oscillator of a spectrum analyzer can be used to determine filter response over a range of frequencies.

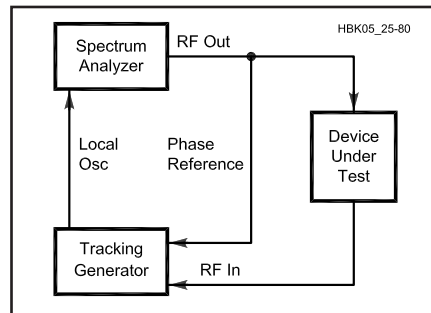

Fig 25.80 — A network analyzer is usually found in commercial communications development labs. It can measure both the phase and magnitude of the filter input and output signals. See text for details.

pear to be a real convenience not to have to continually reset the signal generator to the desired frequency. It is, however, more than a convenience. A signal generator

connected in this way is called a tracking generator because the output frequency tracks the spectrum analyzer input frequency. The tracking generator makes it

possible to make swept frequency measurements of the attenuation characteristics of circuits, even when the attenuation involved is large.

Fig 25.79 shows the connection of a tracking generator to a circuit under test. In order for the tracking generator to create an output frequency exactly equal to the input frequency of the spectrum analyzer, the internal local oscillator frequencies of the spectrum analyzer must be known. This is the reason for the interconnections between the tracking generator and the spectrum analyzer. The test setup shown will measure the gain or loss of the circuit under test. Only the magnitude of the gain or loss is available; in some cases, the phase angle between the input and output would also be an important and necessary parameter.

The spectrum analyzer is not sensitive to the phase angle of the tracking generator output. In the process of generating the tracking generator output, there are no guarantees that the phase of the tracking generator will be either known or constant. This is especially true of VHF spectrum analyzers/tracking generators where a few inches of coaxial cable represents a significant phase shift.

One effective way of measuring the phase angle between the input and output of a device under test is to sample the phase of the input and output of device under test and apply the samples to a phase detector. **Fig 25.80** shows a block diagram of this technique. An instrument that can measure both the magnitude and phase of a signal is called a vector network analyzer or simply a network analyzer. The magnitude and phase can be displayed either separately or together. When the magnitude and phase are displayed together the two can be presented as two separate traces, similar to the two traces on a dual-trace oscilloscope. A much more useful method of display is to present the magnitude and phase as a polar plot where the locus of the points of a vector having the length of the magnitude and the angle of the phase are displayed. Very sophisticated network analyzers can display all of the S parameters of a circuit in either a polar format or a Smith Chart format.

Transmitter Performance Tests

The test setup used in the ARRL Laboratory for measuring an HF transmitter or amplifier is shown in **Fig 25.81**. As can be seen, different power levels dictate different amounts of attenuation between the transmitter or amplifier and the spectrum analyzer.

Spurious Emissions

Fig 25.82 shows the broadband spectrum of a transmitter, showing the harmonics in the output. The horizontal (frequency) scale is 5 MHz per division; the main output of the transmitter at 7 MHz can be seen about 1.5 major divisions from the left of the trace. Although not shown, a very large apparent signal is often seen at the extreme left of the trace. This occurs at what would be zero frequency and it is caused by the first local oscillator frequency being exactly the first IF. All up-converting superheterodyne spectrum analyzers have this IF feed-through; in addition, this signal is occasionally accompanied by a smaller spurious signal, generated within the analyzer. To determine what part of the displayed signal is a spurious response caused by IF feed-through and what is an actual input signal, simply remove the input signal and observe the trace. It is not necessary or desirable that the transmitter be modulated for this broadband test.

Other transmitter tests that can be performed with a spectrum analyzer include measurement of two-tone IMD and SSB carrier and unwanted sideband suppression.

Two-Tone IMD

Investigating the sidebands from a modulated transmitter requires a narrow-band spectrum analysis and produces displays similar to that shown in **Fig 25.83**. In this example, a two-tone test signal is used to modulate the transmitter. The display shows the two test tones plus some of the IMD produced by the SSB transmitter. The test setup used to produce this display is shown in **Fig 25.84**.

In this example, a two-tone test signal with frequencies of 700 and 1900 Hz is used to modulate the transmitter. Set the transmitter output and audio input to the manufacturer's specifications. Each desired tone is adjusted to be equal in amplitude and centered on the display. The step attenuators and analyzer controls are then adjusted to set the two desired signals 6 dB below the 0-dB reference (top line).

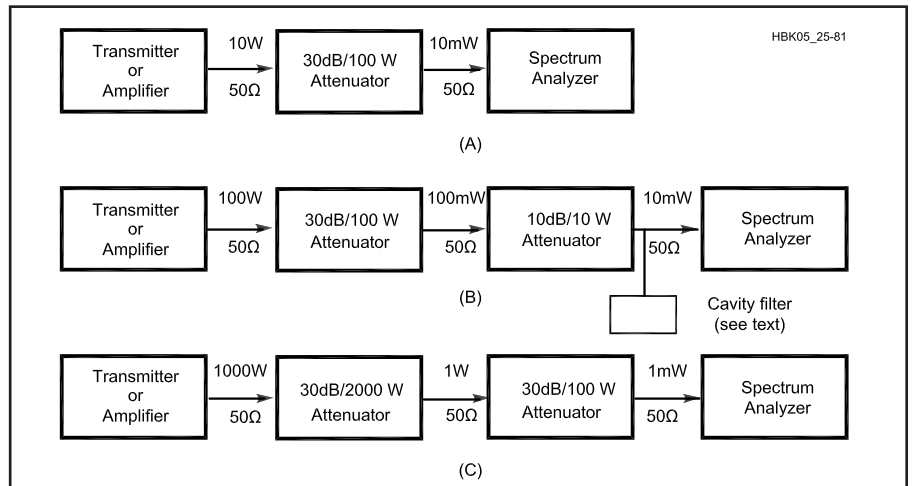

Fig 25.81 — These setups are used in the ARRL Laboratory for testing transmitters or amplifiers with several different power levels.

Fig 25.82 — Comparison of two different transmitters on the 40-m band as typically seen on a spectrum analyzer display. The display at the left shows a relatively clean transmitted signal but the transmitter at the right shows more spurious signal content. Horizontal scale is 5 MHz per division; vertical is 10 dB per division. According to current FCC spectral purity requirements both transmitters are acceptable.

Fig 25.83 — An SSB transmitter two-tone test as seen on a spectrum analyzer. Each horizontal division represents 2 kHz and each vertical division is 10 dB. The third-order products are 30 dB below the PEP (top line), the fifth-order products are down 37 dB and seventh-order products are down 40 dB. This represents acceptable (but not ideal) performance.

The IMD products can then be read directly from the display in terms of “dB below Peak Envelope Power (PEP).” (In the example shown, the third-order products are 30 dB below PEP, the fifth-order products are 37 dB down, the seventh-order products are down 40 dB.)

Carrier and Unwanted Sideband Suppression

Single-tone audio input signals can be used with the same setup to measure unwanted sideband and carrier suppression of SSB signals. In this case, set the single tone to the 0-dB reference line. (Once the level is set, the audio can be disabled for carrier suppression measurements in order to eliminate IMD and other effects.)

Phase Noise

Phase/composite noise is also measured

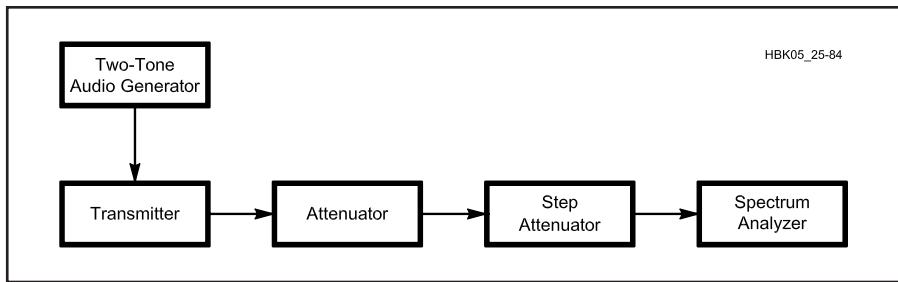

Fig 25.84 — The test setup used in the ARRL Laboratory to measure the IMD performance of transmitters and amplifiers.

Fig 25.86 — CW keying waveform test setup.

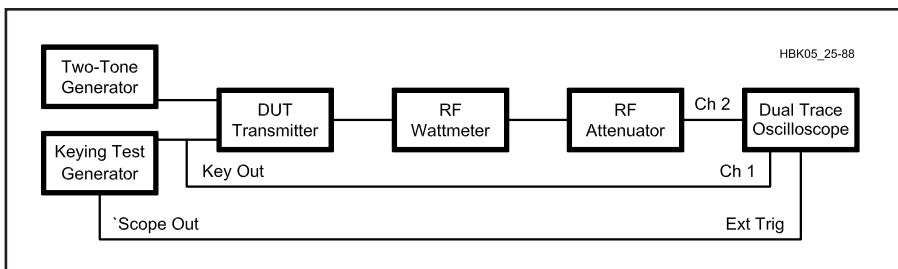

Fig 25.88 — PTT-to-RF-output test setup for voice-mode transmitters.

with spectrum analyzers in the ARRL Lab. This test requires specialized equipment and is included here for information purposes only.

The purpose of the Composite-Noise test is to observe and measure the phase and amplitude noise, as well as any close-in spurious signals generated by a transmitter. Since phase noise is the primary noise component in any well-designed transmitter, almost all of the noise observed during this test is phase noise.

This measurement is accomplished in the lab by converting the transmitter output down to a frequency band about 10 or 20 kHz above baseband. A mixer and a signal generator (used as a local oscillator) are used to perform this conversion. Filters remove the 0-Hz component as well as any unwanted heterodyne components. A spectrum analyzer (see **Fig 25.85**) displays the remaining noise and spurious signals from 2 to 22 kHz from the carrier frequency (in the CW mode).

Tests in the Time Domain

Oscilloscopes are used for transmitter testing in the time domain. Dual-trace instruments are best in most cases, providing easy to read time-delay measurements between keying input and RF- or audio-output signals. Common transmitter measurements performed with 'scopes include CW keying wave shape and time delay and SSB/FM transmit-to-audio turnaround tests (important for many digital modes).

A typical setup for measuring CW keying waveform and time delay is shown in **Fig 25.86**. A keying test generator is used to repeatedly key the transmitter at a controlled rate. The generator can be set to any reasonable speed, but ARRL tests are usually conducted at 20-ms on and 20-ms off (25 Hz, 50% duty cycle). **Fig 25.87** shows a typical display. The rise and fall times of the RF output pulse are measured between the 10% and 90% points on the leading and trailing edges, respectively.

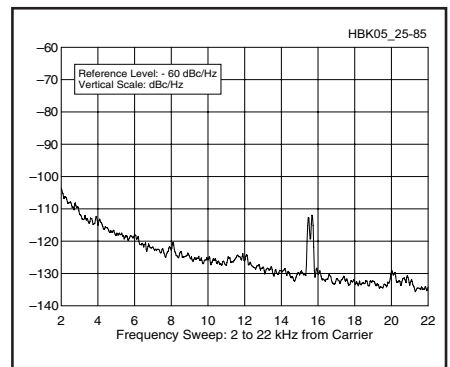

Fig 25.85 — The spectral-display results of a composite-noise test in the ARRL Lab. Power output is 100 W at 14 MHz. Vertical divisions are 10 dB; horizontal divisions are 2 kHz. The log reference level (the top horizontal line on the scale) represents -60 dBc/Hz and the baseline is -140 dBc/Hz. The carrier, off the left edge of the plot, is not shown. This plot shows composite transmitted noise 2 to 22 kHz from the carrier.

Fig 25.87 — Typical CW keying waveform test results. This display is for the ICOM IC-707 (semi-break-in mode) reviewed in April 94 *QST*. The upper trace is the actual key closure; the lower trace is the RF envelope. Horizontal divisions are 10 ms. The transceiver was being operated at 100 W output at 14 MHz.

The delay times are measured between the 50% points of the keying and RF output waveforms. Look at the **Receivers and Transmitters** chapter for further discussion of CW keying issues.

For voice modes (SSB/FM), a PTT-to-RF output test is similar to CW keying tests. It measures rise and fall times, as well as the on- and off-delay times just as in the CW test. See **Fig 25.88** for the test setup.

“Turnaround time” is the time it takes for a transceiver to switch from the 50% fall time of a keying pulse to 50% rise of audio output. The test setup is shown in **Fig 25.89**. Turn-around time measure-

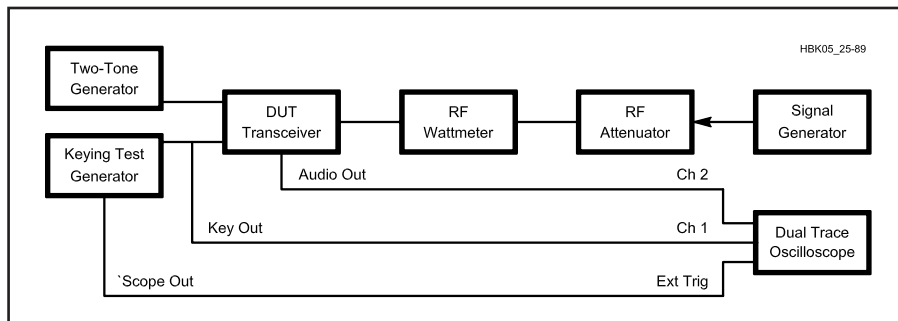

Fig 25.89 — Transmit-receive turn-around time test setup.

ments require extreme care with respect to transmitter output power, attenuation, signal-generator output and the maximum input signal that can be tolerated by the generator. The generator's specifications must not be exceeded and the input to the receiver must be at the required level, usu-

ally S9. Receiver AGC is usually off for this test, but experimentation with AGC and signal input level can reveal surprising variations. The keying rate must be considerably slower than the turn-around time; rates of 200-ms on/200-ms off or faster, have been used with success in

PO Box 9090, Everett, WA 98206.

GLOSSARY

Alternating current (ac) — The polarity constantly reverses, as contrasted to dc (direct current) where polarity is fixed.

Analog — Signals which have a full set of values. If the signal varies between 0 and 10 V all values in this range can be found. Compare this to a *digital* system.

Attenuator — A device which reduces the amplitude of a signal.

Average value — Obtained by recording or measuring N samples of a signal, adding up all of these values, and dividing this sum by N .

Bandwidth — A measure of how wide a signal is in frequency. If a signal covers 14,200 to 14,205 kHz its bandwidth is said to be 5 kHz.

BNC — A small bayonet-type connector used with coax cable.

Bridge circuit — Four passive elements, such as resistors, inductors, connected as a pair of voltage dividers with a meter or other measuring device across two opposite junctions. Used to indicate the relative values of the four passive elements. See the chapter discussion of Wheatstone bridges.

CMOS — A family of digital logic elements usually selected for their low power drain. See the **Electrical Signals and Components** chapter of this *Handbook*.

Coaxial cable (coax) — A cable formed of two conductors that share the same axis. The center conductor may be a single wire or a stranded cable. The outer conductor is called the shield. The shield may be flexible braid, foil, semirigid or rigid metal. For more information, look in the **Transmission Lines** chapter.

Combiners — See *Hybrid*.

D'Arsonval meter — A common mechanical meter consisting of a permanent magnet and a moving coil (with pointer attached).

Direct Current (dc) — The polarity is fixed for all time, as contrasted to ac (alternating current) where polarity constantly reverses.

Digital — A system that allows signals to assume a finite range of states. Binary logic is the most common example. Only two values are permitted in a binary system: one value is defined as a logical 1 and the other value as a logical 0. See the *Handbook* chapter on **Electrical Signals and Components**.

Divider — A network of components that produce an output signal that is a fraction of the input signal. The ratio of the output to the input is the division factor. An analog divider divides voltage (a string of series connected resistors) or current (parallel connected resistors). Digital dividers divide pulse trains or frequency.

DMM (digital multimeter) — A test instrument that usually measures at least:

Product Review tests at the ARRL Lab.

Turn-around time is an important consideration with some digital modes. AMTOR, for example, requires a turn-around time of 35 ms or less.

voltage, current and resistance, and displays the result on a numeric digit display, rather than an analog meter.

Dummy antenna or dummy load — A resistor or set of resistors used in place of an antenna to test a transmitter without radiating any electromagnetic energy into the air.

DVM (digital volt meter) — See *DMM*.

FET voltmeter — See also *VTVM*. An updated version of a VTVM using field effect transistors (FETs) in place of vacuum tubes.

Flip-flop — A digital circuit that has two stable states. See the chapter on **Electrical Signals and Components**.

Frequency marker — Test signals generated at selected intervals (such as 25 kHz, 50 kHz, 100 kHz) for calibrating the dials of receivers and transmitters.

Fundamental — The first signal or frequency in a series of harmonically related signals. This term is often used to describe an oscillator or transmitter's desired signal.

Harmonic — A signal occurring at some integral multiple (such as two, three, four) of a *fundamental* frequency.

Hybrid (hybrid combiners) — A device used to connect two signal generators to one receiver for test purposes, without the two generators affecting each other.

IC (integrated circuit) — A complete circuit built into a single electronic component.

LCD (liquid crystal display) — A low-

- power display device utilizing the physics of liquid crystals. They usually need either ambient light or backlighting to be seen.
- LED (light emitting diode)** — A diode that emits light when an appropriate voltage (usually 1.5 V at about 20 mA) is connected. They are used either as tiny pilot lights or in bar shapes to display letters and numbers.
- Loran** — A navigation system using very-low-frequency transmitters.
- Marker** — See *Frequency marker*.
- Multiplier** — A circuit that purposely creates some desired *harmonic* of its input signal. For example, a frequency multiplier that takes energy from a 3.5-MHz exciter and puts out RF at 7 MHz is a two times multiplier, usually called a frequency doubler.
- N** — A type of coaxial cable connector common at UHF and higher frequencies.
- NAND** — A digital element that performs the *not-and* function. See the **Electrical Signals and Components** chapter.
- Noise (noise figure)** — Noise is generated in all electrical circuits. It is particularly critical in those stages of a receiver that are closest to the antenna (RF amplifier and mixer), because noise generated in these stages can mask a weak signal. The noise figure is a measure of this noise generation. Lower noise figures mean that less noise is generated and weaker signals can be heard.
- NOR** — A digital element that performs the *not-or* function. See the **Electrical Signals and Components** chapter.
- Null (nulling)** — The process of adjusting a circuit for a minimum reading on a test meter or instrument. At a perfect null there is null, or no, energy to be seen.
- Ohmmeter** — A meter that measures the value of resistors. Usually part of a multimeter. See *VOM* and *DMM*.
- Peak value** — The highest value of a signal during the measuring time. If a measured voltage varies in value from 1 to 10 V over a measuring period, the peak value would be the highest measured, 10 V.
- PL-259** — A connector used for coaxial cable, usually at HF. It is also known as a male UHF connector. It is an inexpensive and common connector, but it is not weatherproof, nor is its impedance constant over frequency.
- Prescaler** — A circuit used ahead of a counter to extend the counter range to higher frequencies. A counter capable of operating up to 50 MHz can count up to 500 MHz when used with a divide-by-10 prescaler.
- Q** — The ratio of the reactance to the resistance of a component or circuit. It provides a measure of bandwidth. Lower resistive losses make for a higher Q, and a narrower bandwidth.
- RMS (root mean square)** — A measure of the value of a voltage or current obtained by taking values from successive small time slices over a complete cycle of the waveform, squaring those values, taking the mean of the squares, and then the square root of the mean. Very significant when working with good ac sine waves, where the RMS of the sine wave is 0.707 of the peak value.
- Scope** — Slang for oscilloscope. See the **Oscilloscopes** section of this chapter.
- Shunt** — Elements connected in parallel.
- Sinusoidal (sine wave)** — The nominal waveform for unmodulated RF energy and many other ac voltages.
- Spectrum** — Used to describe a range of frequencies or wavelengths. The RF spectrum starts at perhaps 10 kHz and extends up to several hundred gigahertz. The light spectrum goes from infrared to ultraviolet.
- Spurious emissions, or spurs** — Unwanted energy generated by a transmitter or other circuit. These emissions include, but are not limited to, *harmonics*.
- Thermocouple** — A device made up of two different metals joined at two places. If one joint is hot and the other cold a voltage may be developed, which is a measure of the temperature difference.
- Time domain** — A measurement technique where the results are plotted or shown against a scale of time. In contrast to the frequency domain, where the results are plotted against a scale of frequency.
- TTL (Transistor-transistor-logic)** — A logic IC family commonly used with 5 V supplies. See the chapter on **Electrical Signals and Components**.
- Vernier dial or vernier drive** — A mechanical system of tuning dials, frequently used in older equipment, where the knob might turn 10 times for each single rotation of the control shaft.
- VOM (volt-ohm-meter)** — A multimeter whose design predates digital multimeters (see *DMM*).
- VTVM (vacuum tube voltmeter)** — A meter that was developed to provide a high input resistance and therefore low current drain (loading) from the circuit being tested. Now replaced by the FET meter.
- Wheatstone bridge** — See *Bridge circuit*.

Chapter 26

Troubleshooting and Repair

Traditionally, the radio amateur has maintained a working knowledge of electronic equipment. This knowledge, and the ability to make repairs with whatever resources are available, keeps amateur stations operating when all other communications fail. This troubleshooting ability is not only a tradition; it is fundamental to the existence of the service.

This chapter, by Ed Hare, W1RFI, tells you what to do when you are faced with equipment failure or a circuit that doesn't work. It will help you ask and answer the right questions: "Should I fix it or send it back to the dealer for repair? What do I need to know to be able to fix it myself? Where do I start? What kind of test equipment do I need?" The best answers to these questions will depend on the type of test equipment you have available, the availability of a schematic or service manual and the depth of your own electronic and troubleshooting experience.

Not everyone is an electronics wizard; your set may end up at the repair shop in spite of your best efforts. The theory you learned for the FCC examinations and the information in this *Handbook* can help you decide if you can fix it yourself. If the problem is something simple (and most are), why not avoid the effort of shipping the radio to the manufacturer? It is gratifying to save time and money, but, even better, the experience and confidence you gain by fixing it yourself may prove even more valuable.

Although some say troubleshooting is as much art as it is science, the repair of electronic gear is not magic. It is more like detective work. A knowledge of complex math is not required. However, you must have, or develop, the ability to read a sche-

matic diagram and to visualize signal flow through the circuit.

SAFETY FIRST

Always! Death is permanent. A review of safety must be the first thing discussed in a troubleshooting chapter. Some of the voltages found in amateur equipment can be fatal! Only 50 mA flowing through the body is painful; 100 to 500 mA is usually fatal. Under certain conditions, as little as 24 V can kill.

Make sure you are 100% familiar with all safety rules and the dangerous conditions that might exist in the equipment you are servicing. Remember, if the equipment is not working properly, dangerous conditions may exist where you don't expect them. Treat every component as potentially "live."

Some older equipment uses "ac/dc" circuitry. In this circuit, one side of the chassis is connected directly to the ac line. This is an electric shock waiting to happen.

A list of safety rules can be found in **Table 26.1**. You should also read the **Safety** chapter of this *Handbook* before you proceed.

GETTING HELP

Other hams may be able to help you with your troubleshooting and repair problems, either with a manual or technical help. Check with your local club or repeater group. You may get lucky and find a troubleshooting "wizard." (On the other hand, you may get some advice that is downright dangerous, so be selective.) You can also place a classified ad in one of the ham magazines, perhaps when you are looking for a rare manual.

Your fellow hams in the ARRL Field organization may also help. Technical

Coordinators (TCs) and Technical Specialists (TSs) are volunteers who are willing to help hams with technical questions. For the name and address of a local TC or TS, contact your Section Manager (listed in the front of any recent issue of *QST*).

THEORY

To fix electronic equipment, you need to understand the system and circuits you are troubleshooting. A working knowledge of electronic theory, circuitry and components is an important part of the process. If necessary, review the electronic and circuit theory explained in the other chapters of this book. When you are troubleshooting, you are looking for the unexpected. Knowing how circuits are supposed to work will help you to look for things that are out of place.

TEST EQUIPMENT

Many of the steps involved in troubleshooting efficiently require the use of test equipment. We cannot see electrons flow. However, electrons do affect various devices in our equipment, with results we can measure.

Some people think they need expensive test instruments to repair their own equipment. This is not so! In fact, you probably already own the most important instruments. Some others may be purchased inexpensively, rented, borrowed or built at home. The test equipment available to you may limit the kind of repairs you can do, but you will be surprised at the kinds of repair work you can do with simple test equipment.

Senses

Although they are not "test equipment"

Table 26.1**Safety Rules**

1. Keep one hand in your pocket when working on live circuits or checking to see that capacitors are discharged.
2. Include a conveniently located ground-fault current interrupter (GFCI) circuit breaker in the workbench wiring.
3. Use only grounded plugs and receptacles.
4. Use a GFCI protected circuit when working outdoors, on a concrete or dirt floor, in wet areas, or near fixtures or appliances connected to water lines, or within six feet of any exposed grounded building feature.
5. Use a fused, power limiting isolation transformer when working on ac/dc devices.
6. Switch off the power, *disconnect equipment from the power source, ground the output of the internal dc power supply*, and discharge capacitors when making circuit changes.
7. Do not subject electrolytic capacitors to excessive voltage, ac voltage or reverse voltage.
8. Test leads should be well insulated.
9. Do not work alone!
10. Wear safety glasses for protection against sparks and metal fragments.
11. Always use a safety harness when working above ground level.
12. Wear shoes with nonslip soles that will support your feet when climbing.
13. Wear rubber-sole shoes or use a rubber mat when standing on the ground or on a concrete floor.
14. Wear a hard hat when someone is working above you.
15. Be careful with tools that may cause short circuits.
16. Replace fuses only with those having proper ratings.

in the classic sense, your own senses will tell you as much about the equipment you are trying to fix as the most-expensive spectrum analyzer. We each have some of these natural “test instruments.”

Eyes — Use them constantly. Look for evidence of heat and arcing, burned components, broken connections or wires, poor solder joints or other obvious visual problems.

Ears — Severe audio distortion can be detected by ear. The “snaps” and “pops” of arcing or the sizzling of a burning component may help you track down circuit faults. An experienced troubleshooter can diagnose some circuit problems by the sound they make. For example, a bad audio-output IC sounds slightly different than a defective speaker.

Nose — Your nose can tell you a lot. With experience, the smells of ozone, an overheating transformer and a burned carbon-composition resistor each become unique and distinctive.

Finger — Carefully use your fingers to measure low heat levels in components. Small-signal transistors can be fairly warm to the touch; anything hotter can indicate a circuit problem. (Be careful; some high-power devices or resistors can get downright hot during normal operation.)

Brain — More troubleshooting prob-

lems have been solved with a VOM and a brain than with the most expensive spectrum analyzer. You must use your brain to analyze data collected by other instruments.

“Internal” Equipment

Some “test equipment” is included in the equipment you repair. Nearly all receivers include a speaker. An S meter is usually connected ahead of the audio chain. If the S meter shows signals, it indicates that the RF and IF circuitry is probably functioning. Analyze what the unit is doing and see if it gives you a clue.

Some older receivers include a crystal frequency calibrator. The calibrator signal, which is rich in harmonics, is injected in the RF chain close to the antenna jack and may be used for signal tracing and alignment.

Bench Equipment

Here is a summary of test instruments and their applications. Some items serve several purposes and may substitute for others on the list. The list does not cover all equipment available, only the most common and useful instruments. The theory and operation of much of this test equipment is discussed in more detail in the **Test Procedures** chapter.

Multimeters — The multimeter is the

most often used piece of test equipment. This group includes vacuum-tube voltmeters (VTVMs), volt-ohm-milliammeters (VOMs), field-effect transistor VOMs (FETVOMs) and digital multimeters (DMMs). Multimeters are used to read bias voltages, circuit resistance and signal level (with an appropriate probe). They can test resistors, capacitors (within certain limitations), diodes and transistors.

DMMs have become quite inexpensive. Their high input impedance, accuracy and flexibility are well worth the cost. Many of them contain other test equipment as well, such as capacitance meters, frequency counters, transistor testers and even digital thermometers. Some DMMs are affected by RF, so most technicians keep an analog-display VOM on hand for use near RF equipment.

When buying an analog meter, look for one with an input impedance of 20 k Ω /V or better. Reasonably priced models are available with 30 k Ω /V (\$35) and 50 k Ω /V (\$40). The 10 M Ω or better input impedance of DMMs, FETVOMs, VTVMs and other electronic voltmeters makes them the preferred instruments for voltage measurements.

Test leads — Keep an assortment of wires with insulated, soldered alligator clips. Commercially made leads have a high failure rate because they use small wire that is not soldered to the clips; it is best to make your own.

Open wire leads (Fig 26.1A) are good for dc measurements, but they can pick up unwanted RF energy. This problem is reduced somewhat if the leads are twisted together (Fig 26.1B). A coaxial cable lead is much better, but its inherent capacitance can affect RF measurements.

The most common probe is the low-capacitance ($\times 10$) probe shown in Fig 26.1C. This probe isolates the oscilloscope from the circuit under test, preventing the ‘scope’s input and test-probe capacitance from affecting the circuit and changing the reading. A network in the probe serves as a 10:1 divider and compensates for frequency distortion in the cable and test instrument.

Demodulator probes (see the **Test Procedures** chapter and the schematic shown in Fig 26.1D) are used to demodulate or detect RF signals, converting modulated RF signals to audio that can be heard in a signal tracer or seen on a low-bandwidth ‘scope.

You can make a probe for inductive coupling as shown in Fig 26.1E. Connect a two- or three-turn loop across the center conductor and shield before sealing the end. The inductive pick up is useful for coupling to high-current points.

Fig 26.1—An array of test probes for use with various test instruments.

RF power and SWR meters — Every shack should have one. It is used to measure forward and reflected RF power. A standing-wave ratio (SWR) meter can be the first indicator of antenna trouble. It can also be used between an exciter and power amplifier to spot an impedance mismatch.

Simple meters indicate relative power SWR and are fine for Transmatch adjustment and line monitoring. However, if you want to make accurate measurements, a calibrated wattmeter with a directional coupler is required.

Dummy load — A “dummy” or “phantom” load is a necessity in any shack. Do not put a signal on the air while repairing equipment. Defective equipment can generate signals that interfere with other hams or other radio services. A dummy load also provides a known, matched load (usually 50 Ω) for use during adjustments.

When buying a dummy load, avoid used, oil-cooled dummy loads unless you can be sure that the oil does not contain PCBs. This biologically hazardous compound was common in transformer oil until a few years ago.

Dummy loads in the shack are often required to dissipate a transmitter’s or linear amplifier’s full power output, i.e., up to 1500 W, at least for a short time. They are also used in lower power applications—typically smaller sized and rated, and can also be used as impedance standards or as terminations for low-power

computer or communications lines.

Dip meter — This device is often called a transistor dip meter or a grid-dip oscillator from vacuum-tube days.

Most dip meters can also serve as an absorption frequency meter. In this mode, measurements are read at the current peak, rather than the dip. Some meters have a connection for headphones. The operator can usually hear signals that do not register on the meter. Because the dip meter is an oscillator, it can be used as a signal generator in certain cases where high accuracy or stability are not required.

When purchasing a dip meter, look for one that is mechanically and electrically stable. The coils should be in good condition. A headphone connection is helpful. Battery operated models are easier to use for antenna measurements. Dip meters are not nearly as common as they once were.¹

Oscilloscope — The oscilloscope, or ‘scope, is the second most often used piece of test equipment, although a lot of repairs can be accomplished without one. The trace of a ‘scope can give us a lot of information about a signal at a glance.

The simplest way to display a waveform is to connect the vertical amplifier of the ‘scope to a point in the circuit through a simple test lead. When viewing RF, use a low-capacitance probe that has been adjusted to match the ‘scope. Select the vertical gain and time-base (horizontal scale,

Fig 26.2—An oscilloscope display showing the relationship between time-base setting and graticule lines.

Fig 26.3—Information available from a typical oscilloscope display of a waveform.

Fig 26.2) for the most useful displayed waveform.

A ‘scope waveform shows voltage (if calibrated), approximate period (frequency is the reciprocal of the period) and a rough idea of signal purity (see Fig 26.3). If the ‘scope has dual-trace capability (meaning it can display two signals at once), a second waveform may be displayed and compared to the first. When the two signals are taken from the input and output of a stage, stage linearity and phase shift can be checked (see Fig 26.4).

An important specification of an oscilloscope is its amplifier bandwidth. This tells us the frequency at which amplifier response has dropped 3 dB. The instrument will display higher frequencies, but its accuracy at higher frequencies is not known. Even well below its rated bandwidth a ‘scope is not capable of much more than about 5% accuracy. This is adequate

Fig 26.4—A dual-trace oscilloscope display of amplifier input and output waveforms.

for most amateur applications.

An oscilloscope will show gross distortions of audio and RF waveforms, but it cannot be used to verify that a transmitter meets FCC regulations for harmonics and spurious emissions. Harmonics that are down only 20 dB from the fundamental would be illegal in most cases, but they would not change the oscilloscope waveform enough to be seen.

When buying a 'scope, get the greatest bandwidth you can afford. Old Hewlett-Packard or Tektronix 'scopes are usually quite good for amateur use.

Signal generator — Although signal generators have many uses, in troubleshooting they are most often used for signal injection (more about this later) and alignment.

An AF/RF signal-injector schematic is shown in Fig 26.5. If frequency accuracy is needed, the crystal-controlled signal source of Fig 26.6 can be used. The AF/RF circuit provides usable harmonics up to 30 MHz, while the crystal controlled oscillator will function with crystals from 1 to 15 MHz. These two projects are not meant to compete with standard signal generators, but they are adequate for signal injection.² A better generator is required for receiver alignment or for receiver quality testing.

When buying a generator, look for one that can generate a sine wave signal. A good signal generator is double or triple shielded against leakage. Fixed-frequency audio should be available for modulation of the RF signal and for injection into audio stages. The most versatile generators can generate amplitude and frequency modulated signals.

Good generators have stable frequency controls with no backlash. They also have multiposition switches to control signal level. A switch marked in dBm is a good indication that you have located a high-quality test instrument. The output jack should be a coaxial connector (usually a

BNC or N), not the kind used for microphone connections.

Some older, high-quality units are common. Look for World War II surplus units of the URM series, Boonton, GenRad, Hewlett-Packard, Tektronix, Measurements Inc or other well-known brand names. Some home-built signal generators may be quite good, but make sure to check construction techniques, level control and shielding quality.

Signal tracer — Signals can be traced with a voltmeter and an RF probe, a dip

meter with headphones or an oscilloscope, but there are some devices made especially for signal tracing. A signal tracer is primarily a high-gain audio amplifier. It may have a built-in RF detector, or rely on an external RF probe. Most convert the traced signal to audio through a speaker.

The tracer must function as a receiver and detector for each frequency range in the test circuit. A high-impedance tracer input is necessary to prevent circuit loading.

A general-coverage receiver can be used to trace RF or IF signals, if the receiver covers the necessary frequency range. Most receivers, however, have a low-impedance input that severely loads the test circuit. To minimize loading, use a capacitive probe or loop pickup. When the probe is held near the circuit, signals will be picked up and carried to the receiver. It may also pick up stray RF, so make sure you are listening to the correct signal by switching the circuit under test on and off while listening.

Tube tester — Vacuum-tube testers used to be found in nearly every drug or department store. They are scarce now because tubes are no longer used in modern consumer or (most) amateur equipment. Older tube gear is found in many ham shacks or flea markets, though. There are many aficionados of vintage gear who enjoy working with old vacuum-tube equipment.

Most simple tube testers measure the cathode emission of a vacuum tube. Each grid is shorted to the plate through a switch and the current is observed while the tube operates as a diode. By opening the switches from each grid to the plate (one at a time), we can check for opens and shorts. If the plate current does not drop slightly as a switch is opened, the element connected to that switch is either open or shorted to another element. (We cannot tell an open from a short with this test.) The emission tester does not necessarily indicate the ability of a tube to amplify.

Other tube testers measure tube gain (transconductance). Some transconductance testers read plate current with a fixed bias network. Others use an ac signal to drive the tube while measuring plate current.

Most tube testers also check interelement leakage. Contamination inside the tube envelope may result in current leakage between elements. The paths can have high resistance, and may be caused by gas or deposits inside the tube. Tube testers use a moderate voltage to check for leakage. Leakage can also be checked with an ohmmeter using the $\times 1\text{M}$ range, depending on the actual spacing of tube elements.

Transistor tester — Transistor testers are similar to transconductance tube testers. Device current is measured while the device is conducting or while an ac signal is applied at the control terminal. Commercial surplus units are often seen at ham flea markets. Some DMMs being sold today also include a built-in, simple transistor tester.

Most transistor failures appear as either an open or shorted junction. Opens and

shorts can be found easily with an ohmmeter; a special tester is not required.

Transistor gain characteristics vary widely, however, even between units with the same device number. Testers can be used to measure the gain of a transistor. A tester that uses dc signals measures only transistor dc alpha and beta. Testers that apply an ac signal show the ac alpha or beta. Better testers also test for leakage.

In addition to telling you whether a transistor is good or bad, a transistor tester can help you decide if a particular transistor has sufficient gain for use as a replacement. It may also help when matched transistors are required. The final test is the repair circuit.

Frequency meter — Most frequency counters are digital units, often able to show frequency to a 1-Hz resolution. Some older “analog” counters are sometimes found surplus, but a low-cost digital counter will out-perform even the best of these old “classics.”

Power supplies — A well-equipped test bench should include a means of varying the ac-line voltage, a variable-voltage regulated dc supply and an isolation transformer.

AC-line voltage varies slightly with load. An autotransformer with a movable tap lets you boost or reduce the line voltage slightly. This is helpful to test circuit functions with supply-voltage variations.

As mentioned earlier, ac/dc radios must be isolated from the ac line during testing and repair. Keep an isolation transformer handy if you want to work on table-model broadcast radios or television sets (check for other ac/dc equipment, too. Even some old phonographs or Amateur Radio transceivers used this dangerous circuit design).

A good multivoltage supply will help with nearly any analog or digital troubleshooting project. Many electronics distributors stock bench power supplies. A variable-voltage dc supply may be used to power various small items under repair or provide a variable bias supply for testing active devices. Construction details for a laboratory power supply appear in the **Power Supplies** chapter.

If you want to work on vacuum-tube gear, the maximum voltage available from the dc supply should be high enough to serve as a plate or a bias supply for common tubes (about 300 to 400 V ought to do it).

Accessories — There are a few small items that may be used in troubleshooting. You may want to keep them handy.

Many circuit problems are sensitive to temperature. A piece of equipment may work well when first turned on (cold) but

fail as it warms up. In this case, a cold source will help you find the intermittent connection. When you cool the bad component, the circuit will suddenly start working again (or stop working). Cooling sprays are available from most parts suppliers.

A heat source helps locate components that fail only when hot. A small incandescent lamp can be mounted in a large piece of sleeve insulation to produce localized heat for test purposes.

A heat source is usually used in conjunction with a cold source. If you have a circuit that stops working when it warms up, heat the circuit until it fails, then cool the components one by one. When the circuit starts working again, the last component sprayed was the bad one.

A stethoscope (with the pickup removed — see **Fig 26.7**) or a long piece of sleeve insulation can be used to listen for arcing or sizzling in a circuit.

WHERE TO BEGIN

New Construction

In most repair work, the technician is aided by the knowledge that the circuit once worked. It is only necessary to find the faulty part(s) and replace it. This is not so with newly constructed equipment. Repair of equipment with no working history is a special, and difficult, case. You

Fig 26.7 — A stethoscope, with the pickup removed, is used to listen for arcing in crowded circuits.

may be dealing with a defective component, construction error or even a faulty design. Carefully checking for these defects can save you hours.

All Equipment

Check the Obvious

Try the easy things first. If you are able to solve the problem by replacing a fuse or reconnecting a loose cable, you might be able to avoid a lot of effort. Many experienced technicians have spent hours troubleshooting a piece of equipment only to learn the hard way that the on/off switch was “off” or that they were not using the equipment properly.

Read the manual! Your equipment may be working as designed. Many electronic “problems” are caused by a switch that is set in the wrong position, or a unit that is being asked to do something it was not designed to do. Before you open up your equipment for major surgery, make sure you are using it correctly.

Next, make sure the equipment is plugged in, that the ac outlet does indeed have power, that the equipment is switched “on” and that all of the fuses are good. If the equipment uses batteries or an external power supply, make sure these are working.

Check that all wires, cables and accessories are working and plugged in to the right connectors or jacks. In a “system,” it is often difficult to be sure which component or subsystem is bad. Your transmitter may not work on SSB because the transmitter is bad, but it could also be a bad microphone.

Connector faults are more common than component troubles. Consider poor connections as prime suspects in your troubleshooting detective work. Do a thorough inspection of the connections. Is the antenna connected? How about the speaker, fuses and TR switch? Are transistors and ICs firmly seated in their sockets? Are all interconnection cables sound and securely connected? Many of these problems are obvious to the eye, so look around carefully.

Simplify the Problem

If the broken equipment is part of a system, you need to find out exactly which part of the system is bad. For example, if your amateur station is not putting out any RF, you need to determine if it is a microphone problem, a transmitter problem, an amplifier problem or a problem somewhere in your station wiring. If you are trying to diagnose a bad channel on your home modular stereo system, it could be anything from a bad cable to a bad amplifier to a bad speaker.

Simplify the system as much as possible. To troubleshoot the “no-RF” problem, temporarily eliminate the amplifier from the station configuration. To diagnose the stereo system, start troubleshooting by checking just the amplifier with a set of known good headphones. Simplifying the problem will often isolate the bad component quickly.

Documentation

Once you have determined that a piece of equipment is indeed broken, you need to do some preparation before you diagnose and fix it. First, locate a schematic diagram and service manual. It is possible to troubleshoot without a service manual, but a schematic is almost indispensable.

The original equipment manufacturer is the best source of a manual or schematic. However, many old manufacturers have gone out of business. Several sources of equipment manuals can be located by a web search.

If all else fails, you can sometimes reverse engineer a simple circuit by tracing wiring paths and identifying components to draw your own schematic. If you have access to the databooks for the active devices used in the circuit, the pin-out diagrams and applications notes will sometimes be enough to help you understand and troubleshoot the circuit.

Define Problems

To begin troubleshooting, define the problem accurately. Ask yourself these questions:

1. What functions of the equipment do not work as they should; what does not work at all?
2. What kind of performance can you realistically expect?
3. Has the trouble occurred in the past? (Keep a record of troubles and maintenance in the owner’s manual or log book.)

Write the answers to the questions. The information will help with your work, and may help service personnel if their advice or professional service is required.

Take It Apart

All of the preparation work has been done. It is time to really dig in. You usually will have to start by taking the equipment apart. This is the part that can trap the unwary technician. Most experienced service technicians can tell you the tale of the equipment they took apart and were unable to easily put back together. Don’t let it happen to you.

Take lots of notes about the way you take it apart. Take notes about each component you remove. Write down the order in which you do things, color codes, part

placements, cable routings, hardware notes and anything else you think you might need to be able to reassemble the equipment weeks from now when the back-ordered part comes in.

Put all of the screws in one place. A plastic jar with a lid works well; if you drop it the plastic is not apt to break and the lid will keep all the parts from flying around the work area (you will never find them all). It may pay to have a separate labeled container for each subsystem.

Look Around

Many service problems are visible, if you look for them carefully. Many a technician has spent hours tracking down a failure, only to find a bad solder joint or burned component that would have been spotted in careful inspection of the printed-circuit board. Start troubleshooting by carefully inspecting the equipment.

It is time consuming, but you really need to look at every connector, every wire, every solder joint and every component. A connector may have loosened, resulting in an open circuit. You may spot broken wires or see a bad solder joint. Flexing the printed-circuit board or tugging on components a bit while looking at their solder joints will often locate a defective solder job. Look for scorched components.

Make sure all of the screws securing the printed-circuit board are tight and making good electrical contact. (Do not tighten the adjusting screws, however! You will ruin the alignment.) See if you can find evidence of previous repair jobs; these may not have been done properly. Make sure that each IC is firmly seated in its socket. Look for pins folded underneath the IC rather than making contact with the socket. If you are troubleshooting a newly constructed circuit, make sure each part is of the correct value or type number and is installed correctly.

If your careful inspection doesn’t reveal anything, it is time to apply power to the unit under test and continue the process. Observe all safety precautions while troubleshooting equipment. There are voltages inside some equipment that can kill you. If you are not qualified to work safely with the voltages and conditions inside of the equipment, do not proceed. See Table 26.1 and the **Safety** chapter.

Other Senses

With power applied to the unit, listen for arcs and look and smell for smoke. If no problems are apparent, you will have to start testing the various parts of the circuit.

VARIOUS APPROACHES

There are two fundamental approaches to troubleshooting: the systematic

approach and the instinctive approach. The systematic approach uses a defined process to analyze and isolate the problem. An instinctive approach relies on troubleshooting experience to guide you in selecting which circuits to test and which tests to perform. The systematic approach is usually chosen by beginning troubleshooters.

At the Block Level

The block diagram is a road map. It shows the signal paths for each circuit function. These paths may run together, cross occasionally or not at all. Those blocks that are not in the paths of faulty functions can be eliminated as suspects. Sometimes the symptoms point to a single block, and no further search is necessary.

In cases where more than one block is suspect, several approaches may be used. Each requires testing a block or stage. Signal injection, signal tracing, instinct or combination of all techniques may be used to diagnose and test electronic equipment.

Systematic Approaches

The instinctive approach works well for those with years of troubleshooting experience. Those of us who are new to this game need some guidance. A systematic approach is a disciplined procedure that allows us to tackle problems in unfamiliar equipment with a reasonable hope of success.

There are two common systematic approaches to troubleshooting at the block level. The first is signal tracing; the second is signal injection. The two techniques are very similar. Differences in test equipment and the circuit under test determine which method is best in a given situation. They can often be combined.

Power Supplies

You may be able to save quite a bit of time if you test the power supply first. All of the other circuits may be dead if the power supply is not working. Power supply diagnosis is discussed in detail later in this chapter.

Signal Tracing

In signal tracing, start at the beginning of a circuit or system and follow the signal through to the end. When you find the signal at the input to a specific stage, but not at the output, you have located the defective stage. You can then measure voltages and perform other tests on that stage to locate the specific failure. This is much faster than testing every component in the unit to determine which is bad.

It is sometimes possible to use over-the-air signals in signal tracing, in a receiver

for example. However, if a good signal generator is available, it is best to use it as the signal source. A modulated signal source is best.

Signal tracing is suitable for most types of troubleshooting of receivers and analog amplifiers. Signal tracing is the best way to check transmitters because all of the necessary signals are present in the transmitter by design. Most signal generators cannot supply the wide range of signal levels required to test a transmitter.

Equipment

A voltmeter, with an RF probe, is the most common instrument used for signal tracing. Low-level signals cannot be measured accurately with this instrument. Signals that do not exceed the junction drop of the diode in the probe will not register at all, but the presence, or absence, of larger signals can be observed.

A dedicated signal tracer can also be used. It is essentially an audio amplifier. An experienced technician can usually judge the level and distortion of the signal by ear. You cannot use a dedicated signal tracer to follow a signal that is not amplitude modulated (single sideband is a form of AM). Signal tracing is not suitable for tracing CW signals, FM signals or oscillators. To trace these, you will have to use a voltmeter and RF probe or an oscilloscope.

An oscilloscope is the most versatile signal tracer. It offers high input impedance, variable sensitivity, and a constant display of the traced waveform. If the oscilloscope has sufficient bandwidth, RF signals can be observed directly. Alternatively, a demodulator probe can be used to show demodulated RF signals on a low-bandwidth 'scope. Dual-trace scopes can simultaneously display the waveforms, including their phase relationship, present at the input and output of a circuit.

Procedure

First, make sure that the circuit under test and test instruments are isolated from the ac line by transformers. Set the signal source to an appropriate level and frequency for the unit you are testing. For a receiver, a signal of about 100 μV should be plenty. For other circuits, use the schematic, an analysis of circuit function and your own good judgment to set the signal level.

In signal tracing, start at the beginning and work toward the end of the signal path. Switch on power to the test circuit and connect the signal-source output to the test-circuit input. Place the tracer probe at the circuit input and ensure that you can hear the test signal. Observe the characteristics of the signal if you are using a

'scope (see Fig 26.8). Compare the detected signal to the source signal during tracing.

Move the tracer probe to the output of the next stage and observe the signal. Signal level should increase in amplifier stages and may decrease slightly in other stages. The signal will not be present at the output of a "dead" stage.

Low-impedance test points may not provide sufficient signal to drive a high-impedance signal tracer, so tracer sensitivity is important. Also, in some circuits the output level appears low where there is an impedance change from input to output of a stage (see Fig 26.9). For example, the circuit in Fig 26.9 is a common-collector current amplifier with a high input impedance and low output impedance. The voltages at TP1 and TP2 are approximately equal and in phase.

There are two signals — the test signal and the local oscillator signal — present in a mixer stage. Loss of either one will result in no output from the mixer stage. Switch the signal source on and off repeatedly to make sure that the tracer reading varies (it need not disappear) with source switching.

Signal Injection

Like signal tracing, signal injection is particularly suited to some situations. Signal injection is a good choice for receiver troubleshooting because the receiver already has a detector as part of the design. It is suitable for either high- or low-impedance circuits and can be used with vacuum tubes, transistors or ICs.

Equipment

If you are testing equipment that does not include a suitable detector as part of the circuit, some form of signal detector is required. Any of the instruments used for signal tracing are adequate.

Most of the time, your signal injector will be a signal generator. There are other injectors available, some of which are square-wave audio oscillators rich in RF harmonics (see Fig 26.5). These are usually built into a pen-sized case with a test probe at the end. These "pocket" injectors do have their limits because you can't vary their output level or determine their frequency. They are still useful, though, because most circuit failures are caused by a stage that is completely dead.

Consider the signal level at the test point when choosing an instrument. The signal source used for injection must be able to supply appropriate frequencies and levels for each stage to be tested. For example, a typical superheterodyne receiver requires AF, IF and RF signals that vary from 6 V

Fig 26.8 — Signal tracing in a simple receiver.

Fig 26.9 — The effect of circuit impedance on an oscilloscope display. Although the circuit functions as a current amplifier, the change in impedance from TP1 to TP2 results in the traces described. This is a common-collector amplifier.

at AF, to 0.2 mV at RF. Each conversion stage used in a receiver requires another IF from the signal source.

Procedure

If an external detector is required, set it to the proper level and connect it to the test circuit. Set the signal source for AF, and inject a signal directly into the signal detector to test operation of the injector and detector. Move the signal source to the input of the preceding stage, and observe the signal. Continue moving the signal source to the inputs of successive stages.

When you inject the signal source to the input of the defective stage, there will be no output. Prevent stage overload by

reducing the level of the injected signal as testing progresses through the circuit. Use suitable frequencies for each tested stage.

Make a rough check of stage gain by injecting a signal at the input and output of an amplifier stage. You can then compare how much louder the signal is when injected at the input. This test may mislead you if there is a radical difference in impedance from stage input to output. Understand the circuit operation before testing.

Mixer stages present a special problem because they have two inputs, rather than one. A lack of output signal from a mixer can be caused by either a faulty mixer or a faulty local oscillator (LO). Check oscillator operation with a 'scope or absorption wavemeter, or by listening on another receiver. If none of these instruments are available, inject the frequency of the LO at the LO output. If a dead oscillator is the only problem, this should restore operation.

If the oscillator is operating, but off frequency, a multitude of spurious responses will appear. A simple signal injector that produces many frequencies simultaneously is not suitable for this test. Use a well-shielded signal generator set to an appropriate level at the LO frequency.

Divide and Conquer

Under certain conditions, the block search may be speeded by testing at the middle of successively smaller circuit sections. Each test limits the fault to one half of the remaining circuit (see Fig 26.10). Let's say the receiver has 14 stages and the fault is in stage 12. This approach requires only four tests to locate the faulty stage, a substantial saving of time.

This "divide and conquer" tactic cannot be used in equipment that splits the signal path between the input and the output. Test readings taken inside feedback loops are misleading unless you understand the circuit and the waveform to be expected at each point in the test circuit. It is best to consider all stages within a feedback loop as a single block during the block search.

Both signal tracing and signal injection procedures may be speeded by taking some diagnostic short cuts. Rather than check each stage sequentially, check a point halfway through the system. As an example:

An HF receiver is not working. There is absolutely no response from the speaker. First, substitute a suitable speaker — still no sound. Next, check the power supply — no problem there. No clues indicate any particular stage. Signal tracing or injection must provide the answer.

Get out the signal generator and switch it on. Set the generator for a low-level RF signal, switch the signal off and connect the output to the receiver. Switch the signal on again and place a high-impedance signal-tracer probe at the antenna connection. Instantly, the tracer emits a strong audio note. Good; the test equipment is functioning.

Move the probe to the input of the receiver detector. As the tracer probe touches the circuit the familiar note sounds. Next, set the tracer for audio and place the probe halfway through the audio chain. It is silent! Move the probe halfway back to the detector, and the note appears once again. Yet, no signal is present at the output of the stage. You now know that the defect is somewhere between the two

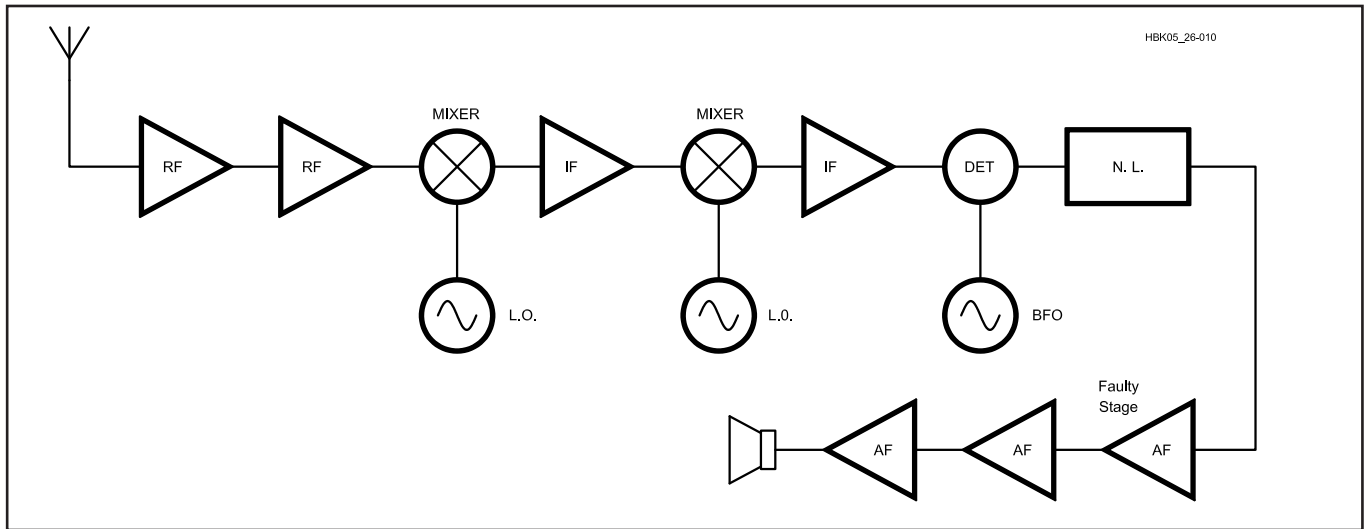

Fig 26.10 — The 14-stage receiver diagnosed by the “divide and conquer” technique.

points tested. In this case, the third audio stage is faulty.

The Instinctive Approach

In an “instinctive” approach to troubleshooting, you rely on your judgment and experience to decide where to start testing, what and how to test. When you immediately check power supply voltages, or the ac fuse on a unit that is completely nonfunctional, that is an example of an instinctive approach. If you are faced with a receiver that has distorted audio and immediately start testing the speaker and audio output stage, or if you immediately start checking the filter and bypass capacitors in an audio stage that is oscillating or “motorboating” you are troubleshooting on instinct.

Most of our discussion on the instinctive approach is really a collection of tips and guidelines. Read them to build your troubleshooting skills.

The check for connector problems mentioned at the beginning of this section is a good idea. Experience has shown connector faults to be so common that they should be checked even before a systematic approach begins.

When instinct is based on experience, searching by instinct may be the fastest procedure. If your instinct is correct, repair time and effort may be reduced substantially. As experience and confidence grow, the merits of the instinctive approach grow with them. However, inexperienced technicians who choose this approach are at the mercy of chance.

TESTING WITHIN A STAGE

Once you have followed all of the troubleshooting procedures and have iso-

lated your problem to a single defective stage or circuit, a few simple measurements and tests will usually pinpoint one or more specific components that need adjustment or replacement.

First, check the parts in the circuit against the schematic diagram to be sure that they are reasonably close to the design values, especially in a newly built circuit. Even in a commercial piece of equipment, someone may have incorrectly changed them during attempted repairs. A wrong-value part is quite likely in new construction, such as a home-brew project.

Voltage Levels

Check the circuit voltages. If the voltage levels are printed on the schematic, this is easy. If not, analyze the circuit and make some calculations to see what the circuit voltages should be. Remember, however, that the printed or calculated voltages are nominal; measured voltages may vary from the calculations.

When making measurements, remember the following points:

- Make measurements at device leads, not at circuit-board traces or socket lugs.
- Use small test probes to prevent accidental shorts.
- Never connect or disconnect power to solid-state circuits with the switch on. Consider the effect of the meter on measured voltages. A 20-k Ω /V meter may load down a high-impedance circuit and change the voltage.

Voltages may give you a clue to what is wrong with the circuit. If not, check the active device. If you can check the active

device in the circuit, do so. If not, remove it and test it, or substitute a known good device. After connections, most circuit failures are caused directly or indirectly by a bad active device. The experienced troubleshooter usually tests or substitutes these first.

Analyze the other components and determine the best way to test each. There is additional information about electronic components in the electronic-theory chapters and in the **Component Data and References** chapter.

There are two voltage levels in most circuits (V+ and ground, for example). Most component failures (opens and shorts) will shift dc voltages near one of these levels.

Typical failures that show up as incorrect dc voltages include: open coupling transformers; shorted capacitors; open, shorted or overheated resistors and open or shorted semiconductors.

Noise

A slight hiss is normal in all electronic circuits. This noise is produced whenever current flows through a conductor that is warmer than absolute zero. Noise is compounded and amplified by succeeding stages. Repair is necessary only when noise threatens to obscure normally clear signals.

Semiconductors can produce hiss in two ways. The first is normal — an even white noise that is much quieter than the desired signal. Faulty devices frequently produce excessive noise. The noise from a faulty device is usually erratic, with pops and crashes that are sometimes louder than the desired signal. In an analog circuit, the end result of noise is usually sound. In a con-

trol or digital circuit, noise causes erratic operation: unexpected switching and so on.

Noise problems usually increase with temperature, so localized heat may help you find the source. Noise from any component may be sensitive to mechanical vibration. Tapping various components with an insulated screwdriver may quickly isolate a bad part. Noise can also be traced with an oscilloscope or signal tracer.

Nearly any component or connection can be a source of noise. Defective components are the most common cause of crackling noises. Defective connections are a common cause of loud, popping noises.

Check connections at cables, sockets and switches. Look for dirty variable-capacitor wipers and potentiometers. Mica trimmer capacitors often sound like lightning when arcing occurs. Test them by installing a series 0.01- μ F capacitor. If the noise disappears, replace the trimmer.

Potentiometers are particularly prone to noise problems when used in dc circuits. Clean them with spray cleaner and rotate the shaft several times.

Rotary switches may be tested by jumpering the contacts with a clip lead. Loose contacts may sometimes be repaired, either by cleaning, carefully rebending the switch contacts or gluing loose switch parts to the switch deck. Operate variable components through their range while observing the noise level at the circuit output.

Oscillations

Oscillations occur whenever there is sufficient positive feedback in a circuit that has gain. (This can even include digital devices.) Oscillation may occur at any frequency from a low-frequency audio buzz (often called “motorboating”) well up into the RF region.

Unwanted oscillations are usually the result of changes in the active device (increased junction or interelectrode capacitance), failure of an oscillation suppressing component (open decoupling or bypass capacitors or neutralizing components) or new feedback paths (improper lead dress or dirt on the chassis or components). It can also be caused by improper design, especially in home-brew circuits. A shift in bias or drive levels may aggravate oscillation problems.

Oscillations that occur in audio stages do not change as the radio is tuned because the operating frequency, and therefore the component impedances, do not change. However, RF and IF oscillations usually vary in amplitude as operating frequency is changed.

Oscillation stops when the positive

feedback is removed. Locating and replacing the defective (or missing) bypass capacitor may effect an improvement. The defective oscillating stage can be found more reliably with a signal tracer or oscilloscope.

Amplitude Distortion

Amplitude distortion is the product of nonlinear operation. The resultant waveform contains not only the input signal, but new signals at other frequencies as well. All of the frequencies combine to produce the distorted waveform. Distortion in a transmitter gives rise to splatter, harmonics and interference.

Fig 26.11 shows some typical cases of distortion. Clipping (also called flat-topping) is the consequence of excessive drive. The corners on the waveform show that harmonics are present. (A square wave contains the fundamental and all odd harmonics.) These odd harmonics would be heard well away from the operating fre-

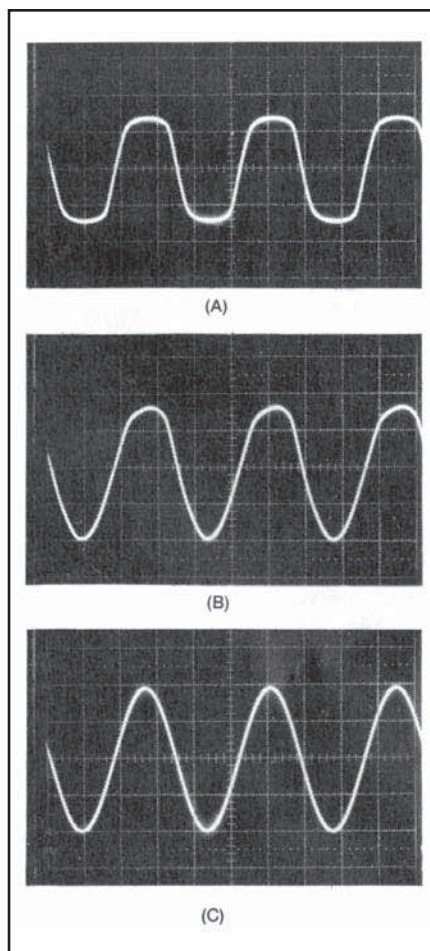

Fig 26.11 — Examples of distorted waveforms. The result of clipping is shown in A. Nonlinear amplification is shown in B. A pure sine wave is shown in C for comparison.

quency, possibly outside of amateur bands. Key clicks are similar to clipping.

Harmonic distortion produces radiation at frequencies far removed from the fundamental; it is a major cause of electromagnetic interference (EMI). Harmonics are generated in nearly every amplifier. When they occur in a transmitter, they are usually caused by insufficient transmitter filtering (either by design, or because of filter component failure).

Incorrect bias brings about unequal amplification of the positive and negative wave sections. The resultant waveform is rich in harmonics.

Frequency Distortion

If a “broadband” amplifier, such as an audio amplifier, doesn’t amplify all frequencies equally, there is frequency distortion. In many cases, this “frequency distortion” is deliberate, as in a transmitter microphone amplifier that has been designed to pass only frequencies from 200 to 2000 Hz. In most cases, the amateur’s ability to detect and measure distortion is limited by available test equipment.

Distortion Measurement

A distortion meter is used to measure distortion of AF signals. A spectrum analyzer is the best piece of test gear to measure distortion of RF signals. If a distortion meter is not available, an estimation of AF distortion can sometimes be made with a function generator (sine and square waves) and an oscilloscope.

To estimate the amount of frequency distortion in an audio amplifier, set the generator for a square wave and look at it on the ‘scope. (Use a low-capacitance probe.) The wave should show square corners and a flat top. Next, inject a square wave at the amplifier input and again look at the input wave on the ‘scope. Any new distortion is a result of the test circuit loading the generator output. (If the wave shape is severely distorted, the test is not valid.) Now, move the test probe to the test circuit output and look at the waveform. Refer to Fig 26.12 to evaluate square-wave distortion and its cause.

The above applies only to audio amplifiers without frequency tailoring. In RF gear, the transmitter may have a very narrow audio passband, so inserting a square wave into the microphone input may result in an output that is difficult to interpret. The frequency of the square wave will have a significant effect.

Anything that changes the proper bias of an amplifier can cause distortion. This includes failures in the bias components, leaky transistors or vacuum tubes with interelectrode shorts. These conditions

Look for the Obvious

The best example of how looking for the obvious can save a lot of repair time comes from my days as the manager of an electronics service shop. We had hired a young engineering graduate to work for us part time. He was the proud holder of a First-Class FCC Radiotelephone license (the predecessor to today's General Radiotelephone license). He was a likable sort, but, well . . . the chip on his young shoulder was a bit hard to take sometimes.

One day, I had asked him to repair a "tube-type" FM tuner. He had been poking around without success: hooking up a voltmeter, oscilloscope and signal generator, pretty much in that order. Finally, in total exasperation, he pronounced that the unit was beyond economical repair and suggested that I return it to the customer unfixed. The particular customer was a "regular," so I wanted to be sure of the diagnosis before I sent the tuner back. I told the tech I wanted to take a look at it before we wrote it off.

He started to expound loudly that there was no way that I, a lowly technician (even though I was also his boss) could find a problem that he, an engineering graduate and holder of a First Class . . . you get the idea. I did remind him gently that I was the boss, and he, realizing that I had him there, stepped aside, mumbling something about my suiting myself. He stepped back to gloat when I couldn't find it either.

I began by giving the tuner a thorough visual inspection. I looked it over carefully from stem to stern, while listening to our young apprentice proclaiming with certainty that one cannot fix electronic equipment by merely looking at it. I didn't see anything obviously wrong, so I decided to move wires and components around, looking for a bad solder joint or broken component. Of course, I had to listen to him telling me that one cannot possibly find bad components by touch. Unfortunately for our loud friend, he couldn't have been more wrong.

I grabbed hold of a ceramic bypass capacitor to give it a little wiggle, and much to my surprise it was hot enough to cause some real pain. I kept my composure; it was an opportunity for a good learning experience. Ceramic capacitors don't get very hot unless they are either shorted or very leaky. I kept silent and never let on that my finger "probe" had indeed located the bad part. I set the tuner down, sighed a bit, and then looked him right in the eye when I pointed to the capacitor and said "Change that part!"

They probably heard his bellowing in the next county! He went on and on about how there was just no way in the world that I could tell a good part from a bad part by just looking and touching things. He alternated between accusing me of pulling his leg and guessing, then back to just plain bellowing again. After letting this "source of great noise" run his course, I offered the ultimate shop challenge — I bet him a can of soda pop.

The traditional shop challenge did the trick. He smugly grabbed a replacement part from the bin and got out his soldering iron. In a matter of seconds (a new shop record, I believe) the capacitor was installed. He hooked the tuner up to a test amplifier and turned them on. After a couple of seconds, he smugly turned to me and started an "I told ya' so!" Just then, the last tube warmed up and the sounds of our local rock station blasted out of the speaker. He stopped in mid "told-ya" and stared at the tuner in disbelief. The tempo and pitch of his voice jumped by an order of magnitude as he asked me how I managed to fix the tuner without using even an ohmmeter to test a fuse. It was weeks before I told him — the soda pop tasted especially good.

The moral of the story is clear; sophisticated test equipment and procedures are useful in troubleshooting, but they are no substitute for the experience of a veteran troubleshooter. — *Ed Hare, W1RFI, ARRL Laboratory Supervisor*

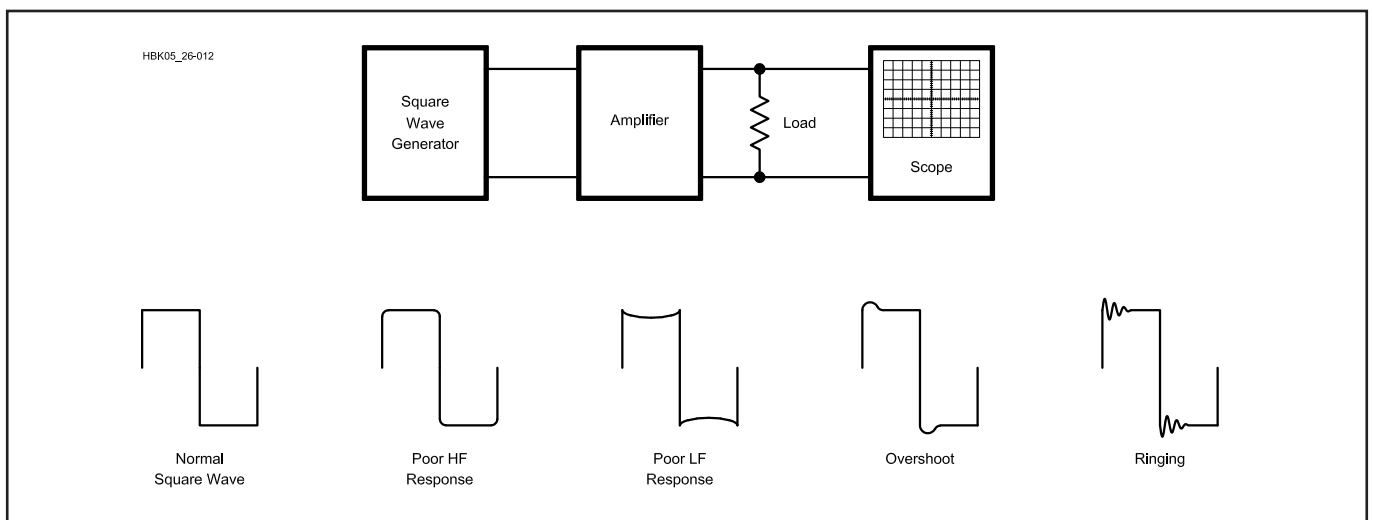

Fig 26.12 — Square-wave distortion and probable causes.

may mimic AGC trouble. Improper bias often results from an overheated or open resistor. Heat can cause resistor values to permanently increase. Leaky, or shorted capacitors and RF feedback can also produce distortion by disturbing bias levels. Distortion is also caused by circuit imbalance in Class AB or B amplifiers.

Oscillations in an IF amplifier may produce distortion. They cause constant, full AGC action, or generate spurious signals that mix with the desired signal. IF oscillations are usually evident on the S meter, which will show a strong signal even with the antenna disconnected.

Alignment

Alignment is rarely the cause of an electronics problem. As an example, suppose an AM receiver suddenly begins producing weak and distorted audio. An inexperienced person frequently suspects poor alignment as a common problem. Even though the manufacturer's instructions and the proper equipment are not available, our "friend" (this would never be one of US!) begins "adjusting" the transformer cores. Before long, the set is hopelessly misaligned. Now our misguided ham must send the radio to a shop for an alignment that was not needed before repairs were attempted.

Alignment does not shift suddenly. A normal signal tracing procedure would have shown that the signal was good up to the audio-output IC, but badly distorted after that. The defective IC that caused the problem would have been easily found and quickly replaced.

Contamination

Contamination is another common service problem. Cold soda pop spilled into a hot piece of electronics is an extreme example (but one that does actually happen).

Conductive contaminants range from water to metal filings. Most can be removed by a thorough cleaning. Any of the residue-free cleaners can be used, but remember that the cleaner may also be conductive. Do not apply power to the circuit until the area is completely dry.

Keep cleaners away from variable-capacitor plates, transformers and parts that may be harmed by the chemical. The most common conductive contaminant is solder, either from a printed-circuit board "solder bridge" or a loose piece of solder deciding to surface at the most inconvenient time.

Solder "Bridges"

In a typical PC-board solder bridge, the solder that is used to solder one component has formed a short circuit to another

PC-board trace or component. Unfortunately, they are common in both new construction and repair work. Look carefully for them after you have completed any soldering, especially on a PC-board. It is even possible that a solder bridge may exist in equipment you have owned for a long time, unnoticed until it suddenly decided to become a short circuit.

Related items are loose solder blobs, loose hardware or small pieces of component leads that can show up in the most awkward and troublesome places.

Arcing

Arcing is a serious sign of trouble. It may also be a real fire hazard. Arc sites are usually easy to find because an arc that generates visible light or noticeable sound also pits and discolors conductors.

Arcing is caused by component failure, dampness, dirt or lead dress. If the dampness is temporary, dry the area thoroughly and resume operation. Dirt may be cleaned from the chassis with a residue-free cleaner. Arrange leads so high-voltage conductors are isolated. Keep them away from sharp corners and screw points.

Arcing occurs in capacitors when the working voltage is exceeded. Air-dielectric variable capacitors can sustain occasional arcs without damage, but arcing indicates operation beyond circuit limits. Transmatches working beyond their ability may suffer from arcing. A failure or high SWR in an antenna circuit may also cause transmitter arcing.

Replacing Parts

If you have located a defective component within a stage, you need to replace it. When replacing socket mounted components, be sure to align the replacement part correctly. Make sure that the pins of the device are properly inserted into the socket.

Some special tools can make it easier to remove soldered parts. A chisel-shaped soldering tip helps pry leads from printed-circuit boards or terminals. A desoldering iron or bulb forms a suction to remove excess solder, making it easier to remove the component. Spring-loaded desoldering pumps are more convenient than bulbs. Desoldering wick draws solder away from a joint when pressed against the joint with a hot soldering iron.

In all cases, remember that soldering tools and melted solder can be hot and dangerous! Wear protective goggles and clothing when soldering. A full course in first aid is beyond the scope of this chapter, but if you burn your fingers, run the burn immediately under cold water and seek first aid or medical attention. Always

seek medical attention if you burn your eyes; even a small burn can develop into serious trouble.

TYPICAL SYMPTOMS AND FAULTS

Power Supplies

Many equipment failures are caused by power-supply trouble. Fortunately, most power-supply problems are easy to find and repair (see **Fig 26.13**). First, use a voltmeter to measure output. Loss of output voltage is usually caused by an open circuit. (A short circuit draws excessive current that opens the fuse, thus becoming an open circuit.)

Most fuse failures are caused by a shorted diode in the power supply or a shorted power device (RF or AF) in the failed equipment. More rarely, one of the filter capacitors can short. If the fuse has opened, turn off the power, replace the fuse and measure the load-circuit dc resistance. The measured resistance should be consistent with the power-supply ratings. A short or open load circuit indicates a problem.

If the measured resistance is too low, check the load circuit with an ohmmeter to locate the trouble. (Nominal circuit resistances are included in some equipment manuals.) If the load circuit resistance is normal, suspect a defective regulator IC or problem in the rest of the unit. Electrolytic capacitors fail with long (two years) disuse; the electrolytic layer may be reformed as explained later in this chapter.

IC regulators can oscillate, sometimes causing failure. The small-value capacitors on the input, output or adjustment pins of the regulator prevent oscillations. Check or replace these capacitors whenever a regulator has failed.

AC ripple (hum) is usually caused by low-value filter capacitors in the power supply. Less likely, hum can also be caused by excessive load, a regulation problem or RF feedback in the power supply. Look for a defective filter capacitor (usually open or low-value), defective regulator or shorted filter choke. In older equipment, the defective filter capacitor will often have visible leaking electrolyte: Look for corrosion residue at the capacitor leads. In new construction projects make sure RF energy is not getting into the power supply.

Here's an easy filter-capacitor test: Temporarily connect a replacement capacitor (about the same value and working voltage) across the suspect capacitor. If the hum goes away, replace the bad component permanently.

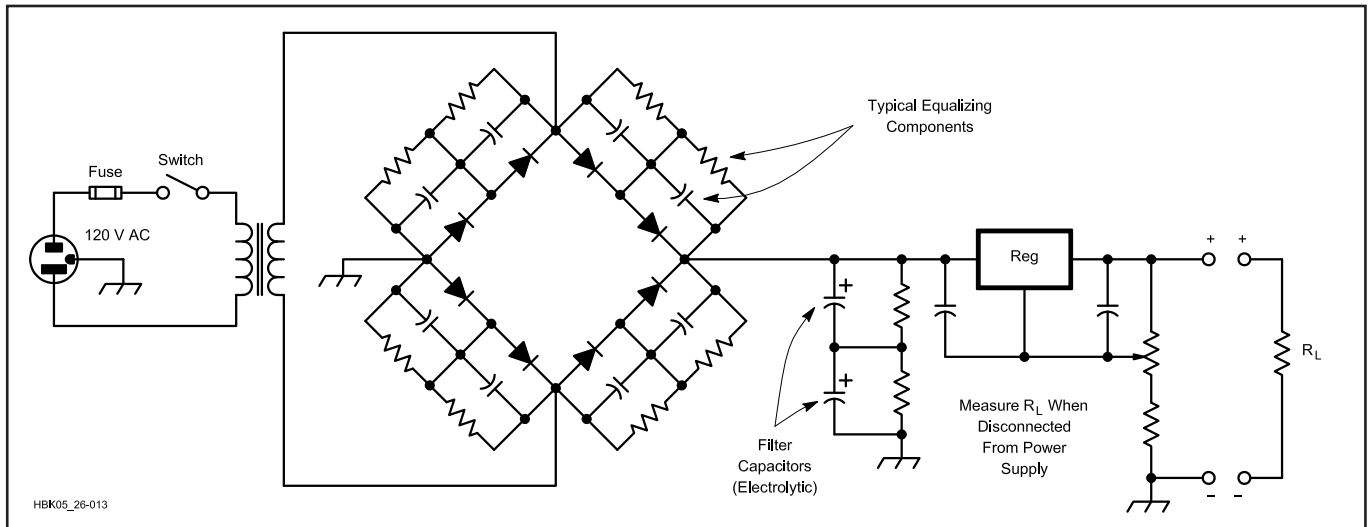

Fig 26.13 — Schematic of a typical power supply showing the components mentioned in the text.

Once the faulty component is found, inspect the surrounding circuit and consider what may have caused the problem. Sometimes one bad component can cause another to fail. For example, a shorted filter capacitor increases current flow and burns out a rectifier diode. While the defective diode is easy to find, the capacitor may show no visible damage.

Switching Power Supplies

Switching power supplies are quite different than conventional supplies. In a “switcher,” a switching transistor is used to change dc voltage levels. They usually have AF oscillators and complex feedback paths. Any component failure in the rectifiers, switch, feedback path or load usually results in a completely dead supply. Every part is suspect. While active device failure is still the number one suspect, it pays to carefully test all components if a diagnosis cannot be made with traditional techniques.

Some equipment, notably TVs and monitors, derive some of the power-supply voltages from the proper operation of other parts of the circuit. In the case of a TV or monitor, voltages are often derived by adding secondary low-voltage windings to the flyback transformer and rectifying the resultant ac voltage (usually about 15 kHz). These voltages will be missing if there is any problem with the circuit from which they are derived.

Amplifiers

Amplifiers are the most common circuits in electronics. The output of an ideal amplifier would match the input signal in every respect except magnitude: No distortion or noise would be added. Real amplifiers always add noise and distortion.

Gain

Gain is the measure of amplification. Gain is usually expressed in decibels (dB) over a specified frequency range, known as the bandwidth or passband of the amplifier. When an amplifier is used to provide a stable load for the preceding stage, or as an impedance transformer, there may be little or no voltage gain.

Amplifier failure usually results in a loss of gain or excessive distortion at the amplifier output. In either case, check external connections first. Is there power to the stage? Has the fuse opened? Check the speaker and leads in audio output stages, the microphone and push-to-talk (PTT) line in transmitter audio sections. Excess voltage, excess current or thermal runaway can cause sudden failure of semiconductors. The failure may appear as either a short, or open, circuit of one or more PN junctions.

Thermal runaway occurs most often in bipolar transistor circuits. If degenerative feedback (the emitter resistor reduces base-emitter voltage as conduction increases) is insufficient, thermal runaway will allow excessive current flow and device failure. Check transistors by substitution, if possible.

Faulty coupling components can reduce amplifier output. Look for component failures that would increase series, or decrease shunt, impedance in the coupling network. Coupling faults can be located by signal tracing or parts substitution. Other passive component defects reduce amplifier output by shifting bias or causing active-device failure. These failures are evident when the dc operating voltages are measured.

In a receiver, a fault in the AGC loop

may force a transistor into cutoff or saturation. Open the AGC line to the device and substitute a variable voltage for the AGC signal. If amplifier action varies with voltage, suspect the AGC-circuit components; otherwise, suspect the amplifier.

In an operating amplifier, check carefully for oscillations or noise. Oscillations are most likely to start with maximum gain and the amplifier input shorted. Any noise that is induced by 60-Hz sources can be heard, or seen with a 'scope synchronized to the ac line.

Unwanted amplifier RF oscillations should be cured with changes of lead dress or circuit components. Separate input leads from output leads; use coaxial cable to carry RF between stages; neutralize interelement or junction capacitance. Ferrite beads on the control element of the active device often stop unwanted oscillations.

Low-frequency oscillations (“motor-boating”) indicate poor stage isolation or inadequate power-supply filtering. Try a better lead-dress arrangement and/or check the capacitance of the decoupling network (see Fig 26.14). Use larger capacitors at the power-supply leads; increase the number of capacitors or use separate decoupling capacitors at each stage. Coupling capacitors that are too low in value can also cause poor low-frequency response. Poor response to high frequencies is usually caused by circuit design.

Amplifiers vs Switches

To help you hone your skills, let’s analyze a few simple circuits. There is often a big difference in the performance of similar-looking circuits. Consider the differences between a common-emitter amplifier and a common-emitter switch circuit.

Common-Emitter Amplifier

Fig 26.15 is a schematic of a common-emitter transistor amplifier. The emitter, base and collector leads are labeled e, b and c, respectively. Important dc voltages are measured at these points and designated V_e , V_b and V_c . Similarly, the important currents are I_e , I_b and I_c . $V+$ indicates the supply voltage.

First, analyze the voltages and signal levels in this circuit. The “junction drop,” is the potential measured across a semiconductor junction that is conducting. It is typically 0.6 V for silicon and 0.2 V for germanium transistors.

This is a Class-A linear circuit. In Class-A circuits, the transistor is always conducting some current. $R1$ and $R2$ form a voltage divider that supplies dc bias (V_b) for the transistor. Normally, V_c is equal to V_b less the emitter-base junction drop. $R4$ provides degenerative dc bias, while $C3$ provides a low-impedance path for the signal. From this information, normal operating voltages can be estimated.

The bias and voltages will be set up so that the transistor collector voltage, V_c , is somewhere between $V+$ and ground potential. A good rule of thumb is that V_c should be about one-half of $V+$, although this can vary quite a bit, depending on component tolerances. The emitter voltage is usually a small percentage of V_c , say about 10%.

Any circuit failure that changes I_c (ranging from a shorted transistor or a failure in the bias circuit) changes V_c and V_e as well. An increase of I_c lowers V_c and raises V_e . If the transistor shorts from collector to emitter, V_c drops to about 1.2 V, as determined by the voltage divider formed by $R3$ and $R4$.

You would see nearly the same effect if the transistor were biased into saturation by collector-to-base leakage, a reduction in $R1$'s value or an increase in $R2$'s value. All of these circuit failures have the same effect. In some cases, a short in $C1$ or $C2$ could cause the same symptoms.

To properly diagnose the specific cause of low V_c , consider and test all of these parts. It is even more complex; an increase in $R3$'s value would also decrease V_c . There would be one valuable clue, however; if $R3$ increased in value, I_c would not increase; V_e would also be low.

Anything that decreases I_c increases V_c . If the transistor failed “open,” $R1$ increased in value, $R2$ were shorted to ground or $R4$ opened, then V_c would be high.

Common-Emitter Switch

A common-emitter transistor switching

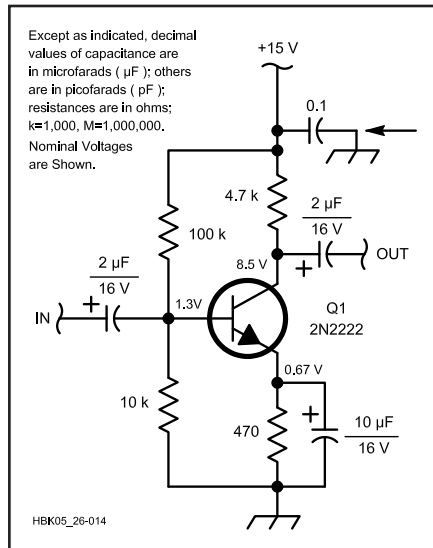

Fig 26.14 — The decoupling capacitor in this circuit is designated with an arrow.

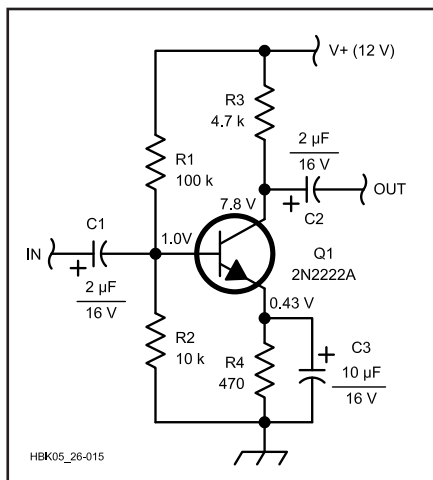

Fig 26.15 — A typical common-emitter audio amplifier.

Fig 26.16 — A typical common-emitter switching amplifier.

circuit is shown in **Fig 26.16**. This circuit functions differently than the circuit shown in **Fig 26.15**. A linear amplifier is designed so that the output signal is a faithful reproduction of the input signal. Its input and output may have any value from $V+$ to ground.

The switching circuit of **Fig 26.16**, however, is similar to a “digital” circuit. The active device is either on or off, 1 or 0, just like digital logic. Its input signal level should either be 0 V or positive enough to switch the transistor on fully (saturate). Its output state should be either full off (with no current flowing through the relay), or full on (with the relay energized). A voltmeter placed on the collector will show either approximately +12 V or 0 V, depending on the input.

Understanding this difference in operation is crucial to troubleshooting the two circuits. If V_c were +12 V in the circuit in **Fig 26.15**, it would indicate a circuit failure. A V_c of +12 V in the switching circuit, is normal when V_b is 0 V. (If V_b measured 0.8 V or higher, V_c should be low and the relay energized.)

DC Coupled Amplifiers

In dc coupled amplifiers, the transistors are directly connected together without coupling capacitors. They comprise a unique troubleshooting case. Most often, when one device fails, it destroys one or more other semiconductors in the circuit. If you don't find all of the bad parts, the remaining defective parts can cause the installed replacements to fail immediately. To reliably troubleshoot a dc coupled circuit, you must test every semiconductor in the circuit and replace them all at once.

Oscillators

In many circuits, a failure of the oscillator will result in complete circuit failure. A transmitter will not transmit, and a superheterodyne receiver will not receive if you have an internal oscillator failure. (These symptoms do not always mean oscillator failure, however.)

Whenever there is weakening or complete loss of signal from a radio, check oscillator operation and frequency. There are several methods:

- Use a receiver with a coaxial probe to listen for the oscillator signal.
- A dip meter can be used to check oscillators. In the absorptive mode, tune the dip meter to within ± 15 kHz of the oscillator, couple it to the circuit, and listen for a beat note in the dip-meter headphones.
- Look at the oscillator waveform on a 'scope. The operating frequency can't

be determined with great accuracy, but you can see if the oscillator is working at all. Use a low capacitance (10×) probe for oscillator observations.

- Tube oscillators usually have negative grid bias when oscillating. Use a high-impedance voltmeter to measure grid bias. The bias also changes slightly with frequency.
- Emitter current varies slightly with frequency in transistor oscillators. Use a sensitive, high-impedance voltmeter across the emitter resistor to observe the current level. (You can use Ohm's Law to calculate the current value.)

Many modern oscillators are phase-locked loops (PLLs). A PLL is a marriage of an analog oscillator and digital control circuitry. Read the Digital Circuitry section in this chapter and the **Oscillators and Synthesizers** chapter of this book in order to learn PLL repair techniques.

To test for a failed oscillator tuned with inductors and capacitors, use a dip meter in the active mode. Set the dip meter to the oscillator frequency and couple it to the oscillator output circuit. If the oscillator is dead, the dip-meter signal will take its place and temporarily restore some semblance of normal operation. Tune the dip meter very slowly, or you may pass stations so quickly that they sound like "birdies."

Stability

We are spoiled; modern amateur equipment is very stable. Drift of several kilohertz per hour was once normal. You may want to modify old equipment for more stability, but drift that is consistent with the equipment design is not a defect. (This applies to new equipment as well as old.) It is normal for some digital displays to flash back and forth between two values for the least-significant digit.

Drift is caused by variations in the oscillator. Poor voltage regulation and heat are the most common culprits. Check regulation with a voltmeter (use one that is not affected by RF). Voltage regulators are usually part of the oscillator circuit. Check them by substitution.

Chirp is a form of rapid drift that is usually caused by excessive oscillator loading or poor power-supply regulation. The most common cause of chirp is poor design. If chirp appears suddenly in a working circuit, look for component or design defects in the oscillator or its buffer amplifiers. (For example, a shorted coupling capacitor increases loading drastically.) Also check lead dress, tubes and switches for new feedback paths (feedback defeats buffer action).

Frequency instability may also result

from defects in feedback components. Too much feedback may produce spurious signals, while too little makes oscillator start-up unreliable.

Sudden frequency changes are frequently the result of physical variations. Loose components or connections are probable causes. Check for arcing or dirt on printed-circuit boards, trimmers and variable capacitors, loose switch contacts, bad solder joints or loose connectors.

Frequency Accuracy

Dial tracking errors may be associated with oscillator operation. Misadjustments in the frequency-determining components make dial accuracy worse at the ends of the dial. Tracking errors that are constant everywhere in the passband can be caused by misalignment or by slippage in the dial drive mechanism or indicator. This is usually cured by calibration of a simple mechanical adjustment.

In LC oscillators, tracking at the high-frequency end of the dial is controlled by trimmer capacitors. A trimmer is a variable capacitor connected in parallel with the main tuning capacitor (see Fig 26.17). The trimmer represents a higher percentage of the total capacitance at the high end of the tuning range. It has relatively little effect on tuning characteristics at the low-frequency end of the dial.

Low-end tracking is adjusted by a padder capacitor. A padder is a variable capacitor that is connected in series with the main tuning capacitor. Padder capacitance has a greater effect at the low-frequency end of the dial. The padder capacitor is often eliminated to save money. In that case, the low-frequency tracking is adjusted by the main tuning coil.

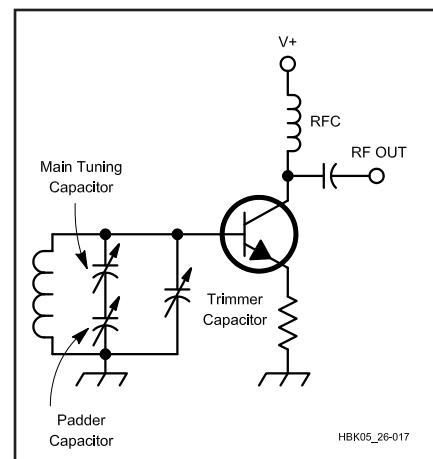

Fig 26.17 — A partial schematic of a simple oscillator showing the locations of the trimmer and padder capacitors.

Control Circuitry

Semiconductors have made it practical to use diodes for switching, running only a dc lead to the switching point. This eliminates problems caused by long analog leads in the circuit. Semiconductor switching usually reduces the cost and complexity of switching components. Switching speed is increased; contact corrosion and breakage are eliminated. In exchange, troubleshooting is complicated by additional components such as voltage regulators and decoupling capacitors (see Fig 26.18). The technician must consider many more components and symptoms when working with diode and transistor switched circuits.

Mechanical switches are relatively rugged. They can withstand substantial voltage and current surges. The environment does not drastically affect them, and there is usually visible damage when they fail. Semiconductor switching offers inexpensive, high-speed operation. When subjected to excess voltage or current, however, most transistors and diodes silently expire. Occasionally, if the troubleshooter is lucky, one sends up a smoke signal to mark its passing.

Temperature changes semiconductor characteristics. A normally adequate control signal may not be effective when transistor beta is lowered by a cold environment. Heat may cause a control voltage regulator to produce an improper control signal.

A control signal is actually a bias for the semiconductor switch. Forward biased diodes and transistors act as closed switches; reverse biased components simulate open switches. If the control (bias) signal is not strong enough to completely saturate the semiconductor, conduction may not continue through a full ac cycle. Severe distortion can be the result.

When dc control leads provide unwanted feedback paths, switching transistors may become modulators or mixers. Additionally, any reverse biased semiconductor junction is a potential source of white noise.

Microprocessor Control

Nearly every new transceiver is controlled by a miniature computer. Entire books have been written about microprocessor (μP) control. Many of the techniques are discussed in the Digital Circuitry section. Many microprocessor related problems end up back at the factory for service; however, the surface mounted components are just too difficult for most hams to replace. For successful repair of microprocessor controlled circuits, you should have the knowledge and

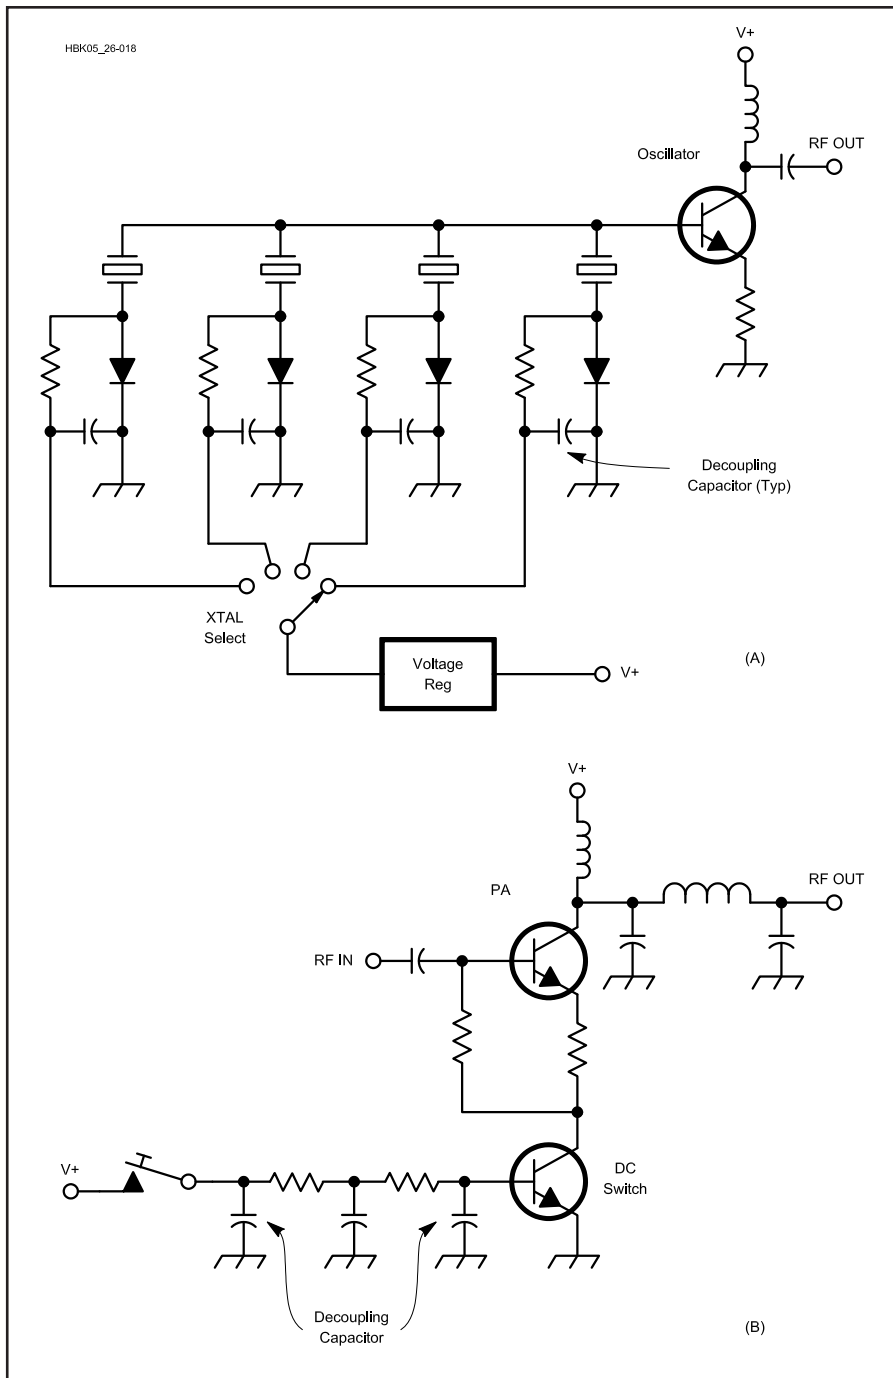

Fig 26.18 — Diode switching selects oscillator crystals at A. A transistor switch is used to key a power amplifier at B.

test equipment necessary for computer repair. Familiarity with machine-language programming may also be desirable.

Digital Circuitry

The digital revolution has hit most ham shacks and amateur equipment. Microprocessors have brought automation to everything from desk clocks to ham transceivers and computer controlled EME antenna arrays. Although every aspect of their operation may be resolved to a simple 1 or

0, or tristate (an infinite impedance or open circuit), the symptoms of their failure are far more complicated. As with other equipment:

- Observe the operating characteristics.
- Study the block diagram and the schematic.
- Test.
- Replace defective parts.

Problems in digital circuits have two elementary causes. First, the circuit may

give false counts because of electrical noise at the input. Second, the gates may lock in one state.

False counts from noise are especially likely in a ham shack. (A 15- to 20- μ s voltage spike can trigger a TTL flip-flop.) Amateur Radio equipment often switches heavy loads; the attendant transients can follow the ac line or radiate directly to nearby digital equipment. Oscillation in the digital circuit can also produce false counts.

How these false counts affect a circuit is dependent on the design. A station clock may run fast, but a microprocessor controlled transceiver may “decide” that it is only a receiver. It might even be difficult to determine that there is a problem without a logic analyzer or a multitrace oscilloscope and a thorough understanding of circuit operation.

Begin by removing the suspect equipment from RF fields. If the symptoms stop when there is no RF energy around, you need to shield the equipment from RF.

In the mid '90s, microprocessors in general use ran clock speeds up to a few hundred megahertz. (They are increasing all the time.) It may be impossible to filter RF signals from the lines when the RF is near the clock frequency. In these cases, the best approach is to shield the digital circuit and all lines running to it.

If digital circuitry interferes with other nearby equipment, it may be radiating spurious signals. These signals can interfere with your Amateur Radio operation or other services. Digital circuitry can also be subject to interference from strong RF fields. Erratic operation or a complete “lock up” is often the result. *The ARRL RFI Book* has a chapter on computer and digital interference. That chapter discusses interference to and from digital devices and circuits.

Logic Levels

To troubleshoot a digital circuit, check for the correct voltages at the pins of each chip. The correct voltages may not always be known, but you should be able to identify the power pins (V_{cc} and ground).

The voltages on the other pins should be either a logic high, a logic low, or tristate (more on this later). In most working digital circuitry the logic levels are constantly changing, often at RF rates. A dc voltmeter may not give reliable readings. An oscilloscope or logic analyzer is usually needed to troubleshoot digital circuitry.

Most digital circuit failures are caused by a failed logic IC. In clocked circuits, listen for the clock signal with a coax probe and a suitable receiver. If the signal is found at the clock chip, trace it to each of the other ICs to be sure that the clock

system is intact. Some digital circuits use VHF clock speeds; an oscilloscope must have a bandwidth of at least twice the clock speed to be useful. If you have a suitable scope, check the pulse timing and duration against circuit specifications.

As in most circuits, failures are catastrophic. It is unlikely that an AND gate will suddenly start functioning like an OR gate. It is more likely that the gate will have a signal at its input, and no signal at the output. In a failed device, the output pin will have a steady voltage. In some cases, the voltage is steady because one of the input signals is missing. Look carefully at what is going into a digital IC to determine what should be coming out. Keep manufacturers' data books handy. These data books describe the proper functioning of most digital devices.

Tristate Devices

Many digital devices are designed with a third logic state, commonly called tristate. In this state, the output of the device acts as if it weren't there at all. Many such devices can be connected to a common "bus," with the devices that are active at any given time selected by software or hardware control signals. A computer's data and address busses are good examples of this. If any one device on the bus fails by locking itself on in a 0 or 1 logic state, the entire bus becomes nonfunctional. These tristate devices can be locked "on" by inherent failure or a failure of the signal that controls them.

Simple Gate Tests

Logic gates, flip-flops and counters can be tested (see Fig 26.19) by triggering them manually, with a power supply (4 to 5 V is a safe level). Diodes may be checked with an ohmmeter. Testing of more complicated ICs requires the use of a logic analyzer, multitrace scope or a dedicated IC tester.

Fig 26.19 — This simple digital circuit can be tested with a few components. In this case, an AND gate is tested. Open and close S1 and S2 while comparing the voltmeter reading with a truth table for the device.

TROUBLESHOOTING HINTS

Receivers

A receiver can be diagnosed using any of the methods described earlier, but if there is not even a faint sound from the speaker, signal injection is not a good technique. If you lack troubleshooting experience, avoid following instinctive hunches. That leaves signal tracing as the best method.

The important characteristics of a receiver are selectivity, sensitivity, stability and fidelity. Receiver malfunctions ordinarily affect one or more of these areas.

Selectivity

Tuned transformers or the components used in filter circuits may develop a shorted turn, capacitors can fail and alignment is required occasionally. Such defects are accompanied by a loss of sensitivity. Except in cases of catastrophic failure (where either the filter passes all signals, or none), it is difficult to spot a loss of selectivity. Bandwidth and insertion-loss measurements are necessary to judge filter performance.

Sensitivity

A gradual loss of sensitivity results from gradual degradation of an active device or long-term changes in component values. Sudden partial sensitivity changes are usually the result of a component failure, usually in the RF or IF stages. Complete and sudden loss of sensitivity is caused by an open circuit anywhere in the signal path or by a "dead" oscillator.

Receiver Stability

The stability of a receiver depends on its oscillators. See the Oscillators section elsewhere in this chapter.

Distortion

Receiver distortion may be the effect of poor connections or faulty components in the signal path. AGC circuits produce many receiver defects that appear as distortion or insensitivity.

AGC

AGC failure usually causes distortion that affects only strong signals. All stages operate at maximum gain when the AGC influence is removed. An S meter can help diagnose AGC failure because it is operated by the AGC loop.

An open AGC bypass capacitor causes feedback through the loop. This often results in a receiver "squeal" (oscillation). Changes in the loop time constant affect tuning. If stations consistently blast, or are too weak for a brief time when first tuned

in, the time constant is too fast. An excessively slow time constant makes tuning difficult, and stations fade after tuning. If the AGC is functioning, but the "timing" seems wrong, check the large-value capacitors found in the AGC circuit — they usually set the AGC time constants. If the AGC is not functioning, check the AGC-detector circuit. There is often an AGC voltage that is used to control several stages. A failure in any one stage could affect the entire loop.

Detector Problems

Detector trouble usually appears as complete loss or distortion of the received signal. AM, SSB and CW signals may be weak and unintelligible. FM signals will sound distorted. Look for an open circuit in the detector near the detector diodes. If tests of the detector parts indicate no trouble, look for a poor connection in the power-supply or ground lead. A BFO that is "dead" or off frequency prevents SSB and CW reception. In modern rigs, the BFO frequency is either crystal controlled, or derived from the PLL.

Receiver Alignment

Unfortunately, IF transformers are as enticing to the neophyte technician as a carburetor is to a shade-tree mechanic. In truth, radio alignment (and for that matter, carburetor repair) is seldom required. Circuit alignment may be justified under the following conditions:

- The set is very old and has not been adjusted in many years.
- The circuit has been subject to abusive treatment or environment.
- There is obvious misalignment from a previous repair.
- Tuned-circuit components or crystals have been replaced.
- An inexperienced technician attempted alignment without proper equipment. ("But all the screws in those little metal cans were loose!")
- There is a malfunction, but all other circuit conditions are normal. (Faulty transformers can be located because they will not tune.)

Even if one of the above conditions is met, do not attempt alignment unless you have the proper equipment. Receiver alignment should progress from the detector to the antenna terminals. When working on an FM receiver, align the detector first, then the IF and limiter stages and finally the RF amplifier and local oscillator stages. For an AM receiver, align the IF stages first, then the RF amplifier and oscillator stages.

Both AM and FM receivers can be aligned in much the same manner. Always

follow the manufacturer's recommended alignment procedure. If one is not available, follow these guidelines:

1. Set the receiver RF gain to maximum, BFO control to zero or center (if applicable to your receiver) and tune to the high end of the receiver passband.
2. Disable the AGC.
3. Set the signal source to the center of the IF passband, with no modulation and minimum signal level.
4. Connect the signal source to the input of the IF section.
5. Connect a voltmeter to the IF output as shown in **Fig 26.20**.
6. Adjust the signal-source level for a slight indication on the voltmeter.
7. Peak each IF transformer in order, from the meter to the signal source. The adjustments interact; repeat steps 6 and 7 until adjustment brings no noticeable improvement.
8. Remove the signal source from the IF-section input, reduce the level to minimum, set the frequency to that shown on the receiver dial and connect the source to the antenna terminals. If necessary, tune around for the signal — if the local oscillator is not tracking, it may be off.
9. Adjust the signal level to give a slight reading on the voltmeter.
10. Adjust the trimmer capacitor of the RF amplifier for a peak reading of the test signal. (Verify that you are reading the correct signal by switching the source on and off.)

11. Reset the signal source and the receiver tuning for the low end of the passband.

12. Adjust the local-oscillator padder for peak reading.

13. Steps 8 through 11 interact, so repeat them until the results are as good as you can get them.

Transmitters

Many potential transmitter faults are discussed in several different places in this chapter. There are, however, a few techniques used to ensure stable operation of RF amplifiers in transmitters that are not covered elsewhere.

High-power RF amplifiers often use parasitic chokes to prevent instability. Older parasitic chokes usually consist of a 51- to 100- Ω noninductive resistor with a coil wound around the body and connected to the leads. It is used to prevent VHF and UHF oscillations in a vacuum-tube amplifier. The suppressor is placed in the plate lead, close to the plate connection.

In recent years, problems with this style of suppressor have been discovered. Look at the **RF Power Amplifiers** chapter for information about suppressing parasitics.

Parasitic chokes often fail from excessive current flow. In these cases, the resistor is charred. Occasionally, physical shock or corrosion produces an open circuit in the coil. Test for continuity with an ohmmeter.

Transistor amplifiers are protected

against parasitic oscillations by low-value resistors or ferrite beads in the base or collector leads. Resistors are used only at low power levels (about 0.5 W), and both methods work best when applied to the base lead. Negative feedback is used to prevent oscillations at lower frequencies. An open component in the feedback loop may cause low-frequency oscillation, especially in broadband amplifiers.

Keying

The simplest form of modulation is on/off keying. Although it may seem that there cannot be much trouble with such an elementary form of modulation, two very important transmitter faults are the result of keying problems.

Key clicks are produced by fast rise and decay times of the keying waveform. Most transmitters include components in the keying circuitry to prevent clicks. When clicks are experienced, check the keying filter components first, then the succeeding stages. An improperly biased power amplifier, or a Class C amplifier that is not keyed, may produce key clicks even though the keying waveform earlier in the circuit is correct. Clicks caused by a linear amplifier may be a sign of low-frequency parasitic oscillations. If they occur in an amplifier, suspect insufficient power-supply decoupling. Check the power-supply filter capacitors and all bypass capacitors.

The other modulation problem associated with on/off keying is called back-

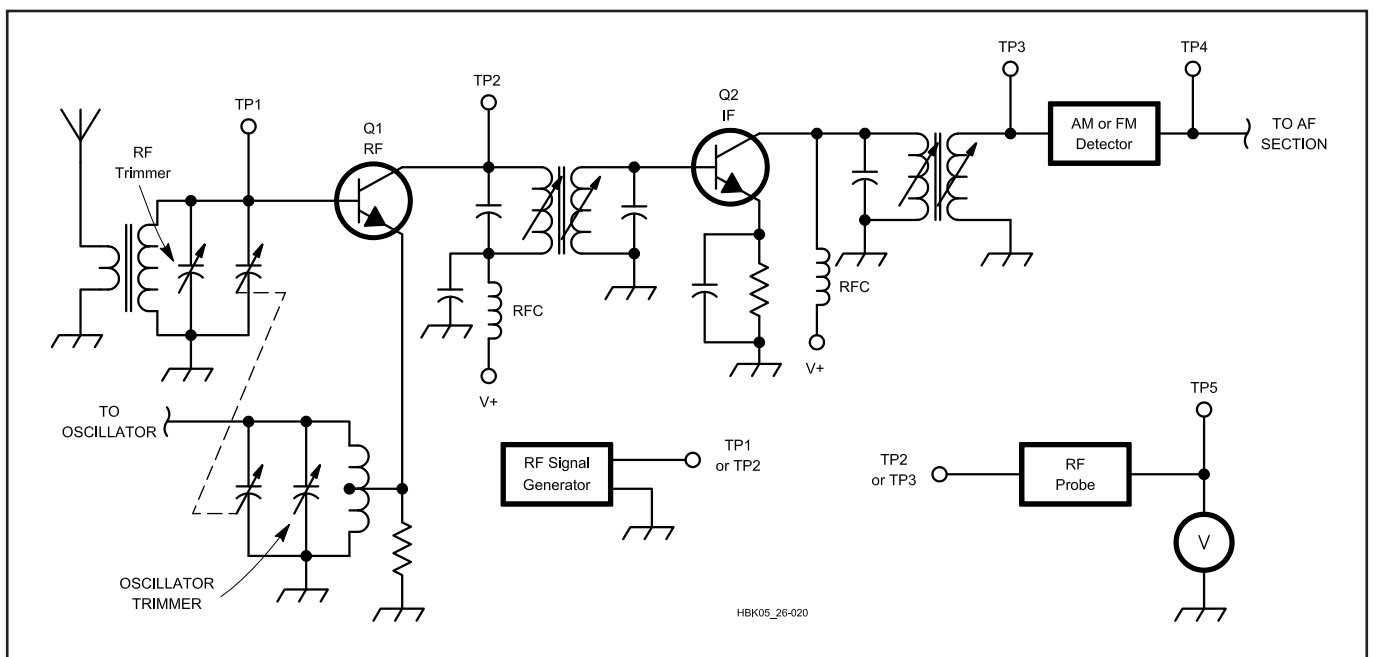

Fig 26.20 — Typical receiver alignment test points. To align the entire radio, connect a dc voltmeter at TP4. Inject an IF signal at TP2 and adjust the IF transformers. Move the signal generator to TP1 and inject an RF signal for alignment of the RF amplifier and oscillator stages. To align a single stage, place the generator at the input and an RF voltmeter (or demodulator probe and dc voltmeter) at the output: TP1/TP2 for RF, TP2/TP3 for IF.

wave. Backwave is a condition in which the signal is heard, at a reduced level, even when the key is up. This occurs when the oscillator signal feeds through a keyed amplifier. This usually indicates a design flaw, although in some cases a component failure or improper keyed-stage neutralization may be to blame.

Low Output Power

Some transmitters automatically reduce power in the TUNE mode. Check the owner's manual to see if the condition is normal. Check the control settings. Transmitters that use broadband amplifiers require so little effort from the operator that control settings are seldom noticed. The CARRIER (OR DRIVE) control may have been bumped. Remember to adjust tuned amplifiers after a significant change in operating frequency (usually 50 to 100 kHz). Most modern transmitters are designed to reduce power if there is high (say 2:1) SWR. Check these obvious external problems before you tear apart your rig.

Power transistors may fail if the SWR protection circuit malfunctions. Such failures occur at the "weak link" in the amplifier chain: It is possible for the drivers to fail without damaging the finals. An open circuit in the "reflected" side of the sensing circuit leaves the transistors unprotected, a short "shuts them down."

Low power output in a transmitter may also spring from a misadjusted carrier oscillator or a defective SWR protection circuit. If the carrier oscillator is set to a frequency well outside the transmitter passband, there may be no measurable output. Output power will increase steadily as the frequency is moved into the passband.

Transceivers

Switching

Elaborate switching schemes are used in transceivers for signal control. Many transceiver malfunctions can be attributed to relay or switching problems. Suspect the switching controls when:

- The S meter is inoperative, but the unit otherwise functions. (This could also be a bad S meter.)
- There is arcing in the tank circuit. (This could also be caused by a bad antenna system.)
- Plate current is high during reception.
- There is excessive broadband PA noise in the receiver.

Since transceiver circuits are shared, stage defects frequently affect both the transmit and receive modes, although the symptoms may change with mode. Oscillator problems usually affect both transmit and receive modes, but different oscilla-

tors, or frequencies, may be used for different emissions. Check the block diagram.

For example, one particular transceiver uses a single carrier oscillator with three different crystals (see **Fig 26.21**). One crystal sets the carrier frequency for CW, AM and FSK transmit. Another sets USB transmit and USB/CW receive, and a third sets LSB transmit and LSB/FSK receive. This radio showed a strange symptom. After several hours of CW operation, the receiver produced only a light hiss on USB and CW. Reception was good in other modes, and the power meter showed full output during CW transmission. An examination of the block diagram and schematic showed that only one of the crystals (and seven support components) was capable of causing the problem.

VOX

Voice operated transmit (VOX) controls are another potential trouble area. If there is difficulty in switching to transmit in the VOX mode, check the VOX-SENSITIVITY and ANTI-VOX control settings. Next, see if the PTT and manual (MOX) transmitter controls work. If the PTT and MOX controls function, examine the VOX control diodes and amplifiers. Test the switches, control lines and control voltage if the transmitter does not respond to other TR controls.

VOX SENSITIVITY and ANTI-VOX settings should also be checked if the transmitter switches on in response to received audio. Suspect the ANTI-VOX circuitry next. Unacceptable VOX timing results from a poor VOX-delay adjustment, or a bad resistor or capacitor in the timing circuit or VOX amplifiers.

Alignment

The mixing scheme of the modern SSB transceiver is complicated. The signal passes through many mixers, oscillators and filters. Satisfactory SSB communication requires accurate adjustment of each stage. Do not attempt any alignment without a copy of the manufacturer's instructions and the necessary test equipment.

Troubleshooting Charts

Tables 26.2, 26.3, 26.4 and 26.5 list some common problems and possible cures. These tables are not all-inclusive. They are a collection of hints and shortcuts that may save you some troubleshooting time. If you don't find your problem listed, continue with systematic troubleshooting.

COMPONENTS

Once you locate a defective part, it is time to select a replacement. This is not

always an easy task. Each electronic component has a function. This section acquaints you with the functions, failure modes and test procedures of resistors, capacitors, inductors and other components. Test the components implicated by symptoms and stage-level testing. In most cases, a particular faulty component will be located by these tests. If a faulty component is not indicated, check the circuit adjustments. As a last resort, use a shotgun approach — replace all parts in the problem area with components that are known to be good.

Check the Circuit

Before you install a replacement component of any type, you should be sure that another circuit defect didn't cause the failure. Check the circuit voltages carefully before installing any new component. Check the potential on each trace to the bad component. The old part may have "died" as a result of a lethal voltage. Measure twice — repair once! (With apologies to the old carpenter.) Of course, circuit performance is the final test of any substitution.

Fuses

Most of the time, when a fuse fails, it is for a reason — usually a short circuit in the load. A fuse that has failed because of a short circuit usually shows the evidence of high current: a blackened interior with little blobs of fuse element everywhere. Fuses can also fail by fracturing the element at either end. This kind of failure is not visible by looking at the fuse. Check even "good" fuses with an ohmmeter. You may save hours of troubleshooting.

For safety reasons, always use *exact* replacement fuses. Check the current and voltage ratings. The fuse timing (fast, normal or slow blow) must be the same as the original. Never attempt to force a fuse that is not the right size into a fuse holder. The substitution of a bar, wire or penny for a fuse invites a "smoke party."

Wires

Wires seldom fail unless abused. Short circuits can be caused by physical damage to insulation or by conductive contamination. Damaged insulation is usually apparent during a close visual inspection of the conductor or connector. Look carefully where conductors come close to corners or sharp objects. Repair worn insulation by replacing the wire or securing an insulating sleeve (spaghetti) or heat-shrink tubing over the worn area.

When wires fail, the failure is usually caused by stress and flexing. Nearly everyone has broken a wire by bending it back

Fig 26.21 — Partial schematic of a transceiver oscillator. The symptoms described in the text are caused by one or more components inside the dashed lines or a faulty USB/CW control signal.

and forth, and broken wires are usually easy to detect. Look for sharp bends or bulges in the insulation.

When replacing conductors, use the same material and size, if possible. Substitute only wire of greater cross-sectional area (smaller gauge number) or material of greater conductivity. Insulated wire should be rated at the same, or higher, temperature and voltage as the wire it replaces.

Connectors

Connection faults are one of the most common failures in electronic equipment. This can range from something as simple as the ac-line cord coming out of the wall, to a connector having been put on the wrong socket, to a defective IC socket. Connectors that are plugged and unplugged frequently can wear out, becoming intermittent or noisy. Check connectors carefully when troubleshooting.

Connector failure can be hard to detect. Most connectors maintain contact as a result of spring tension that forces two

conductors together. As the parts age, they become brittle and lose tension. Any connection may deteriorate because of non-conductive corrosion at the contacts. Solder helps prevent this problem but even soldered joints suffer from corrosion when exposed to weather.

The dissipated power in a defective connector usually increases. Signs of excess heat are sometimes seen near poor connections in circuits that carry moderate current. Check for short and open circuits with an ohmmeter or continuity tester. Clean those connections that fail as a result of contamination.

Occasionally, corroded connectors may be repaired by cleaning, but replacement of the conductor/connector is usually required. Solder all connections that may be subject to harsh environments and protect them with acrylic enamel, RTV compound or a similar coating.

Choose replacement connectors with consideration of voltage and current ratings. Use connectors with symmetrical pin

arrangements only where correct insertion will not result in a safety hazard or circuit damage.

Resistors

Resistors usually fail by becoming an open circuit. More rarely they change value. This is usually caused by excess heat. Such heat may come from external sources or from power dissipated within the resistor. Sufficient heat burns the resistor until it becomes an open circuit.

Resistors can also fracture and become an open circuit as a result of physical shock. Contamination of a high-value resistor (100 kΩ or more) can cause a change in value through leakage. This contamination can occur on the resistor body, mounts or printed-circuit board. Resistors that have changed value should be replaced. Leakage is cured by cleaning the resistor body and surrounding area.

In addition to the problems of fixed-value resistors, potentiometers and rheostats can develop noise problems,

Table 26.2**Symptoms and Their Causes for All Electronic Equipment**

<i>Symptom</i>	<i>Cause</i>
Power Supplies	
No output voltage	Open circuit (usually a fuse or transformer winding)
Hum or ripple	Faulty regulator, capacitor or rectifier, low-frequency oscillation
Amplifiers	
Low gain	Transistor, coupling capacitors, emitter-bypass capacitor, AGC component, alignment
Noise	Transistors, coupling capacitors, resistors
Oscillations	Dirt on variable capacitor or chassis, shorted op-amp input
Untuned (oscillations do not change with frequency)	Audio stages
Tuned	RF, IF and mixer stages
Squeal	Open AGC-bypass capacitor
Static-like crashes	Arcing trimmer capacitors, poor connections
Static in FM receiver	Faulty limiter stage, open capacitor in ratio detector, weak RF stage, weak incoming signal
Intermittent noise	All components and connections, band-switch contacts, potentiometers (especially in dc circuits), trimmer capacitors, poor antenna connections
Distortion (constant)	Oscillation, overload, faulty AGC, leaky transistor, open lead in tab-mount transistor, dirty potentiometer, leaky coupling capacitor, open bypass capacitors, imbalance in tuned FM detector, IF oscillations, RF feedback (cables)
Distortion (strong signals only)	Open AGC line, open AGC diode
Frequency change	Physical or electrical variations, dirty or faulty variable capacitor, broken switch, loose compartment parts, poor voltage regulation, oscillator tuning (trouble when switching bands)
No Signals	
All bands	Dead VFO or heterodyne oscillator, PLL won't lock
One band only	Defective crystal, oscillator out of tune, band switch
No function control	Faulty switch, poor connection, defective switching diode or circuit
Improper Dial Tracking	
Constant error across dial	Dial drive
Error grows worse along dial	Circuit adjustment

Table 26.3**Transmitter Problems**

<i>Symptom</i>	<i>Cause</i>
Key clicks	Keying filter, distortion in stages after keying
Modulation Problems	
Loss of modulation	Broken cable (microphone, PTT, power), open circuit in audio chain, defective modulator
Distortion on transmit	Defective microphone, RF feedback from lead dress, modulator imbalance, bypass capacitor, improper bias, excessive drive
Arcing	Dampness, dirt, improper lead dress
Low output	Incorrect control settings, improper carrier shift (CW signal outside of passband) audio oscillator failure, transistor or tube failure, SWR protection circuit
Antenna Problems	
Poor SWR	Damaged antenna element, matching network, feed line, balun failure (see below), resonant conductor near antenna, poor connection at antenna
Balun failure	Excessive SWR, weather or cold-flow damage in coil choke, broken wire
RFI	Arcing or poor connections anywhere in antenna system or nearby conductors

especially in dc circuits. Dirt often causes intermittent contact between the wiper and resistive element. To cure the problem, spray electronic contact cleaner into the control, through holes in the case, and rotate the shaft a few times.

The resistive element in wire-wound potentiometers eventually wears and

breaks from the sliding action of the wiper. In this case, the control needs to be replaced.

Replacement resistors should be of the same value, tolerance, type and power rating as the original. The value should stay within tolerance. Replacement resistors may be of a different type than the

original, if the characteristics of the replacement are consistent with circuit requirements.

Substitute resistors can usually have a greater power rating than the original, except in high-power emitter circuits where the resistor also acts as a fuse or in cases where the larger size presents a problem.

Table 26.4**Receiver Problems**

<i>Symptom</i>	<i>Cause</i>
Low sensitivity Signals and calibrator heard weakly (low S-meter readings) (strong S-meter readings)	Semiconductor contamination, weak tube, alignment RF chain AF chain, detector
No signals or calibrator heard, only hissing	RF oscillators
Distortion	
On strong signals only	AGC fault
AGC fault	Active device cut off or saturated
Difficult tuning	AGC fault
Inability to receive	Detector fault
AM weak and distorted	Poor detector, power or ground connection
CW/SSB unintelligible	BFO off frequency or dead
FM distorted	Open detector diode

Table 26.5**Transceiver Problems**

<i>Symptom</i>	<i>Cause</i>
Inoperative S meter PA noise in receiver Excessive current on receive Arcing in PA	Faulty relay
Reduced signal strength on transmit and receive	IF failure
Poor VOX operation Poor VOX timing	VOX amplifiers and diodes Adjustment, component failure in VOX timing circuits or amplifiers
VOX consistently tripped by receiver audio	AntiVOX circuits or adjustment

Variable resistors should be replaced with the same kind (carbon or wire wound) and taper (linear, log, reverse log and so on) as the original. Keep the same, or better tolerance and pay attention to the power rating.

In all cases, mount high-temperature resistors away from heat-sensitive components. Keep carbon resistors away from heat sources. This will extend their life and ensure minimum resistance variations.

Capacitors

Capacitors usually fail by shorting, opening or becoming electrically (or physically) leaky. They rarely change value. Capacitor failure is usually caused by excess current, voltage, temperature or age. Leakage can be external to the capacitor (contamination on the capacitor body or circuit) or internal to the capacitor.

Tests

The easiest way to test capacitors is out of circuit with an ohmmeter. In this test, the resistance of the meter forms a timing

circuit with the capacitor to be checked. Capacitors from 0.01 μF to a few hundred μF can be tested with common ohmmeters. Set the meter to its highest range and connect the test leads across the discharged capacitor. When the leads are connected, current begins to flow. The capacitor passes current easily when discharged, but less easily as the charge builds. This shows on the meter as a low resistance that builds, over time, toward infinity.

The speed of the resistance build-up corresponds to capacitance. Small capacitance values approach infinite resistance almost instantly. A 0.01- μF capacitor checked with an 11-M Ω FETVOM would increase from zero to a two-thirds scale reading in 0.11 s, while a 1- μF unit would require 11 s to reach the same reading. If the tested capacitor does not reach infinity within five times the period taken to reach the two-thirds point, it has excess leakage. If the meter reads infinite resistance immediately, the capacitor is open. (Aluminum electrolytics normally exhibit high-leakage readings.)

Fig 26.22 shows a circuit that may be used to test capacitors. To use this circuit, make sure that the power supply is off, set S1 to CHARGE and S2 to TEST, then connect the capacitor to the circuit. Switch on the power supply and allow the capacitor to charge until the voltmeter reading stabilizes. Next, switch S1 to TEST and watch the meter for a few seconds. If the capacitor is good, the meter will show no potential. Any appreciable voltage indicates excess leakage. After testing, set S1 to CHARGE, switch off the power supply, and press the DISCHARGE button until the meter shows 0 V, then remove the capacitor from the test circuit.

Capacitance can also be measured with a capacitance meter, an RX bridge or a dip meter. Some DMMs (digital multimeters) measure capacitance. Capacitance measurements made with DMMs and dedicated capacitance meters are much more accurate than those made with RX bridges or dip meters. To determine capacitance with a dip meter, a parallel-resonant circuit should be constructed using the capacitor of unknown value and an inductor of known value. The formula for resonance is discussed in the **Electrical Fundamentals** chapter of this book.

It is best to keep a collection of known components that have been measured on accurate L or C meters. Alternatively, a “standard” value can be obtained by ordering 1 or 2% components from an electronics supplier. A 10%-tolerance component can be used as a standard; however, the results will only be known to within 10%. The accuracy of tests made with any of these alternatives depends on the accuracy of the “standard” value component. Further information on this technique appears in Bartlett’s article, “Calculating Component Values,” in Nov 1978 *QST*.

Cleaning

The only variety of common capacitor that can be repaired is the air-dielectric variable capacitor. Electrical connection to the moving plates is made through a spring-wiper arrangement (see **Fig 26.23**). Dirt normally builds on the contact area, and they need occasional cleaning. Before cleaning the wiper/contact, use gentle air pressure and a soft brush to remove all dust and dirt from the capacitor plates. Apply some electronic contact cleaning fluid. Rotate the shaft quickly several times to work in the fluid and establish contact. Use the cleaning fluid sparingly, and keep it off the plates except at the contact point.

Replacements

Replacement capacitors should match the original in value, tolerance, dielectric, working voltage and temperature coefficient.

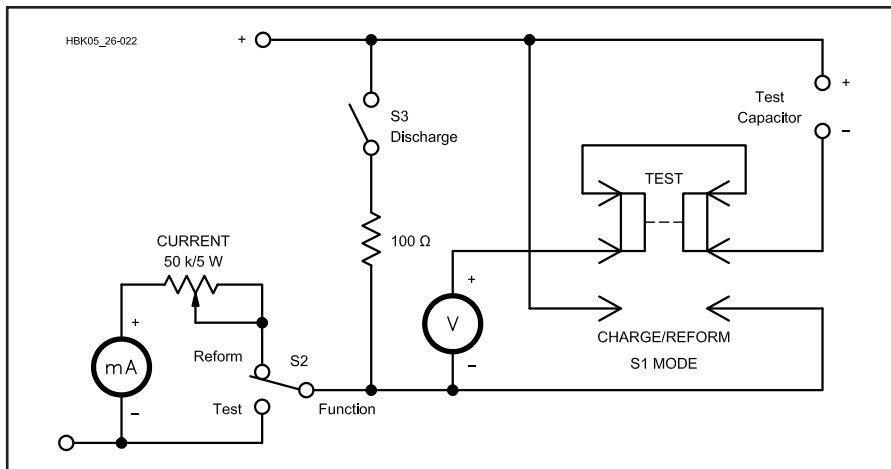

Fig 26.22 — A fixture for testing capacitors and reforming the dielectric of electrolytic capacitors. Use 12 V for testing the capacitor. Use the capacitor working voltage for dielectric reformation.

Fig 26.23 — Partial view of an air-dielectric variable capacitor. If the capacitor is noisy or erratic in operation, apply electronic cleaning fluid where the wiper contacts the rotor plates.

cient. Use only ac-rated capacitors for line service. If exact replacements are not available, substitutes may vary from the original part in the following respects: Bypass capacitors may vary from one to three times the capacitance of the original. Coupling capacitors may vary from one half to twice the value of the original. Capacitance values in tuned circuits (especially filters) must be exact. (Even then, any replacement will probably require circuit realignment.)

If the same kind of capacitor is not available, use one with better dielectric characteristics. Do not substitute polarized capacitors for nonpolarized parts. Capacitors with a higher working voltage may be used, although the capacitance of an electrolytic capacitor used significantly below its working voltage will usually increase with time.

The characteristics of each type of capacitor are discussed in the **Real-World**

Component Characteristics chapter. Consider these characteristics if you're not using an exact replacement capacitor.

Inductors and Transformers

The most common inductor or transformer failure is a broken conductor. More rarely, a short circuit can occur across one or more turns of a coil. In an inductor, this changes the value. In a transformer, the turns ratio and resultant output voltage changes. In high-power circuits, excessive inductor current can generate enough heat to melt plastics used as coil forms.

Inductors may be checked for open circuit failure with an ohmmeter. In a good inductor, dc resistance rarely exceeds a few ohms. Shorted turn and other changes in inductance show only during alignment or inductance measurement.

The procedure for measurement of inductance with a dip meter is the same as that given for capacitance measurement, except that a capacitor of known value is used in the resonant circuit.

Replacement inductors must have the same inductance as the original, but that is only the first requirement. They must also carry the same current, withstand the same voltage and present nearly the same Q as the original part. Given the original as a pattern, the amateur can duplicate these qualities for many inductors. Note that inductors with ferrite or iron-powder cores are frequency sensitive, so the replacement must have the same core material.

If the coil is of simple construction, with the form and core undamaged, carefully count and write down the number of turns and their placement on the form. Also note how the coil leads are arranged and connected to the circuit. Then determine the

wire size and insulation used. Wire diameter, insulation and turn spacing are critical to the current and voltage ratings of an inductor. (There is little hope of matching coil characteristics unless the wire is duplicated exactly in the new part.) Next, remove the old winding—be careful not to damage the form—and apply a new winding in its place. Be sure to dress all coil leads and connections in exactly the same manner as the original. Apply Q dope to hold the finished winding in place.

Follow the same procedure in cases where the form or core is damaged, except that a suitable replacement form or core (same dimensions and permeability) must be found.

Ready-made inductors may be used as replacements if the characteristics of the original and the replacement are known and compatible. Unfortunately, many inductors are poorly marked. If so, some comparisons, measurements and circuit analysis are usually necessary.

When selecting a replacement inductor, you can usually eliminate parts that bear no physical resemblance to the original part. This may seem odd, but the Q of an inductor depends on its physical dimensions and the permeability of the core material. Inductors of the same value, but of vastly different size or shape, will likely have a great difference in Q. The Q of the new inductor can be checked by installing it in the circuit, aligning the stage and performing the manufacturer's passband tests. Although this practice is all right in a pinch, it does not yield an accurate Q measurement. Methods to measure Q appear in the **Test Procedures** chapter.

Once the replacement inductor is found, install it in the circuit. Duplicate the placement, orientation and wiring of the original. Ground-lead length and arrangement should not be changed. Isolation and magnetic shielding can be improved by replacing solenoid inductors with toroids. If you do, however, it is likely that many circuit adjustments will be needed to compensate for reduced coupling and mutual inductance. Alignment is usually required whenever a tuned-circuit component is replaced.

A transformer consists of two inductors that are magnetically coupled. Transformers are used to change voltage and current levels (this changes impedance also). Failure usually occurs as an open circuit or short circuit of one or more windings.

Amateur testing of power transformers is limited to ohmmeter tests for open circuits and voltmeter checks of secondary voltage. Make sure that the power-line voltage is correct, then check the secondary voltage against that specified. There should be less than 10% difference

between open-circuit and full-load secondary voltage.

Replacement transformers must match the original in voltage, volt-ampere (VA), duty cycle and operating-frequency ratings. They must also be compatible in size. (All transformer windings should be insulated for the full power-supply voltage.)

Relays

Although relays have been replaced by semiconductor switching in low-power circuits, they are still used extensively in high-power Amateur Radio equipment. Relay action may become sluggish. AC relays can buzz (with adjustment becoming impossible). A binding armature or weak springs can cause intermittent switching. Excessive use or hot switching ruins contacts and shortens relay life.

You can test relays with a voltmeter by jumpering across contacts with a test lead (power on, in circuit) or with an ohmmeter (out of circuit). Look for erratic readings across the contacts, open or short circuits at contacts or an open circuit at the coil.

Most failures of simple relays can be repaired by a thorough cleaning. Clean the contacts and mechanical parts with a residue-free cleaner. Keep it away from the coil and plastic parts that may be damaged. Dry the contacts with lint-free paper, such as a business card; then burnish them with a smooth steel blade. Do not use a file to clean contacts.

Replacement relays should match or exceed the original specifications for voltage, current, switching time and stray impedance (impedance is significant in RF circuits only). Many relays used in transceivers are specially made for the manufacturer. Substitutes may not be available from any other source.

Before replacing a multicontact relay, make a drawing of the relay, its position, the leads and their routings through the surrounding parts. This drawing allows you to complete the installation properly, even if you are distracted in the middle of the operation.

Semiconductors

Diodes

The primary function of a diode is to pass current in one direction only. They can be easily tested with an ohmmeter.

Signal or switching diodes — The most common diode in electronics equipment, they are used to convert ac to dc, to detect RF signals or to take the place of relays to switch ac or dc signals within a circuit. Signal diodes usually fail open, although shorted diodes are not rare. They can easily be tested with an ohmmeter.

Power-rectifier diodes — Most equipment contains a power supply, so power-rectifier diodes are the second-most common diodes in electronic circuitry. They usually fail shorted, blowing the power-supply fuse.

Other diodes — Zener diodes are made with a predictable reverse-breakdown voltage and used as voltage regulators. Varactor diodes are specially made for use as voltage controlled variable capacitors. (Any semiconductor diode may be used as a voltage-variable capacitance, but the value will not be as predictable as that of a varactor.) A Diac is a special-purpose diode that passes only pulses of current in each direction.

Diode tests — There are several basic tests for most diodes. First, is it a diode? Does it conduct in one direction and block current flow in the other? An ohmmeter is suitable for this test in most cases. An ohmmeter will read high resistance in one direction, low resistance in the other. Make sure the meter uses a voltage of more than 0.7 V and less than 1.5 V to measure resistance. Use a good diode to determine the meter polarity.

Diodes should be tested out of circuit. Disconnect one lead of the diode from the circuit, then measure the forward and reverse resistance. Diode quality is shown by the ratio of reverse to forward resistance. A ratio of 100:1 or greater is common for signal diodes. The ratio may go as low as 10:1 for old power diodes.

The first test is a forward-resistance test. Set the meter to read $\times 100$ and connect the test probes across the diode. When the negative terminal of the ohmmeter battery is connected to the cathode, the meter will typically show about 200 to 300 Ω (forward resistance) for a good silicon diode, 200 to 400 Ω for a good germanium diode. The exact value varies quite a bit from one meter to the next.

Next, test the reverse resistance. Reverse the lead polarity and set the meter to $\times 1M$ (times one million, or the highest scale available on the meter) to measure diode reverse resistance. Good diodes should show 100 to 1000 $M\Omega$ for silicon and 100 $k\Omega$ to 1 $M\Omega$ for germanium. When you are done, mark the meter lead polarity for future reference.

This procedure measures the junction resistances at low voltage. It is not useful to test Zener diodes. A good Zener diode will not conduct in the reverse direction at voltages below its rating.

We can also test diodes by measuring the voltage drop across the diode junction while the diode is conducting. (A test circuit is shown in **Fig 26.24**.) To test, connect the diode, adjust the supply voltage

until the current through the diode matches the manufacturer's specification and compare the junction drop to that specified. Silicon junctions usually show about 0.6 V, while germanium is typically 0.2 V. Junction voltage-drop increases with current flow. This test can be used to match diodes with respect to forward resistance at a given current level.

A final simple diode test measures leakage current. Place the diode in the circuit described above, but with reverse polarity. Set the specified reverse voltage and read the leakage current on a milliammeter. (The currents and voltages measured in the junction voltage-drop and leakage tests vary by several orders of magnitude.)

The most important specification of a Zener diode is the Zener (or avalanche) voltage. The Zener-voltage test also uses the circuit of **Fig 26.24**. Connect the diode in reverse. Set the voltage to minimum, then gradually increase it. You should read low current in the reverse mode, until the Zener point is reached. Once the device begins to conduct in the reverse direction, the current should increase dramatically. The voltage shown on the voltmeter is the Zener point of the diode. If a Zener diode has become leaky, it might show in the leakage-current measurement, but substitution is the only dependable test.

Replacement diodes — When a diode fails, check associated components as well. Replacement rectifier diodes should have the same current and peak inverse voltage (PIV) as the original. Series diode combinations are often used in high-voltage rectifiers, with resistor and capacitor networks to distribute the voltage equally among the diodes.

Switching diodes may be replaced with diodes that have equal or greater current ratings and a PIV greater than twice the peak-to-peak voltage encountered in the circuit. Switching time requirements are not critical except in RF, logic and some keying circuits. Logic circuits may require exact replacements to assure compatible switching speeds and load characteristics. RF switching diodes used near resonant circuits must have exact replacements as the diode resistance and capacitance will affect the tuned circuit.

Voltage, current and capacitance characteristics must be considered when replacing varactor diodes. Once again, exact replacements are best. Zener diodes should be replaced with parts having the same Zener voltage and equal or better current, power, impedance and tolerance specifications. Check the associated current-limiting resistor when replacing a Zener diode.

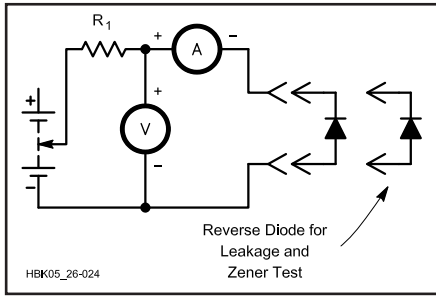

Fig 26.24 — A diode conduction, leakage and Zener-point test fixture. The ammeter should read mA for conduction and Zener point, μA for leakage tests.

Bipolar Transistors

Transistors are primarily used to switch or amplify signals. Transistor failures occur as an open junction, a shorted junction, excess leakage or a change in amplification performance.

Most transistor failure is catastrophic. A transistor that has no leakage and amplifies at dc or audio frequencies will usually perform well over its design range. For this reason, transistor tests need not be performed at the planned operating frequency. Tests are made at dc or a low frequency (usually 1000 Hz). The circuit under repair is the best test of a potential replacement part. Swapping in a replacement transistor in a failed circuit will often result in a cure.

A simple and reliable bipolar-transistor test can be performed with the transistor in a circuit and the power on. It requires a test lead, a 10-k Ω resistor and a voltmeter. Connect the voltmeter across the emitter/collector leads and read the voltage. Then use the test lead to connect the base and emitter (**Fig 26.25A**). Under these conditions, conduction of a good transistor will be cut off and the meter should show nearly the entire supply voltage across the emitter/collector leads. Next, remove the clip lead and connect the 10-k Ω resistor from the base to the collector. This should bias the transistor into conduction and the emitter/collector voltage should drop (**Fig 26.25B**). (This test indicates transistor response to changes in bias voltage.)

Transistors can be tested (out of circuit) with an ohmmeter in the same manner as diodes. Look up the device characteristics before testing and consider the consequences of the ohmmeter-transistor circuit. Limit junction current to 1 to 5 mA for small-signal transistors. Transistor destruction or inaccurate measurements may result from careless testing.

Use the $\times 100 \Omega$ and $\times 1000\text{-}\Omega$ ranges

for small-signal transistors. For high-power transistors use the $\times 1 \Omega$ and $\times 10\text{-}\Omega$ ranges. The reverse-to-forward resistance ratio for good transistors may vary from 30:1 to better than 1000:1.

Germanium transistors sometimes show high leakage when tested with an ohmmeter. Bipolar transistor leakage may be specified from the collector to the base, emitter to base or emitter to collector (with the junction reverse biased in all cases). The specification may be identified as I_{cbo} , I_{bo} , collector cutoff current or collector leakage for the base-collector junction, I_{ebo} , and so on for other junctions.³ Leakage current increases with junction temperature.

A suitable test fixture for base-collector leakage measurements is shown in **Fig 26.26**. Make the required connections and set the voltage as stated in the transistor specifications and compare the measured leakage current with that specified. Small-signal germanium transistors exhibit I_{cbo} and I_{ebo} leakage currents of about 15 μA . Leakage increases to 90 μA or more in high-power components. Leakage currents for silicon transistors are seldom more than 1 μA . Leakage current tends to double for every 10 $^{\circ}\text{C}$ increase above 25 $^{\circ}\text{C}$.

Breakdown-voltage tests actually measure leakage at a specified voltage, rather than true breakdown voltage. Breakdown voltage is known as BV_{cbo} , BV_{ces} or BV_{ceo} . Use the same test fixture shown for leakage tests, adjust the power supply until the specified leakage current flows, and compare the junction voltage against that specified.

A circuit to measure dc current gain is shown in **Fig 26.27**. Transistor gain can range from 10 to over 1000 because it is not usually well controlled during manufacture. Gain of the active device is not critical in a well-designed transistor circuit.

The test conditions for transistor testing are specified by the manufacturer. When testing, do not exceed the voltage, current (especially in the base circuit) or dissipated-power rating of the transistor. Make sure that the load resistor is capable of dissipating the power generated in the test.

While these simple test circuits will identify most transistor problems, RF devices should be tested at RF. Most component manufacturers include a test-circuit schematic on the data sheet. The test circuit is usually an RF amplifier that operates near the high end of the device frequency range.

Semiconductor failure is sometimes the result of environmental conditions. Open junctions, excess leakage (except with

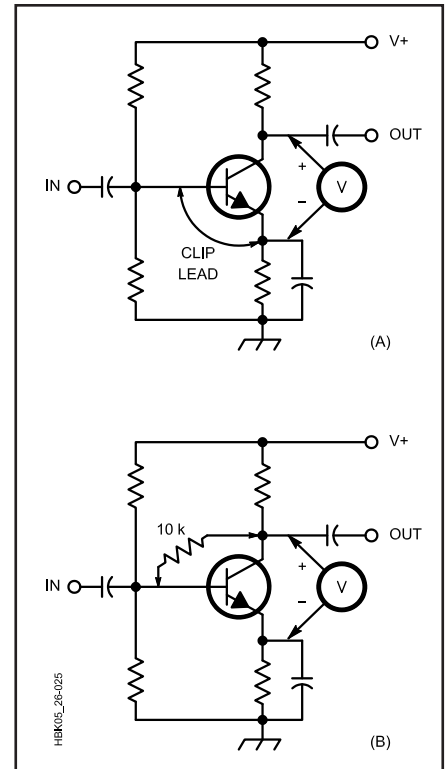

Fig 26.25 — An in-circuit semiconductor test with a clip lead, resistor and voltmeter. The meter should read V+ at (A). During test (B) the meter should show a decrease in voltage, ranging from a slight variation down to a few millivolts. It will typically cut the voltage to about half of its initial value.

Fig 26.26 — A test circuit for measuring collector-base leakage with the emitter shorted to ground, open or connected to ground through a variable resistance, depending on the setting of S1. See the transistor manufacturer's instructions for test conditions and the setting of R1 (if used). Reverse battery polarity for PNP transistors.

germanium transistors) and changes in amplification performance result from overload or excessive current. Electrostatic discharge can destroy a semiconductor in microseconds. Shorted junctions are caused by voltage spikes. Check surrounding parts for the cause of the transistor's demise, and correct the problem before installing a replacement.

JFETs

Junction FETs can be tested with an ohmmeter in much the same way as bipolar transistors (see text and Fig 26.28). Reverse leakage should be several megohms or more. Forward resistance should be 500 to 1000 Ω .

MOSFETs

MOS (metal-oxide semiconductor) layers are extremely fragile. Normal body static is enough to damage them. Even "gate protected" (a diode is placed across the MOS layer to clamp voltage) MOSFETs may be destroyed by a few volts of static electricity.

Make sure the power is off, capacitors discharged and the leads of a MOSFET are shorted together before installing or removing it from a circuit. Use a voltmeter to be sure the chassis is near ground potential, then touch the chassis before and during MOSFET installation and removal. This assures that there is no difference of potential between your body, the chassis and the MOSFET leads. Ground the soldering-iron tip with a clip lead when soldering MOS devices. The FET source should be the first lead connected to and the last disconnected from a circuit. The insulating layers in MOSFETs prevent testing with an ohmmeter. Substitution is the only practical means for amateur testing of MOSFETs.

FET Considerations

Replacement FETs should be of the same kind as the original part: JFET or MOSFET, P-channel or N-channel, enhancement or depletion. Consider the breakdown voltage required by the circuit. The breakdown voltage should be at least two to four times the power-supply and signal voltages in amplifiers. Allow for transients of ten times the line voltage in power supplies. Breakdown voltages are usually specified as $V_{(BR)GSS}$ or $V_{(BR)GDO}$.

The gate-voltage specification gives the gate voltage required to cut off or initiate channel current (depending on the mode of operation). Gate voltages are usually listed as $V_{GS(OFF)}$, V_p (pinch off), V_{TH} (threshold) or $I_{D(ON)}$ or I_{TH} .

Dual-gate MOSFET characteristics are more complicated because of the interac-

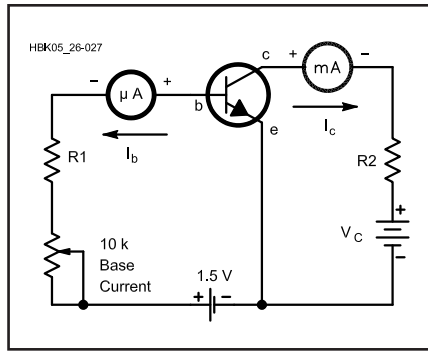

Fig 26.27 — A test circuit for measuring transistor beta. Values for R1 and R2 are dependent on the current range of the transistor tested. Reverse the battery polarity for PNP transistors.

tion of the two gates. Cutoff voltage, breakdown voltage and gate leakage are the important traits of each gate.

Integrated Circuits

The basics of integrated circuits are covered in earlier chapters of this book. Amateurs seldom have the sophisticated equipment required to test ICs. Even a multitrace 'scope can view only their simplest functions. We must be content to check every other possible cause, and only then assume that the problem lies with an IC. Experienced troubleshooters will tell you that — most of the time anyway — if a defective circuit uses an IC, it is the IC that is bad.

Linear ICs — There are two major classes of ICs: linear and digital. Linear ICs are best replaced with identical units. Original equipment manufacturers are the best source of a replacement; they are the only source with a reason to stockpile obsolete or custom-made items. If substitution of an IC is unavoidable, first try the cross-reference guides published by several distributors. You can also look in manufacturers' databooks and compare pinouts and other specifications.

Digital ICs — It is usually not a good idea to substitute digital devices. While it may be okay to substitute an AB74LS00YZ from manufacturer "A" with a CD74LS00WX from a different manufacturer, you will usually not be able to replace an LS (low-power Schottky) device with an S (Schottky), C (CMOS) or any of a number of other families. The different families all have different speed, current-consumption, input and output characteristics. You would have to analyze the circuit to determine if you could substitute one type for another.

Semiconductor Substitution

In all cases try to obtain exact replacement semiconductors. Specifications vary slightly from one manufacturer to the next. Cross-reference equivalents are useful, but not infallible. Before using an equivalent, check the specifications against those for the original part. When choosing a replacement, consider:

- Is it silicon or germanium?
- Is it a PNP or an NPN?
- What are the operating frequency and input/output capacitance?
- How much power does it dissipate (often less than $V_{max} \times I_{max}$)?
- Will it fit the original mount?
- Are there unusual circuit demands (low noise and so on)?
- What is the frequency of operation?

Remember that cross-reference equivalents are not guaranteed to work in every

Fig 26.28 — Ohmmeter tests of a JFET. The junction is reverse biased at A and forward biased at B.

application. There may be cases where two dissimilar devices have the same part number, so it pays to compare the listed replacement specifications with the intended use. If “the book” says to use a diode in place of an RF transistor, it isn’t going to work! Derate power specifications, as recommended by the manufacturer, for high-temperature operation.

Tubes

The most common tube failures in amateur service are caused by cathode depletion and gas contamination. Whenever a tube is operated, the coating on the cathode loses some of its ability to produce electrons. It is time to replace the tube when electron production (cathode current, I_c) falls to 50 - 60% of that exhibited by a new tube.

Gas contamination in a tube can often be identified easily because there may be a greenish or whitish-purple glow between the elements during operation. (A faint deep-purple glow is normal in most tubes.) The gas reduces tube resistance and leads to runaway plate current evidenced by a red glow from the anode, interelectrode arcing or a blown power-supply fuse. Less common tube failures include an open filament, broken envelope and interelectrode shorts.

The best test of a tube is to substitute a new one. Another alternative is a tube tester; these are now rare. You can also do some limited tests with an ohmmeter. Tube tests should be made out of circuit so circuit resistance does not confuse the results.

Use an ohmmeter to check for an open filament (remove the tube from the circuit first). A broken envelope is visually obvious, although a cracked envelope may appear as a gassy tube. Interelectrode shorts are evident during voltage checks on the operating stage. Any two elements that show the same voltage are probably shorted. (Remember that some interelectrode shorts, such as the cathode-suppressor grid, are normal.)

Generally, a tube may be replaced with another that has the same type number. Compare the data sheets of similar tubes to assess their compatibility. Consider the base configuration and pinout, interelectrode capacitances (a small variation is okay except for tubes in oscillator service), dissipated power ratings of the plate and screen grid and current limitations (both peak and average). For example, the 6146A may be replaced with a 6146B (heavy duty), but not vice versa.

In some cases, minor type-number differences signify differences in filament voltages, or even base styles, so check all

specifications before making a replacement. (Even tubes of the same model number, prefix and suffix vary slightly, in some respects, from one supplier to the next.)

AFTER THE REPAIRS

Once you have completed your troubleshooting and repairs, it is time to put the equipment back together. Take a little extra time to make sure you have done everything correctly.

All Units

Give the entire unit a complete visual inspection. Look for any loose ends left over from your troubleshooting procedures — you may have left a few components temporarily soldered in place or overlooked some other repair error. Look for cold solder joints and signs of damage incurred during the repair. Double check the position, leads and polarity of components that were removed or replaced.

Make sure that all ICs are properly oriented in their sockets and all of the pins are properly inserted in the IC socket or printed-circuit board holes. Test fuse continuity with an ohmmeter and verify that the current rating matches the circuit specification.

Look at the position of all of the wires and components. Make sure that wires and cables will be clear of hot components, screw points and other sharp edges. Make certain that the wires and components will not be in the way when covers are installed and the unit is put back together.

Separate the leads that carry dc, RF, input and output as much as possible. Plug-in circuit boards should be firmly seated with screws tightened and lock washers installed if so specified. Shields and ground straps should be installed just as they were on the original.

For Transmitters Only

Since the signal produced by an HF transmitter can be heard the world over, a thorough check is necessary after any service has been performed. Do not exceed the transmitter duty cycle while testing. Limit transmissions to 10 to 20 seconds unless otherwise specified by the owner’s manual.

1. Set all controls as specified in the operation manual, or at midscale.
2. Connect a dummy load and a power meter to the transmitter output.
3. Set the drive or carrier control for low output.
4. Switch the power on.
5. Transmit and quickly set the final-amplifier bias to specifications.
6. In narrowband equipment, slowly tune the output network through reso-

nance. The current dip should be smooth and repeatable. It should occur simultaneously with the maximum power output. Any sudden jumps or wiggles of the current meter indicate that the amplifier is unstable. Adjust the neutralization circuit (according to the manufacturer’s instructions) if one is present or check for oscillation. An amplifier usually requires neutralization whenever active devices, components or lead dress (that affect the output/input capacitance) are changed.

7. Check to see that the output power is consistent with the amplifier class used in the PA (efficiency should be about 25% for Class A, 50 to 60% for Class AB or B, and 70 to 75% for Class C).

8. Repeat steps 4 through 6 for each band of operation from lowest to highest frequency.

9. Check the carrier balance (in SSB transmitters only) and adjust for minimum power output with maximum RF drive and no microphone gain.

10. Adjust the VOX controls.

11. Measure the passband and distortion levels if equipment (wideband scope or spectrum analyzer) is available.

Other Repaired Circuits

After the preliminary checks, set the circuit controls per the manufacturer’s specifications (or to midrange if specifications are not available) and switch the power on. Watch and smell for smoke, and listen for odd sounds such as arcing or hum. Operate the circuit for a few minutes, consistent with allowable duty cycle. Verify that all operating controls function properly.

Check for intermittent connections by subjecting the circuit to heat, cold and slight flexure. Also, tap or jiggle the chassis lightly with an alignment tool or other insulator.

If the equipment is meant for mobile or portable service, operate it through an appropriate temperature range. Many mobile radios do not work on cold mornings, or on hot afternoons, because a temperature-dependent intermittent was not found during repairs.

Button It Up

After you are convinced that you have repaired the circuit properly, put it all back together. If you followed the advice in this book, you have all the screws and assorted doodads in a secure container. Look at the notes you took while taking it apart; put it back together in the reverse order. Don’t forget to reconnect all internal connections, such as ac-power, speaker or antenna leads.

Once the case is closed, and all appears

well, don't neglect the final, important step — make sure it still works. Many an experienced technician has forgotten this important step, only to discover that some minor error, such as a forgotten antenna connector, has left the equipment non-functional.

PROFESSIONAL REPAIRS

This chapter does not tell you how to perform all repairs. Repairs that deal with very complex and temperamental circuits, or that require sophisticated test equipment, should be passed on to a professional.

The factory authorized service personnel have a lot of experience. What seems like a servicing nightmare to you is old hat to them. There is no one better qualified to service your equipment than the factory.

If the manufacturer is no longer in business, check with your local dealer or look in the classified ads in electronics and Amateur Radio magazines. You can usually find one or more companies that service "all makes and models." Your local TV shop might be willing to tackle a repair, especially if you have located a schematic.

If you are going to ship your equipment somewhere for repair, notify the repair center first. Get authorization for shipping and an identification name or number for the package.

Packing It Up

You can always blame shipping damage on the shipper, but it is a lot easier for all concerned if you package your equipment properly for shipping in the first place. Firmly secure all heavy components, either by tying them down or blocking them off with shipping foam. Large vacuum tubes should be wrapped in packing material or shipped separately. Make sure that all circuit boards and parts are firmly attached.

Use a box within a box for shipping. (See Fig 26.29.) Place the equipment and some packing material inside a box and seal it with tape. Place that box inside another that is at least six inches larger in each dimension. Fill the gap with packing material, seal, address and mark the outer box. Choose a good freight carrier and insure the package.

Don't forget to enclose a statement of the trouble, a short history of operation

Fig 26.29 — Ship equipment packed securely in a box within a box.

and any test results that may help the service technician. Include a good description of the things you have tried. Be honest! At current repair rates you want to tell the technician everything to help ensure an efficient repair.

Even if you ended up sending it back to the factory, you can feel good about your experience. You learned a lot by trying, and you have sent it back knowing that it really did require the services of a "pro." Each time you troubleshoot and repair a piece of electronic circuitry, you learn something new. The down side is that you may develop a reputation as a real electronics whiz. You may find yourself spending a lot of time at club meetings offering advice, or getting invited over to a lot of shacks for a late-evening pizza snack. There are worse fates.

Notes

- ¹The ARRL has prepared a list of dip-meter sources. These are available on the **CD-ROM** included with this *Handbook*.
- ²More information about the signal injector and signal sources appears in "Some Basics of Equipment Servicing," February 1982 *QST* (Feedback, May 1982).
- ³The term "I_{cbo}" means "Current from collector to base with emitter open." The subscript notation indicates the status of the three device terminals. The terminals measured are listed first, with the remaining terminal listed as "s" (shorted) or "o" (open).

KENWOOD

Listen to the Future

AIRWAVE SUPERIORITY

Never before has a compact HT offered as many features, and such high powered performance as the TH-F6A. Arm yourself with one today and gain your own airwave superiority.

- Triband (144/220/440 MHz)
- Receives 2 frequencies simultaneously even on the same band
- 0.1~1300MHz high-frequency range RX (B band)¹
- FM/FM-W/FM-N/AM plus SSB/CW receive
- Bar antenna for receiving AM broadcasts
- Special weather channel RX mode
- 435 memory channels, multiple scan functions
- 7.4V 1550mAh lithium-ion battery (std.) for high output² and extended operation
- 16-key pad plus multi-scroll key for easy operation
- Built-in charging circuitry for battery recharge while the unit operates from a DC supply
- Tough construction: meets MIL-STD 810 C/D/E standards for resistance to vibration, shock, humidity and light rain
- Large frequency display for single-band use
- Automatic simplex checker
- Wireless remote control function
- Battery indicator • Internal VOX • MCP software

¹Note that certain frequencies are unavailable. ²5W output

IC-7800

The Ultimate HF

200 Watt Output, Full Duty Cycle | Four 32 Bit IF-DSPs + 24 Bit AD/DA Converters | 2 Independent Receivers | +40 dBm 3rd Order Intercept Point | Selectable IF Filter Shapes

IC-756PROIII

Heard it. Worked it. Logged it.

100 Watt Output, Full Duty Cycle | 32 Bit IF-DSP + 24 Bit AD/DA Converter | +30 dBm 3rd Order Intercept Point | Low-distortion BPF Switching | Real-time Spectrum Scope with Mini Scope

IC-746PRO

HF Hot Rod

100 Watt Output, Full Duty Cycle | 32 Bit IF-DSP + 24 Bit AD/DA Converter | All Mode, including RTTY | Enhanced Receiver Performance | Selectable, "Build Your Own" IF Filter Shapes

IC-718

The "Get into HF" Rig

100 Watt Output, Full Duty Cycle | One-touch Band Switching | RF Gain Control | Built-in CW Keyer | Built-in VOX

IC-910H

Satellite Rig

100 Watt VHF/75 Watt UHF Variable Output | AM, FM, SSB, CW, & Satellite | Work Two Bands at Once | Main & Sub Band Functions for IF Shift, Sweep, NB, & RF Attenuator

IC-7000

New HF to 70CM Multibander

100 Watt HF+6M, 50 Watt 2M, 35 Watt 70CM | DSP² - Dual DSP Processors | Digital IF Filters | Twin Pass Band Tuning | Multiple AGC Loops | MNF² - Dual Manual Notch Filters

IC-706MKIIG

Proven Multiband Performance

100 Watt HF* + 6M, 50 Watt 2M, 20 Watt 70CM | All Mode, Full Duty Cycle | 99 Alphanumeric Memories | CTCSS Encode/Decode with Tone Scan | Built-in DSP

Shack, Car, or Field...

The ARD9000 makes Digital Voice FUN and AFFORDABLE!

Hearing *is* Believing!

Digital voice could be the biggest revolution in HF radio since SSB! All over the world, hams have been discovering how much fun it is to work HF without background noise.

AOR set the pace in this breakthrough technology with its ARD9800. Now, in response to worldwide demand, AOR has developed the ARD9000 which makes digital voice communications even more affordable.

AOR's digital voice technology delivers audio quality you have to hear to believe. Whether you are working digital voice across state lines or across an ocean, amazing doesn't seem strong enough to describe it.

With an ARD9000, it's easy to convert existing HF analog transceivers to work digital voice with NO transceiver modifications. The ARD9000 automatically detects a digital signal and decodes it, so you also maintain full analog capabilities. Whether a contact comes in as digital or analog, the ARD9000 can handle it.

Try it yourself!

You'll be amazed at how much fun it is to work ham radio in digital voice mode.

- NO transceiver modifications necessary
- Digital voice communications using existing analog transceivers
- Works on Single Side Band (SSB) mode.
- Automatic digital receive
- Optional interface cables for most popular transceivers
- Built-in high grade Vocoder (AMBE)
- Built-in FEC error correction
- Compact unit. Easy to operate.
- Utilizes a uniquely designed high performance DSP engine
- Uses the established G4GUO open protocol

Be sure to check the website at www.aorusa.com for FAQs, links to user groups and more!

Special Purchase Discounts Available for Ham Radio Clubs!

UM Unified Microsystems

New! USB Interfaces

Free your PC serial ports. USB to CW/PTT & USB to VK-64 versions.

VK-64 Combo Voice/CW Keyer

Voice keyer and full feature CW memory keyer in a single package. Front panel operation or control through your laptop or PC.

BCD-10 Band Decoder

Use band port signals from selected Yaesu® rigs or PC printer port for automatic antenna switching as you change bands.

XT-4 CW Memory Keyer

Battery powered and small size for VHF rover, FD, DXpeditions and vacations. 4 memories.

XT-4BEACON - CW Beacon IDer

Easy to program IDer for VHF beacons. Low power. Selectable speeds 5-25 WPM.

Visit our web site for new products.

Turn dreams of constructing your first amp or next brick into reality!

ARRL's RF Amplifier Classics

includes two-dozen projects and articles from the pages of QST and QEX, published between 1980 and 2003. There are amps for HF, MF, VHF and microwave.

These are high quality works from respected authors such as Gary Breed, K9AY; Jerry Pittenger, K8RA; Bill Sabin, WØIYH; Al Ward, W5LUA; Dave Meacham, W6EMD and others.

Use this book and...

- Shorten your discovery work
- Find practical designs and construction details for classic tube and solid-state amplifiers at power levels from 5 W to 1.5 kW
- Build safe and reliable amplifiers
- Produce loud and clean signals

MFJ TUNERS

New, Improved MFJ-989D 1500 Watt legal limit Antenna Tuner

World's most popular 1500 Watt Legal Limit Tuner just got better -- much better -- with no increase in price!

New, improved MFJ-989D legal limit antenna tuner gives you better efficiency, lower losses and a new true peak reading meter. It easily handles full 1500 Watts SSB/CW, 1.8 to 30 MHz, including MARS/WARC bands.

New dual 500 pF air variable capacitors give you twice the capacitance for more efficient operation on 160 and 80 Meters.

New, improved AirCore™ Roller Inductor gives you lower losses, higher Q and handles more power more efficiently.

New TrueActive™ peak reading Cross-Needle SWR/Wattmeter lets you read true peak

power on all modes. New high voltage current balun lets you tune balanced lines at high power with no worries. New crank knob lets you reset your roller inductor quickly,

smoothly and accurately. New larger 2-inch diameter capacitor knobs with easy-to-see dials make tuning much easier. New cabinet maintains components' high-Q. Generous air

MFJ-989D
\$359⁹⁵

vents keep components cool. 12⁷/₈Wx6Hx11⁵/₈D inches. Includes six position ceramic antenna switch, 50 Ohm dummy load, indestructible multi-color Lexan front panel with detailed logging scales and legends.

The MFJ-989D uses the superb time-tested T-Network. It has the widest matching range and is the easiest to use of all matching networks. Now with MFJ's new 500 pF air variable capacitors and new low loss roller inductor, it easily handles higher power much more efficiently.

No Matter What™ Warranty
 Every MFJ tuner is protected by MFJ's famous one year No Matter What™ limited warranty. We will repair or replace your MFJ tuner (at our option) for a full year.

More hams use MFJ tuners than all other tuners in the world!

MFJ-986 Two knob Differential-T™

Two knob tuning (differential capacitor and AirCore™ roller inductor) makes tuning foolproof and easier than ever. Gives minimum SWR at only one setting. Handles 3 KW PEP SSB amplifier input power (1.5 KW output). Gear-driven turns counter, lighted peak/average Cross-Needle SWR/Wattmeter, antenna switch, balun. 1.8 to 30 MHz. 10⁷/₄Wx4¹/₂Hx15 in.

MFJ-986
\$329⁹⁵

MFJ-962D compact kW Tuner

A few more dollars steps you up to a kW tuner for an amp later. Handles 1.5 KW PEP SSB amplifier input power (800W output). Ideal for Ameritron's AL-811H! AirCore™ roller inductor, gear-driven turns counter, pk/avg lighted Cross-Needle SWR/Wattmeter, antenna switch, balun. Lexan front, 1.8-30MHz. 10⁷/₄x4¹/₂x10⁷/₈ in.

MFJ-962D
\$269⁹⁵

MFJ-969 300W Roller Inductor Tuner

Superb AirCore™ Roller Inductor tuning. Covers 6 Meters thru 160 Meters! 300 Watts PEP SSB. Active true peak reading lighted Cross-Needle SWR Wattmeter, QRM-Free PreTune™, antenna switch, dummy load, 4:1 balun, Lexan front panel. 3¹/₂Hx10¹/₂Wx9¹/₂D inches.

MFJ-969
\$199⁹⁵

MFJ-949E deluxe 300 Watt Tuner

More hams use MFJ-949s than any other antenna tuner in the world!

Handles 300 Watts. Full 1.8 to 30 MHz coverage, custom inductor switch, 1000 Volt tuning capacitors, full size peak/average lighted Cross-Needle SWR/Wattmeter, 8 position antenna switch, dummy load, QRM-Free PreTune™, scratch proof Lexan front panel. 3¹/₂Hx10⁷/₈Wx7D inches. MFJ-948, \$129.95. Economy version of MFJ-949E, less dummy load, Lexan front panel.

MFJ-949E
\$149⁹⁵

MFJ-941E super value Tuner

The most for your money!

Handles 300 Watts PEP, covers 1.8-30 MHz, lighted Cross-Needle SWR/Wattmeter, 8 position antenna switch, 4:1 balun, 1000 volt capacitors, Lexan front panel. Sleek 10⁷/₂Wx2¹/₂Hx7D in.

MFJ-941E
\$119⁹⁵

MFJ-945E HF/6M mobile Tuner

Extends your mobile antenna bandwidth so you don't have to stop, go outside and adjust your antenna. Tiny 8x2x6 in. Lighted Cross-Needle SWR/Wattmeter. Lamp and bypass switches. Covers 1.8-30 MHz and 6 Meters. 300 Watts PEP. MFJ-20, \$4.95, mobile mount.

MFJ-945E
\$109⁹⁵

MFJ-971 portable/QRP Tuner

Tunes coax, balanced lines, random wire 1.8-30 MHz. Cross-Needle Meter. SWR, 30/300 or 6 Watt QRP ranges. Matches popular MFJ transceivers. Tiny 6x6¹/₂x2¹/₂ in.

MFJ-971
\$99⁹⁵

MFJ-901B smallest Versa Tuner

MFJ's smallest (5x2x6 in.) and most affordable wide range 200 Watt PEP Versa tuner. Covers 1.8 to 30 MHz. Great for matching solid state rigs to linear amps.

MFJ-901B
\$79⁹⁵

MFJ-902 Tiny Travel Tuner

Tiny 4¹/₂x2¹/₄x3 inches, full 150 Watts, 80-10 Meters, has tuner bypass switch, for coax/random wire.

MFJ-902
\$79⁹⁵

MFJ-904H, \$129.95. Same but adds Cross-needle SWR/Wattmeter and 4:1 balun for balanced lines. 7¹/₂x2¹/₄x2¹/₄ inches.

MFJ-16010 random wire Tuner

Operate all bands anywhere with MFJ's reversible L-network. Turns random wire into powerful transmitting antenna. 1.8-30 MHz. 200 Watts PEP. Tiny 2x3x4 in.

MFJ-16010
\$49⁹⁵

MFJ-906/903 6 Meter Tuners

MFJ-906 has lighted Cross-Needle SWR/Wattmeter, bypass switch. Handles 100 W FM, 200W SSB. MFJ-903, \$49.95, Like MFJ-906, less SWR/Wattmeter, bypass switch.

MFJ-906
\$79⁹⁵

MFJ-921/924 VHF/UHF Tuners

MFJ-921 covers 2 Meters/220 MHz. MFJ-924 covers 440 MHz. SWR/Wattmeter. 8x2¹/₂x3 in.

MFJ-921/924
\$69⁹⁵

MFJ-931 artificial RF Ground

Eliminates RF hot spots, RF feedback, TVI/RFI, weak signals caused by poor RF grounding. Creates artificial RF ground or electrically places far away RF ground directly at rig. MFJ-934, \$169.95, Artificial ground/300 Watt Tuner/Cross-Needle SWR/Wattmeter.

1.8-170 MHz plus 415-470 MHz MFJ HF/VHF/UHF Antenna Analyzer

All-in-one handheld antenna test lab lets you quickly check and tune HF, VHF, UHF antennas anywhere. Covers 1.8-170 MHz and 415-470 MHz. Measures: SWR...Return Loss...Reflection Coefficient...Antenna Resistance(R), Reactance(X), Impedance(Z) and Phase Angle(degrees) ... Coax cable loss(dB) ... Coax cable length ... Distance to short or open in coax ... Inductance ... Capacitance ... Resonant Frequency... Bandwidth ... Q... Velocity Factor ... Attenuation ... Has: LCD readout... frequency counter... side-by-side meters... Ni-MH/Ni-Cad charger circuit... battery saver... low battery warning... smooth reduction drive tuning... One year No Matter What™ warranty...

You can instantly get a complete picture, check and tune any antenna from 1.8 to 170 MHz and 415 to 470 MHz -- an MFJ-269 exclusive -- with this rugged easy-to-use handheld antenna test lab! You can measure virtually every antenna parameter. You won't believe its capability and versatility. This rugged handheld unit literally replaces a workbench full of expensive delicate test equipment.

MFJ-269
\$359⁹⁵

SWR Analyzer

You can read SWR, return loss, reflection coefficient and match efficiency at any frequency simultaneously at a single glance.

Complex Impedance Analyzer

Read Complex Impedance (1.8 to 170 MHz) as series equivalent resistance and reactance ($R_s + jX_s$) or as magnitude (Z) and phase (degrees). Also reads parallel equivalent resistance and reactance ($R_p + jX_p$) -- an MFJ-269 exclusive!

Coax Analyzer

You can determine velocity factor, coax loss in dB, length of coax and distance to short or open in feet (it's like a built-in TDR).

Coax Calculator™ lets you calculate coax line length in feet given electrical degrees and vice versa for any frequency and any velocity factor -- an MFJ-269 exclusive!

Use any Characteristic Impedance

You can measure SWR and loss of coax with any characteristic impedance (1.8 to 170 MHz) from 10 to over 600 Ohms, including 50, 51, 52, 53, 73, 75, 93, 95, 300, 450 Ohms -- an MFJ-269 exclusive!

Inductance/Capacitance Meter

Measures inductance in uH and capacitance in pF at RF frequencies, 1.8-170 MHz.

Frequency Counter/Signal Source

You can also use it as a handy frequency counter up to 170 MHz and as a signal source for testing and alignment.

Digital and Analog displays

A high contrast LCD gives precision readings and two side-by-side analog meters make antenna adjustments smooth and easy.

415 to 470 MHz Range features

Just plug in your UHF antenna coax, set frequency and read SWR, return loss and reflection coefficient simultaneously. You can read coax cable loss in dB and match efficiency.

You can adjust UHF dipoles, verticals,

yagis, quads and others and determine their SWR, resonant frequency and bandwidth.

You can test and tune stubs and coax lines. You can manually determine velocity factor and impedances of transmission lines.

You can adjust/test RF matching networks and RF amplifiers without applying power.

Has easy-to-read LCD logarithmic SWR bargraph and SWR meter for quick tuning.

Much Better Accuracy

New 12-bit A/D converter gives much better accuracy and resolution than common 8-bit A/D converters -- an MFJ-269 exclusive!

Super Easy-to-Use

Select a band and mode. Set frequency. Your measurements are instantly displayed! Smooth reduction drive tuning makes setting frequency easy.

Take it anywhere

Take it anywhere - to remote sites, up towers, in cramp places. Fully portable -- battery operated, compact 4Wx2Dx6¼ in., weighs 2 lbs. Free "N" to SO-239 adapter.

Has battery saver, low battery warning and built-in charging circuit for rechargeables.

Use 10 AA Ni-MH or Ni-Cad or alkaline batteries (not incl.) or 110VAC with MFJ-1312D, \$14.95.

MFJ SWR Analyzer Accessories
Carrying Case, MFJ-39C, \$24.95. Tote your MFJ-269 anywhere with this genuine MFJ custom carrying case. Has back pocket with security cover for carrying dip coils, adaptors and accessories.

Made of special foam-filled fabric, the MFJ-39C cushions blows, deflects scrapes, and protects knobs, meters and displays from harm.

Wear it around your waist, over your shoulder, or clip it onto the tower while you work -- the fully-adjustable webbed-fabric carrying strap has snap hooks on both ends.

Has clear protective window for LCD display and cutouts for knobs, connectors.

Dip Coils, MFJ-66, \$19.95.

Plug these MFJ dip meter coupling coils into your MFJ-269 and turn it into a sensitive, accurate band switched dip meter. Two coils cover 1.8-170 MHz.

Power Pack, MFJ-99C, \$34.95 -- Save \$5! 10 MFJ Ni-MH batteries, MFJ-1312D AC adapter.

Accessory Pack, MFJ-98, \$54.85 -- Save \$5! MFJ-39C custom Carrying case, MFJ-66 dip coils, MFJ-1312D AC adapter.

Deluxe Accessory Pack, MFJ-98B, \$77.85. Save \$7! Complete accessory pack! MFJ-39C carry case, 10 Ni-MH batteries, MFJ-66 dip coils, MFJ-1312D AC adapter.

MFJ-259B SWR Analyzer™

\$259.95. Has most of the features of the MFJ-269, but covers 1.8-170 MHz.

Deluxe Accessory Pack MFJ-99B, \$77.85. Save \$7! 10 Ni-MH batteries, MFJ-1312D AC adapter, MFJ-29C carrying case, MFJ-66 dip coils.

ADVANCED ANTENNA ANALYSTS™

VA1 RX VECTOR Analyst

0.5 to 32 MHz.
Freq., SWR,
Impedance,
L & C, R & X.
Sign of X.
Much More!
\$199.95 + S/H

Some say this is the best there is without spending thousands on a network analyzer. Yet it is easy to use and fits in your pocket. Check our web site for all the features of this marvelous instrument!

RF1 RF Analyst

1.2 to 35 MHz.
Frequency, SWR,
Impedance, L & C.
Advanced and low priced.
\$139.95 + S/H

RF5 VHF Analyst

35 to 75 MHz & 138 to 500 MHz. Frequency, SWR, Impedance.
Finds lowest SWR or Z automatically!
\$229.95 + S/H

Each analyst has a low power "xmtr" to go anywhere in its range – not just the ham bands. Measures SWR, feedline loss, baluns, 1/4-wave lines. Measure at the antenna or in the shack. Adjust Yagis, quads, loops, dipoles, verticals, slopers, networks, traps and much more! Each is microprocessor-based and pocket-sized – about the size of the battery pack in others! Only about 8 oz. Uses one 9V standard battery. For much more information, please visit our web site.

WM1 COMPUTING METER

PEP/AVG
Lit Meters
Remote RF
Head
Accurate
Convenient
**\$149.95
+ S/H**

Our WM1 gives you what you want – **SWR on one meter; power on the other!** No adjustments or crossed needles. Even reads SWR in PEP mode on SSB. 5% FS. 1.5 to 30 MHz. Usable on 6M. 1 to 2000 Watts. 8 to 18V DC. 115V AC adaptor, free. 6 3/8 X 3 3/4 X 3" D. Owners call it the best wattmeter even made!

Call to order with MC, VISA or send Check, MO. Add \$8 S/H in 48 States. Add tax in FL. We ship worldwide. See our web site for all rates and combo discounts.

A picture is worth a thousand words...

With the all-new

ANTENNA MODEL™

wire antenna analysis program for Windows you get true 3D far field patterns that are far more informative than conventional 2D patterns or wire-frame pseudo-3D patterns.

Describe the antenna to the program in an easy-to-use spreadsheet-style format, and then with one mouse-click the program shows you the antenna pattern, front/back ratio, front/rear ratio, input impedance, efficiency, SWR, and more.

An optional **Symbols** window with formula evaluation capability can do your computations for you. A **Match Wizard** designs Gamma, T, or Hairpin matches for Yagi antennas. A **Clamp Wizard** calculates the equivalent diameter of Yagi element clamps. A **Yagi Optimizer** finds Yagi dimensions that satisfy performance objectives you specify. Major antenna properties can be graphed as a function of frequency.

There is **no built-in segment limit**. Your models can be as large and complicated as your system permits.

ANTENNA MODEL is only \$85US. This includes a Web site download and a permanent backup copy on CD-ROM. Visit our Web site for more information about **ANTENNA MODEL**.

SIGNAL STRENGTH METER

<3 MHz to >5 GHz

The ZC 185 is an extremely sensitive Radio Frequency (RF) Detector that operates over a broad span of frequencies.

MODEL ZC 185

HAM RADIO uses: Detects and locates Fox Xmtrs, far-field tune-ups of milliwatt to kilowatt rigs, measures antenna patterns, detects oscillations, locates cable leaks & RFI, monitors power.

COMPUTER WIRELESS uses: Super Wi Fi sniffer, detects Hot & Cold spots, measures baseline RF, optimizes hub & satellite network sites, locates hacker sites, strengthens RF signal links.

SECURITY uses: Supersensitive covert camera and bug detector, simplifies wireless installations, aligns antennas, verifies transmissions, identifies hacker sites, locates interference.

Quality Radio Equipment Since 1942

AMATEUR TRANSCEIVERS

Universal Radio is your authorized dealer for all major amateur radio equipment lines including: Alinco, Icom, Yaesu, Kenwood and SGC.

SHORTWAVE RECEIVERS

Whether your budget is \$50, \$500 or \$5000, Universal can recommend a shortwave receiver to meet your needs. Universal is the *only* North American authorized dealer for *all* major shortwave lines including: Elad, Icom, Yaesu, Japan Radio Company, Ten-Tec, Grundig, etón, Sony, Sangean, Palstar, RFspace and Kaito.

WIDEBAND RECEIVERS

Universal Radio carries a broad selection of wideband and scanner receivers. Alinco, AOR, Icom, Yaesu and Uniden models are offered at competitive prices. Portable and tabletop models are available.

ANTENNAS AND ACCESSORIES

Your antenna is just as important as your radio. Universal carries antennas for every need, space requirement and budget. Please visit our website or request our catalog to learn more about antennas.

BOOKS

Whether your interest is amateur, shortwave or collecting; Universal has the very best selection of radio books and study materials.

USED EQUIPMENT

Universal carries an extensive selection of used amateur and shortwave equipment. All items have been tested by our service department and carry a 60 day warranty unless stated otherwise. Request our monthly printed used list or visit our website:

- Continuous duty cycle
- Fault protection
- Better than 50dB below rated harmonic output
- Better than 30dB below rated intermodulation output

Wattmeter

- Covers 1.8MHz to 30 MHz frequency range
- Each unit is individually calibrated for frequency and temperature
- Unit is accurate to within 4% of actual value, independent of scale. Most wattmeters are only accurate within 5% of the measurement scale (for example measuring 150watts on a 1kW scale would only provide a plus or minus 50 watt accuracy on a traditional wattmeter, where as an Alpha wattmeter will only have a deviation of plus or minus 6 watts, irrespective of scale).
- The analog meter displays Forward power, Reflected power or SWR. The included PC application with a serial connection will simultaneously show all three measurements.

The Alpha 99 utilizes two 4CX800 Svetlana ceramic tetrodes. It is capable of 1.5kW continuous RF output on all commonly used modes and on any authorized amateur frequency from 1.8 to 29.7 MHz with no time limit.

Hands-on Ham Radio™

Top Performing Transceivers and Accessories
from America's leading kit company.

The T1 ATU

The pocket-size Elecraft stand-alone automatic antenna tuner. Can be used with any 0.5 to 20-watt HF transceiver! Available as a kit, or assembled!

The K2

Our high-performance multiband 100W HF transceiver with features and specifications that exceed those of most high-end factory-assembled HF transceivers!

The K1

A compact, high-performance 4 (K1-4) or 2 (K1-2) band CW transceiver kit that's easy to build. A great choice for first-time kit builders!

The KX1

An ultra-light, multi-band, transceiver with an internal battery and an automatic antenna tuner. This "CW-station-in-a-box" is a backpacker's dream!

Transceivers

Visit our web page for details on our complete product line, on-line secure ordering, customer and magazine review reprints, downloadable manuals and more!

BitScope

Analog + Digital

100MHz Digital Oscilloscope

- ✓ Dual Channel Digital Scope using industry standard BNC probes or analog inputs on the POD.

40MS/s Logic Analyzer

- ✓ 8 logic, External Trigger and special purpose inputs to capture digital signals down to 25nS.

Mixed Signal Oscilloscope

- ✓ True MSO to capture analog waveforms time-aligned with logic using sophisticated cross-triggering on any input.

Real-Time Spectrum Analyzer

- ✓ See spectra and waveforms in real-time displayed simultaneously

Waveform Generator

- ✓ Load up to 128K arbitrary waveform and replay via BNC B. Capture circuit response simultaneously on BNC A

PC Oscilloscopes & Analyzers

Get the full picture with BitScope Mixed Signal Oscilloscopes

Turn your PC into a powerful Digital Storage Oscilloscope!

See inside your circuit with simultaneous analog, logic and spectrum displays to make tracking down those elusive real-time bugs much easier.

BitScope combines a high speed synchronized storage scope and logic analyzer with a programmable waveform generator and spectrum analyzer.

With "Smart POD" connected active probes and multiple software options you've got the perfect low cost high performance test and debug solution!

Standard 1M/20pF BNC Inputs

200uV-20V/div with x10 probe S/W select AC/DC coupling Switchable 50ohm termination Arbitrary Waveform Generator

BitScope Smart POD probe connector

8 logic channels, cross-triggering Dual channel analog inputs Async serial I/O for external control Supports active probes

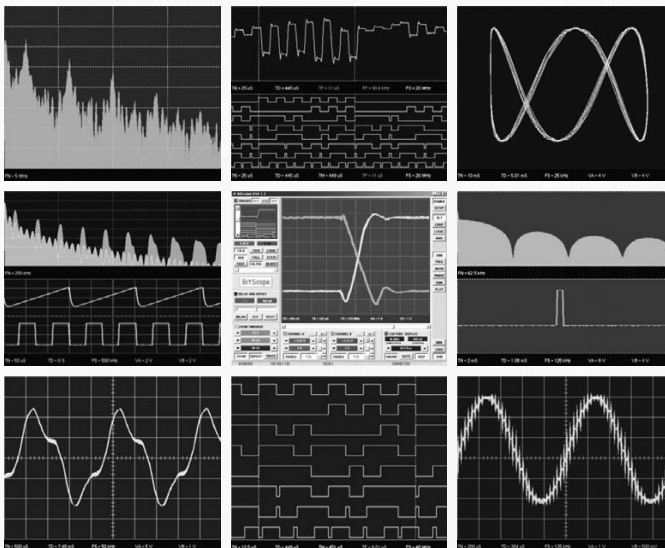

USB 2.0 or Ethernet Connectivity

Single cable to PC or switch Compressed data transmission Ethernet option uses UDP/IP Internet addressable device

Expandable and Programmable

Simple ASCII Protocol BitScope Scripting Language Add active probes and devices Supplies up to 500mA via POD

BitScope and your PC provide an array of Virtual Instruments

BitScope DSO software for Windows and Linux

BitScope's integrated design uses standard oscilloscope probes and a growing range of custom probes to provide functionality equal to instruments many times the price.

BitScope plugs into third party software tools and has an open API for user programming and custom data acquisition.

Alpha Delta Broadband (HF thru 3 GHz) Coax Surge Protectors

Tested and Certified to the Toughest
Commercial Wireless Standards!

Effective protection from antenna induced atmospheric surges, wind driven electrical static discharges and nearby lightning strikes. Our commercial and military wireless customers wouldn't think of operating their expensive 2-way comm, LMDS, MMDS, GPS, ISM and satellite systems without **Alpha Delta Model TT3G50 Coax Surge Protectors** installed on their antenna coax feed lines. **Every** amateur station should also utilize these devices!

▪ **Broadband**—One unit covers 0-3 GHz, instead of multiple units required in bandpass designs.

▪ **Unique Design**—Allows control voltages to be passed thru the Alpha Delta design, eliminating the "wire around" requirement of DC blocked designs. Customer approvals show performance is as good or better than DC blocked designs. **UL tested** and listed to spec 497B for comm circuits.

▪ **Field Replaceable ARC-PLUG™ Module**—The screw-in gas tube module is easily removed/replaced with the knurled knob with no tools required. This feature eliminates a major maintenance issue since the protector doesn't need to be removed from the coax connections, which are often sealed. Other designs require the entire unit to be removed from the circuit and discarded.

▪ **Weather Protected**—Entire unit is weather protected using "O" ring seals under connectors and the ARC-PLUG module knurled knob.

▪ **Variety of Connector Styles and Power Levels Available**—Type N, UHF (SO239), F, TNC, and BNC types in various configurations. Stocked in female/female type N, UHF, and F types. 200 watt and 2 kW power levels—same price. Simply add suffix "HP" for high power type. For OEM/commercial **bulk pack** orders, use Model number **TT3G50** series. Same units but not on point of sale cards. Individual orders add \$8.00 ea, s/h in U.S.; OEM qtls and Exports quoted.

Model ATT3G50 (200 watts, female N connectors, 0-3 GHz) \$59.95 ea.

Model ATT3G50U (200 watts, female UHF connectors, 0-500 MHz) \$49.95 ea.

Books, CDs & Software for Radio Designers!

"Like many radio engineers, I started in amateur radio. These titles were written for professionals, but you'll find them easy to read. I welcome your business."

Randy Rhea, N4HI

SOFTWARE

\$149 **winSMITH**
Design transmission line & L-C circuits & learn how to use the Smith chart. Written by the engineers at Eagleware. Runs on Windows 98 & XP

TUTORIAL CDs

\$99 **Introduction to the Smith Chart**
A great way to learn about the Smith chart & to begin solving antenna, matching & other problems.

\$99 **Theory & Practice of Transmission Line Transformers**
History & practical theory by Jerry Sevick, W2FMI. Covers many types of these broadband devices.

\$297 **Practical Issues in HF Frequency Design**
This series of 3 CDs explains why HF circuits often don't behave as expected. You'll learn how to fix them.

\$99 **AMW Magazine Archive**
A searchable archive of over 500 great technical articles from Applied Microwave & Wireless magazine published from 1989 to 2002.

BOOKS

The Radioman's Manual of RF Devices **\$69**
Complete guide to radio system measurements & test equipment.

RF Power Amplifiers **\$75**
Excellent coverage of class A, B, AB, C, D, E, F & S amplifiers. Also good coverage of transformers & matching.

Radio Receiver Design **\$89**
In depth guide to RF design including receivers, amplifiers, noise, mixers, oscillators, IFs & linearity.

HF Radio Systems & Circuits **\$89**
This 2nd edition contains over 600 pages of modern receiver & exciter design techniques from the front-end preselector to speech processing. Includes disk for Windows.

Radio-Electronics Transmission Fundamentals **\$75**
Easy to read & complete introduction to electrical circuit theory & electronic systems. Good review for professionals & introduction for amateurs.

HF Filter Design & Computer Simulation **\$69**
Complete guide to L-C and printed filter design. This was Noble's first book & it remains a best seller today!

Electronic Applications of the Smith Chart **\$69**
The original book by Phil Smith, call sign 1ANB. Covers the history design & use of his famous chart.

Oscillator Design & Computer Simulation **\$69**
The popular & authoritative book on oscillator design. Covers VCO, xtal & transmission line oscillators.

PUBLISHING

Flash Crystal Frequency Synthesizer

- **Clean, Stable RF Signal Source** – Great for local oscillators and lab test equipment applications!
- **Several Models Available** – Covering from 7 MHz up to 148 MHz
- **Can Store Up to 10 Frequencies** – Board-mounted mini rotary dip switch for frequency selection
- **Completely Re-Programmable** – Program the 10 frequencies using any PC running *Hyperterminal* (included in *Windows* operating systems)
- **Economical** – A fraction of the cost of comparable lab-grade RF signal synthesizers
- **Outputs Approximately 5 mW (+7 dBm)** – Female SMA RF output connector
- **Fully Assembled, Tested, and Ready to Go!** – Just \$80 (plus \$4.30 S/H in US)
- **Super Compact** – Measures less than 2 by 2 inches!
- **Power Requirements** – 8 to 15V dc at approximately 55 mA

ARRL's HF DIGITAL HANDBOOK

3rd Edition

Get on air and enjoy the fascinating world of HF digital communication. You'll learn how to...

- Assemble your own HF digital station.
- Operate PSK31—the "hot" HF digital mode.
- Chase DX and contest contacts with RTTY—radioteletype.
- Connect to the Internet from any location using the WinLink2000 PACTOR network.
- Explore other HF digital modes such as Hellschreiber, Clover, MFSK16, MT-63, Q15X25 and Throb.

...and much more!

Includes a handy **Resources** section. Find downloadable software, manufacturers and complete technical specifications for many HF digital modes.

Alinco delivers more operating fun for less.

Dual Band Dynamos for your pocket or your car!

DR-635T 2M/440MHz Mobile/Base Transceiver

Dual Band Transceiver with Full Duplex Capability

Alinco's new DR-635T is an easy-to-use, high-quality transceiver for simplex and repeater operations on the VHF and UHF bands. With cross-band repeat, full duplex capability and a remote mountable control head, the DR-635T features newly designed RF circuitry that delivers increased resistance to interference from adjacent signals. Plus, a new protection circuit automatically lowers the power setting whenever the internal temperature rises. This protects the radio when used as a cross-band repeater. But, that's just the beginning:

- Large, 6 character alphanumeric display with freely and separately selectable three color display illumination in blue, violet or orange for TX/RX/stand-by
- TCXO that is stable to ± 2.5 ppm
- Narrow FM mode
- Power supply voltage display
- Ignition key on/off feature & theft alarm feature
- CTCSS, DCS encode/decode and DTMF encode functions plus European Tone Bursts
- Multiple scan modes and extended receive capabilities including broadcast FM
- Backlit DTMF microphone allows direct frequency entry and more
- VHF: 50/20/5, UHF: 35/20/5 watt power output settings
- 200 Memory channels that can operate in splits of 80ch/VHF, 80ch/UHF and 40ch freely programmable with 1 call channel each for VHF and UHF operation
- Extended receive from 108.000 ~ 173.995MHz / 335.000 ~ 479.995MHz / 87.5 ~ 107.995MHz, transmits from 144.000 ~ 147.995MHz / 430.000 ~ 449.995MHz, plus reception on AM aircraft band and the ability to operate on MARS frequencies
- Can also operate with Alinco's optional EJ-50U digital data packet board that fits inside or the EJ-47U digital voice board

Thanks to
Alinco,
you can
have a
dual band
dynamo
in your
pocket
AND in
your car!

DJ-C7T 2M/440MHz "Pocket-size" HT

Hams are packing some serious radio power in their pockets with the DJ-C7T, the new dual band mini HT. Alinco led the way in breakthrough miniature electronics technology with its revolutionary "credit card" size transceivers. Now, the DJ-C7T offers a "pocket size" HT that's small in size but BIG in added memories and modes.

Check out the features of this "new generation" DJ-C7T

- Internal speaker with great audio!
- 200 Memories
- VFO, Memory and Scan modes
- 39 CTCSS tone squelch (encode+decode) settings
- Split function
- SMA antenna port
- As thin as 0.57in. and just 3.59 oz. total weight with antenna and battery
- Cloning feature
- Lithium-ion battery
- Wide-band receive; includes FM broadcast and AM aircraft bands
- Auto repeater setting

The DJ-C7T can fit in a pocket or purse, but it's a versatile dual band HT with an enhanced receiver. So, you can enjoy twice the operating fun in half the size.

Check regulations before operating in crossband mode. Products intended for properly licensed operators. Permits required for MARS use. CAP use subject to equipment approval. Specifications subject to change without notice or obligation. Performance specifications only apply to amateur bands. NOTICE: Effective 5/1/2004, ALL warranty claims and requests for repair/technical assistance for Alinco products should be sent to Ham Distribution, Inc. regardless of contact information found on the warranty certificate packed with the product.

ATTENTION DRAKE OWNERS!

Does your Drake drift? Tired of continually retuning?

Then You Need this External VFO!

The brainchild of Don Jackson, K5ATW, and Roger Bankston, W5IAB, these new **RB7500-series** DDS (Direct Digital Synthesizer) VFOs will **put an end to your Drake's drifting problems**. These devices employ a Zilog EZ80F91 CPU @ 50 MHz, and an Analog Devices AD9851 DDS chip to deliver a high-stability replacement for the signal from the rig's internal PTO.

Highlights include a smooth spinning shaft encoder with 1000 steps/revolution, selectable tuning rates of 1 kHz, 10 kHz, or 100 kHz per revolution, and a heavy solid cast aluminum tuning knob that delivers a *truly* professional feel. **Installation is as easy as "plug in and play!"** These **RB7500-series** DDS VFOs provide state-of-the-art frequency stability for your classic Drake gear!

- Dual VFOs with TX/RX/Transceiver/Split*
- 4-Line Backlit LCD Display
- TCXO Reference with 2.5 ppm Stability
- 6 5/8" W x 4 1/8" H x 6 1/4" D
- AC Power Adapter & Interconnect Cable Included

Prices:

RB7500 (for the Drake TR-7): **\$475**

RB7501 (for the Drake TR-7, TR-7A, R-7 and TR-4310): **\$500**

RB7510 (for the Drake TR-4): **\$475 NEW!**

Plus Shipping and Insurance.

*Transmit capabilities are unavailable on the R-7.

Announcing the RB5000 Calibrator, a highly accurate TCXO-based Marker Generator for any brand of Vintage, Classic or Contemporary Gear

Place one of these at your operating position, and you'll always be able to determine your operating frequency with **precision!**

The **RB5000 Calibrator** is a very simple piece of test equipment that's just what the doctor ordered for **checking the accuracy of the frequency display** – be it **analog or digital** – of any HF radio receiver (or the receiver section within a transceiver). It generates calibration "marker" signals from 25 kHz to well over 100 MHz.

A TCXO (Temperature Compensated Crystal Oscillator) and frequency divider chain provides harmonic-rich switch-selectable calibration signals at 500, 250, 100, 50 or 25 kHz spacings. The frequency accuracy is 2.5 ppm (± 9 Hz at 3.5 MHz; ± 75 Hz at 30 MHz). Even if your vintage/classic receiver already *has* a built-in marker generator, it's no match for the precision of the RB5000.

No "hook up" is required! A short wire "antenna" is connected to the **RB5000 Calibrator's** RF output and is positioned to couple the signal to the receiver. Powered from 5 "AA" batteries (included).

Price: RB5000 Calibrator: \$69.95
Plus Shipping and Insurance.

KØXG Systems

– Rotating Tower Equipment for LF, HF, VHF and UHF Applications –

Ground and Tower Mounted Rotators

And a Complete Line of Tower Accessories, Including:

- Ground Mounted Base Bearings
- Internal-Mount Tower Rotator Shelves
- Heavy Duty Roller Thrust Bearings
- Guy Ring Bearings for All Size Towers
- Guy Ring Ice Covers
- Boom To Tower Plates and Brackets for Most Brands and Tower Sizes
- Boom To Mast Brackets
- Tower Insulator Adaptors
- ...and Much, Much More!

Ground mounted base for 300 feet of Rohn 55G/AB105.

Guy ring bearing installed on Rohn 55G tower.

Rotate those VHF/UHF stacks

V
H
F

U
H
F

Don't waste money on useless masts and pipe that you cannot climb. With one guy ring bearing and our elevated tower rotor you can rotate 50 feet of tower. This gives you the ability to add, remove or service any or all of your antennas without having to remove the lower beams. Install an HF tri-band beam, stack 6 meter and VHF/UHF antennas on one tower and run the hard line all the way to the antennas where it should be, instead of high loss coax.

Systems available for rotating from 30 feet of Rohn 25G tower up to over 300 feet of Rohn 80 tower.

The Fine Art of Hand Sent Morse Code... It's So Much More than Just Dots and Dashes!

*Upon its debut at Dayton Hamvention in
May of 2005, the STRAIGHTBRASS
CW Key immediately captured the attention
of both Seasoned Old Timers and
New Comers to Amateur Radio alike!*

Loaded with features you *just won't find* in any other CW straight key, the STRAIGHTBRASS key is more than just a "presentation piece", it's a finely-crafted precision instrument specifically designed to accentuate the on-air "voice" of the discerning brass pounder. In bands that these days seem awash in the mechanized drone of electronic keyer and computer-generated Morse, isn't it about time you put some "swing" into your CW notes?

Just a few of the Highlights...

- Major Frame, Pivot and Lever Components are Finely Crafted of Solid and Nickel-Plated Brass, and Polished with Diamond Paste to a Mirror-Like Finish.
- Base of Solid Granite – Heavy Enough to Stay Put Under Nearly Any Operating Conditions. Felt Padding on a Plate on the Underside of the Key Protects the Surface of Your Operating Desk.
- Stainless Steel Springs and Bearings Ensure Years of Smooth, Trouble-Free Service. (This Key Should Last a Lifetime!)
- Keying Contacts Made of Fine Silver (0.995) for Superior Electrical Performance. Electrical Contact Via Leaf Springs Makes the Current Paths Independent of the Bearings. Dual Blades for QSK (Full Break-In) Operation.
- Exclusive Triple-Start Threads on the Spring Tension Adjustment Screw and a Large Easy-to-Grip Adjustment Knob Make for Rapid Keying Force Adjustments that Precisely Retain Their Settings. Contact Spacing is Also Easily Adjustable by Hand.
- Connections for Both Dual Transmitter Keying and Dual Receiver Blocking, Selectable by the Placement of a "Plug" on Either Side. Connection Cables are Hidden, Discretely Exiting at the Lower Edge of the Rear of the Key.

Order Yours Today!

STRAIGHTBRASS: *The Key to True CW Enjoyment!*

Problems with noise and interference?

DSP noise cancelling at its best

Listen clearly on SSB, UHF, VHF, HF and FM

**Our products use fully adaptive Digital Signal Processing (DSP) to give:
Excellent speech quality * Superb Noise Cancellation 9 - 35dB * Tone reduction up to
65dB * up to 8 filter levels * Wide audio bandwidth 50Hz - 4.3KHz**

HEAR-IT Speaker (NES10-2)

- Amplified DSP noise cancellation speaker
- Power On/Off audio bypass switch
- DSP On/Off switch
- LED indication of DSP function
- Mono headphone socket
- Up to 5W input and 2.5W output
- 6' 3.5mm jack plug audio lead
- 12 - 24V DC supply (500mA)

"level 4 provided remarkable noise suppression, without making the SSB sound hollow and brassy" CQ Jan 2005

HEAR-IT In-line module (NEIM1031)

- Fully featured in-line 'desk top' DSP noise cancellation unit
- Simply connects between your equipment and extension speaker
- Supplied with audio and power leads
- 2.5W max output
- Audio and line level inputs and outputs
- On/Off audio bypass
- Headphone socket
- 12 - 24V DC supply (500mA)

"the GAP noise-cancellation circuits pull the signal out of the noise and reduce the noise dramatically. We were impressed" CQ Jan 2005

Optional mounting stand

HEAR-IT DSP module (NEDSP1061-KBD)

- DSP noise cancelling PCB module for retrofit applications
- Easy to use single button operation
- LED and audio indication of DSP function
- 5 - 15V DC supply
- Low power consumption
- Complete internal fitting - no external wires
- Small size 1.06" x 1.45" x 0.6"
- Installation hardware and labels supplied with full fitting instructions
- Instruction manuals available for FT-817, TS-50, 706MII G, FRG-100, DX-77, Realistic DX-394

"When you are communicating with weak and noisy QRP stations, the bhi add-on DSP filter could be worth its weight in gold" RadCom Dec 2003

HEAR-IT Amplified DSP module (NEDSP1062-KBD)

- Installs easily into your extension speaker or speaker path of your transceiver/receiver
- Amplified DSP noise cancellation PCB module
- Audio bypass when switched off or power removed
- 3W audio power (4 Ohm)
- Supply voltage 12 - 18V DC (500mA max)
- Small size 2" x 1.5"
- Installation hardware and labels supplied with full fitting instructions
- Instruction manual with details for Yaesu SP8 and Kenwood SP31

"the on air performance in improving readability of weak SSB signals or those in noisy conditions were excellent" RadCom July 2005

Contesting and DXing Products from Array Solutions

We Distribute a Tremendous Variety of High Quality Products from the Most Respected Companies in the Amateur Radio Market, Including those of...

- ACE HF • AN-Wireless • AY Technologies • Bushcomm Pty Ltd • Custom Metal Works • GeoClock • ICE Radio Products
- Integrated Tower Systems • Nello Corporation • Nittany Scientific, Inc • OptiBeam • Pro.Sis.Tel. • W3NQN • Yagistress

From the Labs at Array Solutions: The PowerMaster

The Next Generation of SWR/Wattmeter; Delivering Outstanding Accuracy and Functionality at a Price You Can Afford!

- Available in Two Versions – 1 W to 3 kW (amateur) and 1 W to 10 kW (military/commercial)
- Accuracy Within $\leq 5\%$ from 1.8 to 54 MHz – Temperature and frequency compensated
- Separate Control Head and Coupler/Sensor – Sensor can be remotely located for the ultimate in shack and mobile installation convenience, and moves high levels of RF away from your operating position – Say goodbye to RF!
- High VSWR and Low and High RF Output Power Alarms – Programmable trip points with warning LEDs and relay outputs – tremendously handy for contesters and DXers! Lightning fast trigger response will protect your rig, your amplifier, and your rate!
- Auto-Ranging Bar Graph Display Operates in Two Modes – Simplifies peaking your RF output or dipping your VSWR
- Large Vacuum Fluorescent Display – Easy to read, even in bright sunlight
- Peak Hold Modes – Programmable for fast, medium and slow response for CW and SSB
- Effective 12-bit A/D Processing – Resulting in outstanding resolution and accuracy
- Meter Operation and Menu Functions Accessible from Front Panel or Via RS232 Connection – Capable of displaying up to 16 alphanumeric characters – your call sign, for example
- RS232 Application for Your PC – Complete control and programming via computer, perfect for remote station applications; firmware can be updated via Web site downloads
- All Metal Enclosure – Rack mount option available (1 or 2 units in a 19-inch 2U panel)
- Choice of Connectors – SO239 or Type-N (Sensor connector: 7/16-inch DIN)
- Control/Display Head Dimensions – $3\frac{1}{2} \times 8\frac{1}{4} \times 4\frac{1}{4}$ inches (HWD)
- Remote Coupler/Sensor Dimensions – $2\frac{1}{4} \times 2\frac{3}{4} \times 6\frac{1}{2}$ inches (HWD)

We've got your stuff!

BUDDIPOLE

The Buddipole™ Portable Dipole fits in your travel bag and assembles in minutes. The Buddipole™ is more than an antenna, it's a versatile system for launching your signal. Optimized for transmit power and proven for DX work, the Buddipole™ is the secret weapon used by HF portable operators all over the world.

What is the Buddipole™?

- Portable Dipole Antenna System
- Multi-band design works 9 bands – 40 meters thru 2 meters with one set of adjustable coils!
- Rated from QRP to 250 Watts PEP
- Modular Design
- Rotatable/Directional
- Lightweight, rugged components
- Optional Rotating Arm Kit allows users to instantly change antenna configurations
- Used by the U.S. Military Special Forces and Emergency Services Groups throughout the world

The Buddipole™ Deluxe Package

The Buddipole Deluxe Package includes all the items that come with the standard Buddipole antenna plus these following extras:

- A Buddipole tripod
- B Collapsible mast
- C Rotating arm kit
- D extra telescopic whip
- E extra set of coil clips
- F Everything fits within our padded 1000 denier cordura plus nylon carrying case.

Overall length is only 24" and total weight is under 10 lbs!

Antenna Attention!

Design, build and install antennas that work.

The ARRL Antenna Book — 20th Edition

In depth coverage of antennas, feed lines, and propagation.

Book with CD-ROM. ARRL Order No. 9043—\$39.95*

The ARRL Antenna Book is THE SOURCE for current antenna theory and a wealth of practical, how-to construction projects. Extensively revised, and featuring antenna designs enhanced by the latest advances in computer modeling. Design, build and install any imaginable type of antenna—from the most simple wire varieties, to specialized or highly optimized arrays.

Fully searchable CD-ROM included

Bundled with this edition is the fully-searchable book on CD-ROM and additional software utilities**. The CD-ROM supports Windows and Macintosh systems. At your command is the entire book—every word and every page—PLUS pages of band-by-band propagation tables for locations around the world! Uses the widely popular Adobe® Acrobat® Reader software (included) to view, navigate, search and print from all chapters.

The CD-ROM also includes three updated and improved programs (for Windows):

YW—Yagi for Windows

TLW—Transmission Line for Windows

HFTA—HF Terrain Assessment

EZNECARRL—Antenna Modeling by W7EL

Contents:

- Safety First
 - Antenna Fundamentals
 - The Effects of the Earth
 - Antenna Modeling and System Planning
 - Loop Antennas
 - Low-Frequency Antennas
 - Multiband Antennas
 - Multielement Arrays
 - Broadband Antennas
 - Log Periodic Arrays
 - HF Yagi Arrays
 - Quad Arrays
 - Long Wire and Traveling Wave Antennas
 - Direction Finding Antennas
 - Portable Antennas
 - Mobile and Maritime Antennas
 - Repeater Antenna Systems
 - VHF and UHF Antenna Systems
 - Antenna Systems for Space Communications
 - Antenna Materials and Accessories
 - Antenna Products Suppliers
 - Antenna Supports
 - Radio Wave Propagation
 - Transmission Lines
 - Coupling the Transmitter to the Line
 - Coupling the Line to the Antenna
 - Transmission-Line and Antenna Measurements
 - Smith Chart Calculations
- Includes a comprehensive glossary and index

**CD-ROM System Requirements: Microsoft Windows 95 or later; or Apple Power Macintosh computer, Apple System Software version 7.1.2 or later. Additional software utilities are included, for Windows and DOS only.

The ARRL Antenna Classics series!

ARRL's Wire Antenna Classics and More Wire Antenna Classics

So many wire antenna designs have proven to be first class performers! Here's an entire book devoted to wire antennas, from the simple to the complex. Includes articles on dipoles, loops, rhombics, wire beams and receive antennas—and some time-proven classics! An ideal book for Field Day planners or the next wire antenna project at your home station.

Volume 1. ARRL Order No. 7075—\$14*

Volume 2. ARRL Order No. 7709—\$14*

Build portable, mobile and fixed antenna designs

ARRL's VHF/UHF Antenna Classics

Ground planes, J-poles, mobile antennas, Yagis and more. Build a better antenna for your hand-held radio. Construct a 2-meter Yagi that will rival similar commercial antennas. Build a dual-band vertical for 146 and 445-MHz. The results will be rewarding!

ARRL Order No. 9078—\$14.95*

ARRL's Yagi Antenna Classics

Yagis, Quads, Loops, and other Beam Antennas

A wealth of ideas from some of the leaders in antenna design and experimentation of the last 70 years. Covers monobanders; multibanders; HF, VHF and UHF beams from 80 meters to 2304 MHz; computer modeling; towers, masts and guys. Some of the very best articles from QST, QEX, NCJ and other ARRL publications.

ARRL Order No. 8187—\$17.95*

Vertical Antenna Classics

Vertical antennas are everywhere—on cell phones, broadcast towers and portable radios. You'll also see them on the roofs, towers and vehicles from Altoona to Australia. And for good reason! Here are some top-notch performers from ARRL publications, brought together in one book. Vertical antenna theory and modeling, VHF and UHF, HF, directional arrays, radials and ground systems, and more.

ARRL Order No. 5218—\$12*

*Shipping and Handling charges apply. Sales tax is required for orders shipped to CA, CT, VA and Canada. Prices and product availability are subject to change without notice.

Index

Editor's Note: Except for commonly used phrases and abbreviations, topics are indexed by their noun names. Many topics are also cross-indexed, especially when noun modifiers appear (such as "Voltage, back" and "Back voltage"). Numerous terms and abbreviations pertaining to Amateur Radio but not contained in the index may be found in the glossaries indexed herein. The letters "ff" after a page number indicate coverage of the indexed topic on succeeding pages.

10-GHz converter: 10.43
120-V ac chassis connector wiring: 3.11
1200C modes: 9.34
144-MHz 3CX1200Z7 amplifier: 18.40ff
144-MHz amplifier example: 18.23ff

About the ARRL

The national association for Amateur Radio

The seed for Amateur Radio was planted in the 1890s, when Guglielmo Marconi began his experiments in wireless telegraphy. Soon he was joined by dozens, then hundreds, of others who were enthusiastic about sending and receiving messages through the air—some with a commercial interest, but others solely out of a love for this new communications medium. The United States government began licensing Amateur Radio operators in 1912.

By 1914, there were thousands of Amateur Radio operators—hams—in the United States. Hiram Percy Maxim, a leading Hartford, Connecticut inventor and industrialist, saw the need for an organization to band together this fledgling group of radio experimenters. In May 1914 he founded the American Radio Relay League (ARRL) to meet that need.

Today ARRL, with approximately 170,000 members, is the largest organization of radio amateurs in the United States. The ARRL is a not-for-profit organization that:

- promotes interest in Amateur Radio communications and experimentation
- represents US radio amateurs in legislative matters, and
- maintains fraternalism and a high standard of conduct among Amateur Radio operators.

At ARRL headquarters in the Hartford suburb of Newington, the staff helps serve the needs of members. ARRL is also International Secretariat for the International Amateur Radio Union, which is made up of similar societies in 150 countries around the world.

ARRL publishes the monthly journal *QST*, as well as newsletters and many publications covering all aspects of Amateur Radio. Its headquarters station, W1AW, transmits bulletins of interest to radio amateurs and Morse code practice sessions. The ARRL also coordinates an extensive field organization, which includes volunteers who provide technical information and other support services for radio amateurs as well as communications for public-service activities. In addition, ARRL represents US amateurs with the Federal Communications Commission and other government agencies in the US and abroad.

Membership in ARRL means much more than receiving *QST* each month. In addition to the services already described, ARRL offers membership services on a personal level, such as the ARRL Volunteer Examiner Coordinator Program and a QSL bureau.

Full ARRL membership (available only to licensed radio amateurs) gives you a voice in how the affairs of the organization are governed. ARRL policy is set by a Board of Directors (one from each of 15 Divisions). Each year, one-third of the ARRL Board of Directors stands for election by the full members they represent. The day-to-day operation of ARRL HQ is managed by an Executive Vice President and his staff.

No matter what aspect of Amateur Radio attracts you, ARRL membership is relevant and important. There would be no Amateur Radio as we know it today were it not for the ARRL. We would be happy to welcome you as a member! (An Amateur Radio license is not required for Associate Membership.) For more information about ARRL and answers to any questions you may have about Amateur Radio, write or call:

About the Included CD-ROM

On the included CD-ROM you'll find this entire *Handbook*, including text, drawings, tables, illustrations and photographs—many in color. Using the industry-standard Adobe *Reader* (included), you can view and print the text of the book, zoom in and out on pages, and copy selected parts of pages to the clipboard. A powerful search engine—Acrobat Search—helps you find topics of interest. Also included are Template Packages for many of the projects in this book, the companion software mentioned throughout, the short videos *Amateur Radio Today* and *ARRL goes to Washington*, and the free Adobe *Reader 7.0* to view the *Handbook* files.

INSTALLING YOUR ARRL HANDBOOK CD

Windows

1. Close any open applications and insert the CD-ROM into your CD-ROM drive. (Note: If your system supports “CD-ROM Insert Notification,” the *ARRL Handbook CD* may automatically run the installation program when inserted.)
2. Select **Run** from the *Windows Start* menu.
3. Type **d:\setup** (where d: is the drive letter of your CD-ROM drive; if the CDROM is a different drive on your system, type the appropriate letter) and press **Enter**.
4. Click “Install the ARRL Handbook CD” and follow the instructions that appear on your screen.

Macintosh

No installation procedure is needed for the Macintosh. To install so the CD is not required, drag the “ARRL Handbook CD 10.0” icon onto your hard drive.

USING YOUR ARRL HANDBOOK CD

Windows

Note: If your systems supports “CD-ROM Insert Notification,” the *ARRL Handbook CD* may run automatically when inserted.

1. To run the program after installation, start *Windows* and place the disc in your CD-ROM drive. (Not required if a “complete” installation was chosen during setup.)
2. From the **Start** menu select **Programs**, then select **ARRL Software** and the **2006 ARRL Handbook CD 10.0** item.

Macintosh

To run the program after installation, place the disc in your CD-ROM drive. Adobe *Reader* should launch automatically to view the book.

HAM RADIO OUTLET

WORLDWIDE DISTRIBUTION

GO MOBILE WITH ICOM!

IC-2720H Dual Band Mobile

- 2M/70cm • VV/UU/VU
- Wide band RX inc. air & weather bands
- Dynamic Memory Scan (DMS)
- CTCSS/DTCS encode/decode w/tone scan
- Independent controls for each band
- DTMF Encode • 212 memory channels
- Remote Mounting Kit Included

IC-208H Dual Band Mobile

- 55 watts VHF (2M), 50 watts UHF (70cm)
- Wide Band RX**
- 500 alphanumeric memories
- CTCSS/DTCS encode/decode w/tone scan
- Detachable remote head
- DMS w/linked banks

IC-T2H SPORT 2M Transceiver

- 6W output
- 40 alphanumeric memories
- Customizable keys
- Auto repeater
- PC Programmable
- CTCSS encode/decode w/tone scan
- Mil spec 810, C/D/E*1

IC-V8000 2M Mobile Transceiver

- 75 watts • ICOM DMS scanning
- CTCSS/DTCS encode/decode w/tone scan
- Weather alert • Weather channel scan
- 200 alphanumeric memories • Backlit remote control mic

IC-2100H 25N 2M Mobile Transceiver

- Cool dual display
- 50 watts
- CTCSS encode/decode w/tone scan
- Backlit remote control mic
- Mil spec 810, C/D/E*1
- Auto repeater
- 113 alphanumeric memories

IC-T7H Dual Band Transceiver

- 2M/70cm
- 70 alphanumeric memories
- 6W output
- CTCSS encode/decode w/tone scan
- Auto repeater
- Easy operation!
- Mil spec 810, C/D/E*1

IC-W32A Dual Band Transceiver

- 2M & 70cm @ 5W
- V/V, U/U, V/U
- Independent controls for each band
- 200 alphanumeric memories
- Auto repeater
- CTCSS encode/decode w/tone scan
- IRLP compatible

IC-2200H 2M Mobile Transceiver

- 65W Output
- Opt. Digital Operation & NEMA Compatible GPS interface
- CTCSS/DTCS encode/decode w/tone scan
- 207 Alphanumeric Memories
- Weather Alert • and More!

IC-T90A Tri-Band Transceiver

- 6M/2M/70cm @ 5W
- Wide band receiver 495kHz - 999.999MHz**
- 500 alphanumeric memories
- Dynamic memory scan
- Backlit keypad & display
- CTCSS/DTCS encode/decode w/tone scan
- Weather Alert

IC-V8 2M Transceiver

- 5.5W output
- 107 alphanumeric memories
- Customizable keys
- Auto repeater
- PC Programmable
- CTCSS encode/decode w/tone scan
- Drop-in trickle charger included

80 Years of Excellence.

In 1926, ARRL published the first edition of *The Radio Amateur's Handbook*, subtitled "A Manual of Amateur Short-Wave Radiotelegraphic Communication." Its eighty-year evolution is an unwavering tribute to innovations and advances made by radio amateurs and experimenters. Generations of hams, engineers and technicians have come to know **The ARRL Handbook** as THE standard in applied electronics and communications.

ALWAYS REVISED

This 2006 edition builds on the extensive rewrite of the previous edition, and includes the most up-to-date theory, references and practical projects for receivers and transmitters, transceivers, power supplies, RF amplifiers, station accessories, and antennas.

An impressive addition to **The ARRL Handbook** is a *brand-new*, high-power HF linear amplifier project using the new Eimac 3CX1500D7 power triode (this tube has a rugged 50-W grid dissipation!).

CD-ROM INCLUDED

This edition is bundled with **The ARRL Handbook CD (version 10.0)**—the complete and fully searchable book on CD-ROM, including many color images, additional software and reference material not found in the printed book.

PROJECTS

- **NEW!** 3CX1500D7 High-Power HF Amplifier
- 10-W, 60-meter SSB Transceiver
- 13.8-V, 40-A Switching Power Supply
- 6-meter kW Amplifier
- 20-W ATV Transceiver
- Computer-Controlled Two-Radio Switchbox
- Trio of Transceiver/Computer Interfaces
- Automatic Antenna Switches
- Rock-Bending 7-MHz Receiver

WEEKEND-BUILDS

- 2-m Hardware-Store Beam
- Wideband MMIC Preamp
- Compact Vertical Dipoles (CVDs)
- 2-m/70-cm Mobile Whip
- Ground-plane Version of a 2-m/70-cm Antenna
- 75/10-m Dipole
- Multiband Trap Dipoles
- Simple Regenerative Receiver Projects
- Earth-Continuity Tester for Establishing Safe Grounds
- Noise-Source Detector for the Shack

...and MORE!

Table of Contents

- Introduction to Amateur (Ham) Radio
- Activities in Amateur Radio
- Safety
- Electrical Fundamentals
- Electrical Signals and Components
- Real-World Component Characteristics
- Component Data and References
- Circuit Construction
- Modes and Systems
- Oscillators and Synthesizers
- Mixers, Modulators and Demodulators
- RF and AF Filters
- EMI/Direction Finding
- Receivers and Transmitters
- Transceivers, Transverters and Repeaters
- DSP and Software Radio Design
- Power Supplies
- RF Power Amplifiers
- Station Layout and Accessories
- Propagation of RF Signals
- Transmission Lines
- Antennas
- Space Communications
- Web, Wi-Fi, Wireless and PC Technology
- Test Procedures and Projects
- Troubleshooting and Repair
